The physical picture that results is exact and coherent. Reality is not an infinitely writable continuum. It is a finite-capacity realization medium. Quantum fields are not exempt from that fact. Their propagators carry the burden law of the substrate. Their loop amplitudes inherit the finite support of realizable propagation. Their coherent phases inherit the stochasticity of realized proper time. Once this is understood, the ultraviolet catastrophe, the persistence of the infrared theory, and the emergence of decoherence all become parts of one continuous architecture.

That is the physical meaning of the present branch. It does not decorate the finite-capacity program with a quantum field theoretic analogy. It opens the genuine QFT interface of the program and shows that the same canonical substrate law governing gravity, cosmology, thermodynamics, and stochasticity also governs quantum propagation and coherence. The result is a unified field-theoretic descendant sector in which ultraviolet divergence is replaced by bounded realizability, and decoherence is derived as the stochastic signature of the same finite-capacity substrate.

10. Conclusion

We have constructed the quantum field theoretic branch of the finite-capacity latency–erasure framework by deriving propagator dressing, perturbative ultraviolet completion, infrared recovery, and stochastic decoherence from one and the same substrate architecture.

The starting point of the construction is exact. Physical reality is not an infinitely permissive continuum. It is a finite-capacity realization substrate with bounded local update rate, bounded realized-load fraction, and a canonical latency field

$$\chi = -\ln(1 - x),$$

which governs proper-time generation through

$$d\tau = e^{-\chi} dt.$$

Once quantum modes are interpreted as realized substrate excitations rather than abstract continuum disturbances, their momentum and frequency become realization burden. High-energy propagation is therefore not free. It consumes finite local update bandwidth and drives the substrate toward saturation.

From that canonical structure we derived the decisive field-theoretic result. The Schwinger proper-time representation of the propagator acquires a physical lower bound because arbitrarily short propagation intervals are not realizable in a finite-capacity medium. The continuum propagator is thereby replaced by a latency-dressed propagator with exponential ultraviolet suppression and exact infrared recovery. In the low-burden regime, standard perturbative Quantum Field Theory is recovered. In the high-burden regime, unrealizable ultraviolet support collapses dynamically.

That same mechanism closes the loop sector. One-loop self-energy amplitudes become finite without external regulators, without ad hoc subtraction, and without formal ultraviolet repair strategies imposed from outside the theory. More strongly, the line-by-line exponential suppression of internal propagators yields general perturbative ultraviolet convergence across fixed-order diagrams and their subdiagrams. The ultraviolet problem is therefore not managed after it appears. It is removed at the level of physical propagation itself.

We also derived the quantum coherence sector of the branch. The latency field carries a stochastic descendant

$$\delta\chi,$$

inherited directly from the pre-existing fluctuation and overwrite sectors of the finite-capacity program. Because quantum phase accumulates with realized proper time, stochastic latency produces stochastic phase diffusion. Off-diagonal density-matrix elements are therefore suppressed by a calculable finite-capacity decoherence kernel. Decoherence emerges here as a direct substrate process rather than as an external interpretive supplement. The same canonical field that governs ultraviolet propagator suppression governs phase-noise-induced coherence loss.

This establishes a unified result of broad scope. In the finite-capacity framework, ultraviolet completion, infrared recovery, and quantum decoherence are not separate mechanisms patched together after the fact. They are three manifestations of one bounded realization law. Deterministic latency controls the ultraviolet fate of propagators. Stochastic latency controls the fate of quantum coherence. Low burden recovers the ordinary perturbative quantum field theory that succeeds empirically in the infrared. High burden closes the continuum extrapolation that fails in the ultraviolet.

The consequences for the finite-capacity program are decisive. The framework no longer terminates at gravity, cosmology, thermodynamics, stochastic timing, microphysical closure, compact-binary dynamics, and strong-field evolution. It now possesses a genuine quantum field theoretic descendant sector built from the same canonical kernel. The program therefore spans weak-field gravity, cosmological dynamics, nonequilibrium timing, stochastic fluctuations, microphysical realization, compact-object structure, strong-field numerical evolution, and perturbative quantum field theory within one continuous architecture.

The conceptual result is equally strong. Ultraviolet divergence is revealed as the artifact of assigning quantum fields to a fictitious continuum with unbounded realization capacity. The finite-capacity framework replaces that fiction with a physical substrate whose burden state determines what propagation is realizable. Classicality is revealed as the stochastic large-burden limit of the same substrate. The quantum-to-classical transition and the ultraviolet closure of perturbative field theory are therefore not unrelated mysteries. They are regime consequences of one finite-capacity reality.

This completes the QFT interface of the finite-capacity latency–erasure framework. Quantum fields now enter the program not as external structures to be reconciled later, but as direct descendants of the canonical substrate law. Propagators become latency-dressed. Loop amplitudes become dynamically finite. Decoherence becomes a physical consequence of stochastic proper-time realization. Low-energy field theory is recovered in the correct regime, while the ultraviolet catastrophe is closed by bounded realizability. The finite-capacity program now contains its own quantum field theoretic branch, and with it, a unified extension from ontological time to high-energy perturbative physics.

Appendix A. Canonical Variable Map for the QFT Descendant Sector

The quantum field theoretic branch of the finite-capacity latency–erasure framework is not built from an independent symbolic system. It is a descendant sector of the canonical FCLET kernel. For that reason, every quantity appearing in the QFT branch must be read as either a core kernel variable or a controlled descendant of one.

The foundational variables inherited without modification are the following.

The canonical realized-load fraction is

$$x(\mathbf{x}, t) \in [0,1).$$

This quantity measures the fraction of local realization capacity already consumed by maintained states, dynamical propagation, overwrite activity, and active update burden.

The canonical latency field is

$$\chi(\mathbf{x}, t) = -\ln(1 - x).$$

This map is exact in the FCLET kernel. It guarantees weak latency for small burden and divergent latency as the substrate approaches local saturation.

The canonical realized proper-time law is

$$d\tau = e^{-\chi} dt.$$

This law is also exact. Proper time is not a background coordinate parameter independent of the substrate. It is a realized quantity generated by the substrate at a rate controlled by local latency.

The deterministic–stochastic decomposition of latency is

$$\chi = \bar{\chi} + \delta\chi.$$

Here $\bar{\chi}$is the coarse-grained deterministic latency background and $\delta\chi$is the stochastic descendant generated by patch irregularity, overwrite burden, and local response imbalance.

The QFT branch then introduces the following descendant variables.

The microphysical update timescale of the substrate is

$$\tau_{\mathrm{micro}}.$$

The associated maximal unsaturated update rate is

$$\Gamma_\star = \tau_{\mathrm{micro}}^{-1}.$$

In units $c = \hbar = 1$, this also defines the bare microphysical substrate scale

$$\Lambda_\star = \Gamma_\star.$$

A relativistic field mode with momentum $p$and frequency

$$\omega(p) = \sqrt{p^2 + m^2}$$

imposes the descendant realized burden

$$x_q(p) = \frac{\omega(p)}{\Gamma_\star}.$$

This quantity is the QFT descendant of the core load fraction. It measures the fraction of local update bandwidth consumed by the realization of a single mode.

The deterministic local burden seen by a propagating mode is

$$x_{\mathrm{det}}(p) = \bar{x} + x_q(p),$$

where the background burden $\bar{x}$is related to the background latency by

$$\bar{\chi} = -\ln(1-\bar{x}), 1-\bar{x} = e^{-\bar{\chi}}.$$

The deterministic local latency felt by the mode is therefore

$$\chi_{\mathrm{loc}}(p) = -\ln(1-x_{\mathrm{det}}(p)).$$

Using the background relation, this becomes

$$\chi_{\mathrm{loc}}(p) = \bar{\chi} - \ln\left(1-\frac{\omega(p)}{\Lambda_\chi}\right),$$

where the effective local QFT ultraviolet threshold is

$$\Lambda_\chi = \Lambda_\star e^{-\bar{\chi}}.$$

This is the principal descendant scale of the QFT branch. It is not an arbitrary regulator. It is the locally available quantum field theoretic burden ceiling after background load has already reduced the realizable bandwidth of the substrate.

The residual update rate available to realize propagation at momentum $p$is

$$\Gamma_{\mathrm{res}}(p) = \Gamma_\star e^{-\chi_{\mathrm{loc}}(p)}.$$

The associated minimal realizable local propagation interval is

$$\tau_{\mathrm{step}}(p) = \Gamma_{\mathrm{res}}^{-1}(p) = \tau_{\mathrm{micro}} e^{\chi_{\mathrm{loc}}(p)}.$$

This induces the Schwinger proper-time floor

$$s_{\mathrm{min}}(p) = \tau_{\mathrm{step}}^2(p) = \Lambda_\star^{-2} e^{2\chi_{\mathrm{loc}}(p)}.$$

Substituting the descendant latency map gives the exact QFT floor

$$s_{\mathrm{min}}(p) = \Lambda_\chi^{-2}\left(1-\frac{\omega(p)}{\Lambda_\chi}\right)^{-2}.$$

The exact Euclidean scalar propagator of the QFT branch is therefore

$$\Delta_E^{(\chi)}(p) = \frac{\exp\left[-s_{\min}(p)(p^2+m^2)\right]}{p^2+m^2}.$$

Its broad unsaturated ultraviolet descendant is

$$\Delta_E^{(\chi)}(p) \approx \frac{\exp[-(p^2+m^2)/\Lambda_\chi^2]}{p^2+m^2}.$$

The stochastic descendant sector is controlled by the latency correlator

$$C_\chi(t,t') = \langle \delta\chi(t)\delta\chi(t')\rangle.$$

For stationary noise this becomes

$$C_\chi(t,t') = C_\chi(t-t').$$

The integrated latency-noise strength is

$$D_\chi = \int_0^\infty d\tau\ C_\chi(\tau),$$

whenever the correlation function is sufficiently short-ranged for the integral to converge.

For a quantum superposition with energy gap

$$\Delta E_{nm} = E_n - E_m,$$

the finite-capacity Markovian decoherence rate is

$$\gamma_{nm}^{(\chi)} = (\Delta E_{nm})^2 e^{-2\bar{\chi}} D_\chi.$$

These variables constitute the canonical QFT descendant set:

$$\{x, \chi, \bar{\chi}, \delta\chi, \tau_{\text{micro}}, \Gamma_\star, \Lambda_\star, x_q(p), x_{\text{det}}(p), \chi_{\text{loc}}(p), \Lambda_\chi, s_{\min}(p), \Delta_E^{(\chi)}(p), C_\chi, D_\chi, \gamma_{nm}^{(\chi)}\}.$$

This set is sufficient to define the perturbative ultraviolet branch, the infrared recovery branch, and the stochastic decoherence branch of the finite-capacity QFT sector. No additional primitive ontology is required.

Appendix B. Proper-Time Derivation of the Latency-Dressed Propagator

The purpose of this appendix is to derive the finite-capacity propagator directly from the substrate proper-time floor.

Start from the standard Euclidean scalar propagator

$$\Delta_E(p) = \frac{1}{p^2 + m^2}.$$

Its Schwinger representation is

$$\Delta_E(p) = \int_0^\infty ds\ e^{-s(p^2+m^2)}.$$

In continuum QFT the lower limit is zero because arbitrarily short propagation intervals are treated as physically admissible. In the finite-capacity framework, that lower limit must be replaced by the smallest propagation interval the substrate can realize at the burden carried by the mode.

The bare patch update rate is

$$\Gamma_\star = \tau_{\mathrm{micro}}^{-1}.$$

A mode of frequency $\omega(p)$contributes the burden

$$x_q(p) = \frac{\omega(p)}{\Gamma_\star}.$$

In a deterministic background with burden $\bar{x}$, the total deterministic local burden becomes

$$x_{\mathrm{det}}(p) = \bar{x} + x_q(p).$$

The corresponding local latency is

$$\chi_{\mathrm{loc}}(p) = -\ln(1 - x_{\mathrm{det}}(p)).$$

The residual update rate left available to realize additional propagation is therefore

$$\Gamma_{\mathrm{res}}(p) = \Gamma_\star e^{-\chi_{\mathrm{loc}}(p)}.$$

The minimal realizable propagation interval is the inverse residual rate:

$$\tau_{\mathrm{step}}(p) = \Gamma_{\mathrm{res}}^{-1}(p) = \tau_{\mathrm{micro}} e^{\chi_{\mathrm{loc}}(p)}.$$

Since the Schwinger parameter has dimension $[\text{mass}]^{-2}$, the proper-time floor is

$$s_{\min}(p) = \tau_{\text{step}}^2(p) = \tau_{\text{micro}}^2 e^{2\chi_{\text{loc}}(p)}.$$

Using $\Lambda_\star = \tau_{\text{micro}}^{-1}$, this becomes

$$s_{\min}(p) = \Lambda_\star^{-2} e^{2\chi_{\text{loc}}(p)}.$$

Now use the background relation

$$\bar{\chi} = -\ln(1-\bar{x}), \Lambda_\chi = \Lambda_\star e^{-\bar{\chi}}.$$

The local latency may then be rewritten as

$$\chi_{\text{loc}}(p) = \bar{\chi} - \ln\left(1 - \frac{\omega(p)}{\Lambda_\chi}\right).$$

Substituting this into the proper-time floor gives

$$s_{\min}(p) = \Lambda_\star^{-2} e^{2\bar{\chi}} \left(1 - \frac{\omega(p)}{\Lambda_\chi}\right)^{-2}.$$

Because

$$\Lambda_\chi^{-2} = \Lambda_\star^{-2} e^{2\bar{\chi}},$$

the exact lower bound is

$$\boxed{s_{\min}(p) = \Lambda_\chi^{-2} \left(1 - \frac{\omega(p)}{\Lambda_\chi}\right)^{-2}.}$$

The finite-capacity scalar propagator is therefore

$$\Delta_E^{(\chi)}(p) = \int_{s_{\min}(p)}^{\infty} ds\ e^{-s(p^2+m^2)}.$$

Evaluating the integral gives

$$\boxed{\Delta_E^{(\chi)}(p) = \frac{\exp\left[-s_{\min}(p)(p^2+m^2)\right]}{p^2+m^2}.}$$

Substituting the exact floor yields

$$\boxed{\Delta_E^{(\chi)}(p) = \frac{\exp\left[-\dfrac{p^2+m^2}{\Lambda_\chi^2\left(1-\omega(p)/\Lambda_\chi\right)^2}\right]}{p^2+m^2}.}$$

This is the exact Euclidean finite-capacity descendant propagator.

The broad unsaturated ultraviolet approximation follows when the mode is still below the local burden threshold:

$$\omega(p) \ll \Lambda_\chi.$$

In that regime,

$$\left(1-\frac{\omega(p)}{\Lambda_\chi}\right)^{-2} = 1 + \mathcal{O}\left(\frac{\omega(p)}{\Lambda_\chi}\right),$$

so

$$s_{\min}(p) \approx \Lambda_\chi^{-2}.$$

The propagator then reduces to the Gaussian descendant form

$$\boxed{\Delta_E^{(\chi)}(p) \approx \frac{\exp[-(p^2+m^2)/\Lambda_\chi^2]}{p^2+m^2}.}$$

This approximation is sufficient for the perturbative ultraviolet-finiteness arguments in the main text. The exact expression remains the correct formula near the saturation-adjacent regime.

The same lower-bound logic extends immediately to spinor and gauge propagators because the proper-time floor acts on the denominator structure universally, while the field-specific numerator algebra remains unchanged.

Appendix C. One-Loop Euclidean Evaluation with Exponential Suppression

This appendix evaluates the one-loop scalar self-energy explicitly in the Gaussian descendant regime.

Consider Euclidean $\lambda\phi^4$ theory. The finite-capacity one-loop tadpole contribution is

$$\Sigma_E^{(\chi)} = \frac{\lambda}{2}\int \frac{d^4k}{(2\pi)^4}\,\frac{e^{-(k^2+m^2)/\Lambda_\chi^2}}{k^2+m^2}.$$

Use the Schwinger representation with a finite lower bound:

$$\frac{e^{-(k^2+m^2)/\Lambda_\chi^2}}{k^2+m^2} = \int_{1/\Lambda_\chi^2}^{\infty} ds\; e^{-s(k^2+m^2)}.$$

Then

$$\Sigma_E^{(\chi)} = \frac{\lambda}{2}\int_{1/\Lambda_\chi^2}^{\infty} ds\; e^{-sm^2}\int \frac{d^4k}{(2\pi)^4} e^{-sk^2}.$$

The Gaussian momentum integral is

$$\int d^4k\, e^{-sk^2} = \left(\frac{\pi}{s}\right)^2,$$

so

$$\int \frac{d^4k}{(2\pi)^4} e^{-sk^2} = \frac{1}{16\pi^2 s^2}.$$

Hence

$$\Sigma_E^{(\chi)} = \frac{\lambda}{32\pi^2}\int_{1/\Lambda_\chi^2}^{\infty} ds\,\frac{e^{-sm^2}}{s^2}.$$

To evaluate the remaining integral, set

$$u = m^2 s, ds = \frac{du}{m^2}.$$

Then

$$\int_{1/\Lambda_\chi^2}^{\infty} ds\,\frac{e^{-sm^2}}{s^2} = m^2\int_{m^2/\Lambda_\chi^2}^{\infty} du\,\frac{e^{-u}}{u^2}.$$

Integrating by parts gives

$$\int_a^\infty du\,\frac{e^{-u}}{u^2} = \frac{e^{-a}}{a} - \int_a^\infty du\,\frac{e^{-u}}{u},$$

with

$$a = \frac{m^2}{\Lambda_\chi^2}.$$

Therefore

$$\int_{1/\Lambda_\chi^2}^\infty ds\,\frac{e^{-sm^2}}{s^2} = \Lambda_\chi^2 e^{-m^2/\Lambda_\chi^2} - m^2 E_1\left(\frac{m^2}{\Lambda_\chi^2}\right),$$

where

$$E_1(z) = \int_z^\infty dt\,\frac{e^{-t}}{t}.$$

The exact one-loop finite-capacity self-energy is therefore

$$\boxed{\Sigma_E^{(\chi)} = \frac{\lambda}{32\pi^2}\left[\Lambda_\chi^2 e^{-m^2/\Lambda_\chi^2} - m^2 E_1\left(\frac{m^2}{\Lambda_\chi^2}\right)\right].}$$

This expression is finite for every finite Λ_χ.

To extract the large-Λ_χ behavior, use the standard expansion

$$E_1(z) = -\gamma_{\mathrm{E}} - \ln z + z + \mathcal{O}(z^2), z \ll 1,$$

and

$$e^{-z} = 1 - z + \frac{z^2}{2} + \cdots.$$

Then

$$\Lambda_\chi^2 e^{-m^2/\Lambda_\chi^2} = \Lambda_\chi^2 - m^2 + \mathcal{O}(m^4/\Lambda_\chi^2),$$

so

$$\Sigma_E^{(\chi)} = \frac{\lambda}{32\pi^2}\left[\Lambda_\chi^2 - m^2 - m^2\left(-\gamma_{\mathrm{E}} - \ln\frac{m^2}{\Lambda_\chi^2}\right) + \mathcal{O}\left(\frac{m^4}{\Lambda_\chi^2}\right)\right].$$

Equivalently,

$$\boxed{\Sigma_E^{(\chi)} = \frac{\lambda}{32\pi^2}\left[\Lambda_\chi^2 - m^2\ln\left(\frac{\Lambda_\chi^2}{m^2}\right) - m^2(1+\gamma_{\mathrm{E}}) + \mathcal{O}\left(\frac{m^4}{\Lambda_\chi^2}\right)\right].}$$

This is the finite descendant of the usual continuum one-loop structure. The leading large-Λ_χ behavior reproduces the familiar scaling pattern, but the expression never becomes divergent because the substrate scale is physical and finite.

The same method extends directly to other one-loop amplitudes with dressed internal lines. The precise tensor and numerator algebra varies from diagram to diagram, but the convergence mechanism is identical: the exponential suppression inherited from the finite-capacity proper-time floor destroys the ultraviolet support of the loop integral.

Appendix D. Decoherence Kernel and Stochastic Phase Averaging

This appendix derives the coarse-grained decoherence kernel from stochastic latency fluctuations.

Let $|\, n\rangle$be an energy eigenstate with energy E_n. Its phase evolution is controlled by realized proper time:

$$|\, n; t\rangle = e^{-iE_n\tau(t)}\,|\, n\rangle.$$

The proper time is

$$\tau(t) = \int_0^t e^{-\chi(t')}\,dt' = \int_0^t e^{-(\bar{\chi}+\delta\chi(t'))}\,dt'.$$

For weak instantaneous stochastic noise,

$$|\,\delta\chi\,| \ll 1,$$

expand to first order:

$$e^{-(\bar{\chi}+\delta\chi)} = e^{-\bar{\chi}}(1 - \delta\chi + \mathcal{O}(\delta\chi^2)).$$

Hence

$$\tau(t) \approx e^{-\bar{\chi}}t - e^{-\bar{\chi}}\int_0^t d\,t'\,\delta\chi(t').$$

For two energy eigenstates $n$and m, the relative phase is

$$\Phi_{nm}(t) = -\Delta E_{nm}\tau(t), \Delta E_{nm} = E_n - E_m.$$

Therefore

$$\Phi_{nm}(t) = -\Delta E_{nm}e^{-\bar{\chi}}t + \Delta E_{nm}e^{-\bar{\chi}}\int_0^t d\,t'\,\delta\chi(t').$$

The density-matrix element is

$$\rho_{nm}(t) = \rho_{nm}(0)e^{i\Phi_{nm}(t)}.$$

After noise averaging,

$$\langle\rho_{nm}(t)\rangle = \rho_{nm}(0)e^{-i\Delta E_{nm}e^{-\bar{\chi}}t}\langle\exp\left[i\Delta E_{nm}e^{-\bar{\chi}}\int_0^t d\,t'\,\delta\chi(t')\right]\rangle.$$

Assume the stochastic process is Gaussian with zero mean:

$$\langle\delta\chi(t)\rangle = 0.$$

For a Gaussian variable X,

$$\langle e^{iX}\rangle = \exp\left(-\frac{1}{2}\langle X^2\rangle\right).$$

Set

$$X = \Delta E_{nm}e^{-\bar{\chi}}\int_0^t d\,t'\,\delta\chi(t').$$

Then

$$\langle X^2\rangle = (\Delta E_{nm})^2 e^{-2\bar{\chi}}\int_0^t d\,t_1\int_0^t d\,t_2\,\langle\delta\chi(t_1)\delta\chi(t_2)\rangle.$$

Introducing the correlation function

$$C_\chi(t_1, t_2) = \langle \delta\chi(t_1)\delta\chi(t_2)\rangle,$$

gives

$$\boxed{\langle \rho_{nm}(t)\rangle = \rho_{nm}(0)\exp[-i\Delta E_{nm}e^{-\bar{\chi}}t]\exp\left[-\frac{(\Delta E_{nm})^2 e^{-2\bar{\chi}}}{2}\int_0^t d\,t_1\int_0^t d\,t_2\,C_\chi(t_1,t_2)\right].}$$

Define the decoherence kernel

$$\Gamma_{nm}(t) = \frac{(\Delta E_{nm})^2 e^{-2\bar{\chi}}}{2}\int_0^t d\,t_1\int_0^t d\,t_2\,C_\chi(t_1,t_2).$$

Then

$$\boxed{\langle \rho_{nm}(t)\rangle = \rho_{nm}(0)\,e^{-i\Delta E_{nm}e^{-\bar{\chi}}t}e^{-\Gamma_{nm}(t)}.}$$

This is the exact Gaussian coarse-grained finite-capacity decoherence law.

For stationary noise,

$$C_\chi(t_1, t_2) = C_\chi(t_1 - t_2),$$

one may rewrite the kernel as

$$\Gamma_{nm}(t) = (\Delta E_{nm})^2 e^{-2\bar{\chi}}\int_0^t d\tau\,(t-\tau)\,C_\chi(\tau).$$

This form is especially useful for extracting asymptotic limits.

Markovian limit

If the correlation time of the noise is short compared with the observational timescale, write

$$C_\chi(\tau) \approx 2D_\chi\,\delta(\tau).$$

Then

$$\Gamma_{nm}(t) = (\Delta E_{nm})^2 e^{-2\bar{\chi}}D_\chi\,t,$$

and

$$\boxed{\langle \rho_{nm}(t) \rangle = \rho_{nm}(0)\, e^{-i\Delta E_{nm} e^{-\bar{\chi}} t} e^{-(\Delta E_{nm})^2 e^{-2\bar{\chi}} D_\chi\, t}.}$$

The corresponding decoherence rate is

$$\boxed{\gamma_{nm}^{(\chi)} = (\Delta E_{nm})^2 e^{-2\bar{\chi}} D_\chi.}$$

Short-time non-Markovian limit

If the noise is smooth near $\tau = 0$, then for very short times

$$C_\chi(\tau) \approx C_\chi(0),$$

and

$$\Gamma_{nm}(t) \approx \frac{(\Delta E_{nm})^2 e^{-2\bar{\chi}}}{2} C_\chi(0) t^2.$$

Hence the coherence envelope is Gaussian in time:

$$\boxed{\langle \rho_{nm}(t) \rangle \approx \rho_{nm}(0)\, e^{-i\Delta E_{nm} e^{-\bar{\chi}} t} \exp\left[-\frac{(\Delta E_{nm})^2 e^{-2\bar{\chi}}}{2} C_\chi(0) t^2 \right].}$$

This shows that the finite-capacity decoherence law naturally accommodates both exponential and Gaussian coherence loss, depending on the correlation structure of the latency-noise branch.

The decisive point is unchanged in every regime: stochastic substrate latency produces stochastic proper-time accumulation, and that process suppresses the off-diagonal structure of the density matrix.

Appendix E. Ultraviolet Convergence Theorem and Diagrammatic Remarks

This appendix states the perturbative ultraviolet-completion result in a sharper diagrammatic form and clarifies its scope.

E.1 General convergence statement

Consider a connected Euclidean Feynman amplitude at fixed loop order L, written schematically as

$$\mathcal{A}_L = \int_{\mathbb{R}^{4L}} d^{4L}\, k\, P(\{k_r\}) \prod_{\ell=1}^{I} \Delta_\ell\,(q_\ell),$$

where:

- $k_r$are the loop variables,
- $q_\ell$are internal momenta linear in the loop variables and external data,
- $P$is a polynomial numerator produced by local vertices, derivatives, or tensor contractions,
- $I$is the number of internal lines.

In the finite-capacity descendant theory, each internal propagator satisfies a large-momentum bound of the form

$$|\,\Delta_\ell^{(\chi)}(q_\ell)\,| \leq \frac{C_\ell}{1+q_\ell^2} \exp\big(\quad -\alpha_\ell q_\ell^2/\Lambda_\chi^2\big), \alpha_\ell > 0.$$

This includes the Gaussian descendant propagators derived in the main text and is conservatively weaker than the exact saturation-adjacent branch, which suppresses even more strongly near the local capacity threshold.

Then the integrand obeys a bound

$$|\,\mathcal{I}_L(\{k_r\})\,| \leq C\,(1+\|\,k\,\|)^M \exp\left[-Q(\{k_r\})/\Lambda_\chi^2\right],$$

where:

- $C$is finite,
- $M$is some integer,
- $Q$is a positive semidefinite quadratic form in the loop variables.

Along every genuine ultraviolet direction in loop-momentum space, $Q$is strictly positive and grows as $\|\,k\,\|^2$. Therefore there exists $c > 0$such that in the ultraviolet region

$$|\,\mathcal{I}_L(\{k_r\})\,| \leq C'(1+\|\,k\,\|)^M e^{-c\|k\|^2/\Lambda_\chi^2}.$$

Since polynomial growth is dominated by Gaussian decay, the amplitude is absolutely convergent in the ultraviolet.

This proves that fixed-order perturbation theory in the finite-capacity QFT branch is ultraviolet finite whenever every internal line carries the finite-capacity realizability dressing derived in the main text.

E.2 Subdiagram convergence

The same argument applies to every ultraviolet subdiagram. Let $G' \subset G$be any subgraph of the full diagram. Its internal lines are a subset of the full set of internal lines and therefore inherit the same exponential damping bound. The corresponding subdiagram amplitude is of the same form as the full amplitude but with fewer loop variables and fewer internal propagators.

Therefore each subdiagram also satisfies a Gaussian-damped ultraviolet bound and is absolutely convergent. In particular:

- superficial divergences are removed,
- subdivergences are removed,
- overlapping divergences are removed.

The finite-capacity descendant theory therefore eliminates the entire conventional hierarchy of ultraviolet singular structures, not merely the overall divergence of a few special diagrams.

E.3 Relation to ordinary power counting

In standard continuum perturbation theory, the superficial degree of divergence

$$D = 4L - 2I + N$$

plays the decisive role, where $N$is the total degree of momentum dependence in the numerator. In the finite-capacity descendant theory, Dno longer determines convergence. It describes only the polynomial skeleton of the undressed algebraic integrand.

Physical convergence is instead controlled by the realizability dressing carried by each internal line. The correct ultraviolet classification is therefore not polynomial power counting alone, but polynomial structure plus exponential burden suppression.

The practical consequence is exact: every continuum diagram retains its algebraic numerator–denominator architecture in the infrared, but loses its ultraviolet singular support because the substrate suppresses unrealizable internal momentum.

E.4 Exact floor versus Gaussian descendant

The convergence theorem above was stated using the Gaussian descendant propagator

$$\Delta_E^{(\chi)}(p) \approx \frac{e^{-(p^2+m^2)/\Lambda_\chi^2}}{p^2+m^2},$$

because that form is sufficient to prove perturbative ultraviolet finiteness and is convenient for analytic calculation.

The exact finite-capacity propagator is stronger:

$$\Delta_E^{(\chi)}(p) = \frac{\exp\left[\quad -\frac{p^2+m^2}{\Lambda_\chi^2(1-\omega(p)/\Lambda_\chi)^2}\right]}{p^2+m^2}.$$

As

$$\omega(p) \to \Lambda_\chi^-,$$

the denominator inside the exponential shrinks and the suppression becomes stronger than Gaussian. The exact branch therefore exceeds the bound required by the theorem. The Gaussian descendant is already enough to prove perturbative finiteness; the exact finite-capacity theory imposes an even harder ultraviolet closure near the realizability boundary.

E.5 Scope of the perturbative result

The theorem proved here is a perturbative fixed-order statement. It establishes that the finite-capacity descendant propagator removes ultraviolet divergence from ordinary loop amplitudes built from local vertices and finitely many internal lines.

This is exactly the result needed to open the QFT interface of the finite-capacity program. It demonstrates that once quantum propagation is treated as a burdened substrate process rather than as an abstract continuum freedom, perturbative ultraviolet divergence disappears as a physical phenomenon.

The theorem does not need any external regulator language, because the finite-capacity proper-time floor has already replaced formal ultraviolet support with a physical realizability threshold. This is why the perturbative result is stronger than ordinary regularization. It is not a temporary control device awaiting removal. It is the physical completion of the high-energy branch.

The result may therefore be stated in its strongest clean form:

Finite-capacity realizability dressing removes perturbative ultraviolet divergence at fixed loop order.

That statement is not an auxiliary remark. It is the mathematical core of the QFT descendant sector constructed in this paper.

Galactic Rotation Curves, Baryonic Tully–Fisher Scaling, and Dark Matter Mimicry from Latency Gradients in a Finite-Capacity Universe

Capacity-Limited Galactic Realization Burden, Effective Radial Acceleration, and the Emergence of Flat Rotation Curves without Exotic Dark Matter

Ali Caner Yücel

Abstract

We construct the galactic dynamics branch of the finite-capacity latency–erasure framework and show that the phenomenology commonly attributed to particle dark matter emerges from baryon-sourced latency structure in a finite-capacity universe. In this framework, visible matter does not act only through the Newtonian potential it sources. It also loads the underlying realization substrate, generating a radial realized-load profile $x(r)$and an associated latency field

$$\chi(r) = -\ln(1 - x(r)).$$

Because galactic disks are extended finite-capacity systems rather than isolated point-mass configurations, the spatial gradients of the latency field contribute an additional radial term to the effective orbital dynamics. This latency-gradient contribution becomes subdominant in high-acceleration inner regions, preserving the ordinary Newtonian limit, but grows comparatively important in low-acceleration outer disks, where it supplies the missing centripetal support required by observed flat rotation curves.

From this structure we derive the asymptotic galactic acceleration law of the finite-capacity branch, show how approximately radius-independent circular velocities emerge in the outer disk, and obtain a baryon-controlled dark-matter-mimicry regime without invoking exotic nonbaryonic halo particles. We then show that the same finite-capacity scaling yields the baryonic Tully–Fisher relation as a direct consequence of the latency-gradient branch rather than as an imposed empirical fit. The observed coupling between visible baryonic mass and outer-disk orbital speed is therefore elevated from phenomenological regularity to dynamical consequence.

This construction integrates the galactic missing-mass problem into the existing FCLET canon. The same bounded-realization architecture that governs weak-field gravity, matter coupling, cosmological moderation, perturbative structure, stochastic sectors, and strong-field

completion now also governs disk-galaxy rotation support. Dark matter phenomenology at galactic scales is thus reinterpreted as the macroscopic signature of a finite-capacity gravitational substrate. The result is a unified baryon-driven explanation of flat rotation curves and Tully–Fisher scaling from latency gradients alone.

Keywords: galactic rotation curves; dark matter mimicry; baryonic Tully–Fisher relation; finite-capacity universe; latency gradients; weak-field gravity; disk galaxies; modified radial acceleration; FCLET

1. Introduction

The galactic missing-mass problem is one of the most persistent structural tensions in modern astrophysics. In the Newtonian description of a rotationally supported galaxy, the circular velocity at radius $r$is determined by the enclosed gravitating mass through

$$v_c^2(r) = \frac{GM(<r)}{r}.$$

For luminous baryonic matter alone, this predicts that once the visible mass profile has largely saturated, the orbital speed should decline approximately as

$$v_c(r) \propto r^{-1/2}.$$

Observed spiral galaxies do not obey that expectation. Their outer rotation curves remain nearly flat across large radial intervals, and the discrepancy is systematic rather than exceptional. The standard response has been to introduce an extended nonbaryonic dark matter halo whose gravitational pull supplies the missing centripetal support. That response has dominated the field for decades, yet the underlying problem remains conceptually unfinished. The dark halo is not a directly established local material component of galactic dynamics; it is an inferred sector introduced to rescue the orbital law of a theory whose large-radius support is otherwise insufficient.

The finite-capacity latency–erasure framework replaces that rescue strategy with a different dynamical architecture. In this framework, gravitation is not sourced only through the familiar mass-energy terms of an idealized passive continuum. Physical matter also loads an active realization substrate of finite local capacity. The local burden of realized structure is encoded by the bounded load fraction

$$x \in [0,1),$$

and the associated latency field

$$\chi = -\ln(1-x).$$

This field is not an auxiliary decorative scalar. It is the canonical substrate response to realized burden. In weak-load regimes it remains small, preserving ordinary low-field physics. In extended low-acceleration systems, however, its spatial structure becomes dynamically relevant. Galactic disks are precisely such systems. Their visible baryonic content is distributed over large radii, their outer regions probe low-acceleration dynamics, and the cumulative substrate burden sourced by the disk produces radial latency structure that standard Newtonian gravity does not contain.

That structure changes the problem at its root. The finite-capacity program does not ask what invisible matter halo must be added to preserve the observed orbital speed. It asks what additional effective radial support is generated when visible baryons are treated as sources of both Newtonian attraction and substrate burden. The answer developed in this paper is direct: the radial gradient of the latency field contributes an additional centripetal term to the effective circular-balance law. In the inner galaxy, where the baryonic Newtonian field is strong, the latency-gradient contribution is subleading and the ordinary recovery branch is preserved. In the outer galaxy, where the Newtonian field weakens, the latency-gradient branch becomes comparatively important and arrests the Keplerian falloff. Flat rotation curves then emerge as a finite-capacity consequence rather than as evidence for an unseen particle halo.

This result is not a disconnected modification grafted onto the program at late stage. It is the natural galactic descendant of branches already established in the FCLET canon. The weak-field gravity sector already fixed the latency-mediated structure of finite-capacity corrections. The matter-coupling and perturbation-consistency sectors already tied visible matter content to the scalar-burden architecture. The empirical survival and benchmark papers already established that viable branches of the program must recover ordinary weak-field limits while opening controlled deviations in low-acceleration or long-baseline regimes. Disk galaxies lie exactly in that window. They are extended, weakly accelerated, baryon-structured systems in which finite-capacity corrections can organize coherently over macroscopic radial scales.

The present paper constructs that branch in full. We begin by defining the galactic realized-load profile sourced by the observed baryonic mass distribution of a disk galaxy. From this we derive the radial latency profile $\chi(r)$appropriate to an extended finite-capacity system. We then show how the radial derivative of $\chi(r)$enters the orbital support law as an effective additional inward acceleration. The resulting total acceleration contains the ordinary Newtonian term and a finite-capacity latency-gradient term. This structure yields two decisive outcomes. First, it generates approximately flat outer-disk rotation curves without invoking exotic dark matter particles. Second, it produces a direct scaling relation between total baryonic mass and asymptotic circular speed, thereby deriving the baryonic Tully–Fisher relation from the capacity law itself.

That second result is especially important. The baryonic Tully–Fisher relation is not merely one more observational regularity among many. It is one of the clearest empirical signs that the outer-disk dynamics of galaxies are tightly coupled to the visible baryonic sector rather

than arbitrarily controlled by an independent dark halo population. Any successful galactic theory must explain not only why the outer rotation curve remains flat, but why the asymptotic speed tracks the baryonic mass so cleanly. In the finite-capacity branch, this is no surprise. The same visible baryons that source the Newtonian field also source the realized-load profile and therefore the latency gradient. The apparent dark-sector phenomenology is consequently baryon-locked from the start.

This changes the interpretation of the galactic missing-mass problem. In the standard particle picture, one begins with visible matter, finds insufficient outer support, and then appends an unseen halo sector. In the finite-capacity picture, one begins with visible matter, recognizes that it loads a finite-capacity substrate, and derives an additional baryon-controlled radial support term from the resulting latency structure. The missing mass is not replaced by one more adjustable phenomenological patch. It is dissolved into the dynamics of finite-capacity realization itself. Dark matter phenomenology at the scale of disk galaxies is reinterpreted as the macroscopic orbital signature of latency gradients sourced by baryonic burden.

The structure of the paper is as follows. Section 2 formulates the galactic missing-mass problem in the language of the finite-capacity program and defines the finite-capacity alternative to particle halo support. Section 3 constructs the baryon-sourced galactic realized-load profile and derives the associated latency field. Section 4 derives the effective radial acceleration law produced by latency gradients and identifies the regime in which the new term modifies orbital balance. Section 5 proves the emergence of flat outer rotation curves from the asymptotic branch of the theory. Section 6 derives the baryonic Tully–Fisher relation from the same capacity law and shows why its baryon-locked scaling is a direct consequence of the finite-capacity framework. Section 7 discusses observational windows, including low-surface-brightness systems, compact baryonic disks, and the relation of the present branch to lensing and broader dark-sector phenomenology. Section 8 locks the galactic branch to the existing FCLET canon, especially the weak-field, matter-coupling, perturbative-consistency, empirical-survival, and unified-framework sectors. The concluding sections state the physical meaning of the result.

The outcome is decisive. The finite-capacity latency–erasure framework does not merely tolerate galactic dark-matter phenomenology; it generates it from the visible baryonic sector through latency gradients on an active substrate. Flat rotation curves are no longer evidence that galaxies must be embedded in massive invisible particle halos. They are the orbital signature of a finite-capacity universe responding to extended baryonic burden. The galactic dark-matter problem is therefore absorbed into the same canonical architecture that already governs gravity, cosmology, thermodynamics, stochasticity, and strong-field completion in the FCLET program.

2. The Galactic Missing-Mass Problem and the Finite-Capacity Alternative

2.1 The Rotation-Curve Crisis in the Standard Picture

The galactic rotation-curve problem is not a minor residual anomaly. It is a direct failure of the bare Newtonian orbital law when that law is fed only the visible baryonic mass profile of real disk galaxies. Once the stellar disk and gaseous content are mapped, the enclosed baryonic mass $M_b(<r)$determines the expected circular speed through

$$v_N^2(r) = \frac{GM_b(<r)}{r}.$$

If the baryonic profile becomes radially dilute and the enclosed mass saturates beyond a characteristic optical radius, then the Newtonian prediction approaches the Keplerian falloff

$$v_N(r) \sim r^{-1/2}.$$

Observed galaxies do not generically do this. Their outer circular speeds remain approximately constant across large radial baselines, often far beyond the region where the visible matter density is sufficient to sustain such motion within ordinary Newtonian gravity.

This discrepancy is not confined to a narrow population of special systems. It appears across spiral galaxies, low-surface-brightness disks, gas-rich dwarfs, and extended baryonic systems spanning a wide range of total mass and size. The crisis is therefore not the failure of a few outliers. It is the systematic mismatch between visible-matter gravity and the observed large-radius orbital law.

The standard response is familiar: introduce a second gravitating sector. In this picture, the visible baryonic disk is embedded in an extended nonluminous halo whose mass profile grows with radius in precisely the way needed to prevent the velocity curve from falling. The dark halo framework has been extraordinarily influential, but its galactic role remains inferential. The halo is not inserted because a local nonbaryonic matter density profile is directly measured inside individual galaxies. It is inserted because the standard baryonic gravitational law is insufficient to explain the observed motion without it.

This is the point where the finite-capacity program takes a different path. The galactic anomaly is not treated here as evidence that an unseen particulate reservoir must be postulated first and interpreted later. It is treated as evidence that the orbital law of visible matter has been computed on an incomplete physical background. Once the background is recognized as a finite-capacity realization substrate rather than a passive continuum, baryonic matter generates more than the Newtonian field alone. It also generates realized burden and therefore latency structure. The galactic crisis is then reinterpreted not as missing mass but as missing substrate response.

2.2 Limits of Particle Dark Matter as a Galactic Explanation

The standard halo picture remains empirically serviceable in many contexts, but as a galactic explanation it carries a structural weakness that the finite-capacity framework does not share: it treats the dominant support term in disk dynamics as a sector that is not itself baryon-generated, yet observed galaxy phenomenology repeatedly shows extraordinarily tight coupling to the baryonic distribution.

The most striking signal of that coupling is the baryonic Tully–Fisher relation. The asymptotic rotation speed of a disk galaxy is not loosely correlated with its visible mass. It tracks total baryonic mass through a clean scaling law of the approximate form

$$M_b \propto v_f^4,$$

where v_f is the outer flat velocity. A second related regularity is the radial acceleration relation, which ties the observed acceleration field of disk galaxies to the acceleration predicted from the baryonic mass distribution with far less scatter than one would expect if the dominant support were provided by an independently structured invisible halo sector.

These facts do not by themselves exclude dark matter, but they force any successful halo model to explain why an unseen gravitating component should conspire so tightly with the visible baryons across widely varying galactic environments. The halo picture is therefore burdened not only with producing the right total acceleration, but with reproducing the very specific way in which that acceleration tracks the luminous and gaseous content of the galaxy.

A second limit is conceptual. At the galactic level, the standard explanation begins by assuming that visible matter is dynamically insufficient and therefore demands a second matter component. But this inference is valid only if the gravitational background is already complete. If the gravitational response of visible matter is modified by the finite-capacity state of the substrate it inhabits, then the inference to invisible mass is not compelled. One may instead derive an additional baryon-linked radial support term from the substrate response itself.

A third limit is ontological economy. The finite-capacity program already possesses a canonical mechanism by which realized matter generates substrate burden, substrate burden generates latency, and latency modifies dynamics in controlled weak-field or low-acceleration regimes. Once that architecture exists, invoking an entirely separate invisible-particle sector to explain galactic support becomes less economical than first asking what the canonical substrate response of the theory itself predicts.

This paper therefore does not attempt to phenomenologically imitate a halo profile while remaining agnostic about first principles. It does something stronger. It derives the additional galactic support term from the same bounded-load and latency-field architecture already used elsewhere in the FCLET canon. The resulting dark-matter mimicry is not a fit ansatz. It is the galactic weak-field descendant of a deeper finite-capacity gravitational program.

2.3 Finite-Capacity Gravity as a Baryon-Driven Alternative

The finite-capacity alternative begins from a simple but decisive fact: visible baryonic matter does not merely curve an abstract passive background. It consumes realizational resources of an active substrate. A galactic baryonic distribution therefore generates not only the ordinary Newtonian potential $\Phi_N(r)$, but also a radial realized-load profile $x(r)$, and hence a radial latency field

$$\chi(r) = -\ln(1 - x(r)).$$

In a weak-load inner regime, where $x(r) \ll 1$, the latency is small and the ordinary baryonic Newtonian branch dominates. In extended low-acceleration regions, however, the cumulative radial structure of $x(r)$need not be dynamically negligible. Disk galaxies are precisely the kind of systems in which this can occur. Their visible matter is not concentrated into an idealized point source. It is spread over a broad radial domain, and its substrate burden inherits that broad structure.

The finite-capacity claim is therefore exact:

the same baryonic matter that sources the Newtonian term also sources a latency-gradient contribution to the effective radial acceleration.

The orbital law is modified not by appending invisible gravitating mass, but by recognizing that baryon-sourced substrate burden carries its own dynamical consequence. The total effective circular-balance condition becomes

$$\frac{v_c^2(r)}{r} = a_N(r) + a_\chi(r),$$

where

$$a_N(r) = \frac{GM_b(< r)}{r^2}$$

is the ordinary Newtonian baryonic term, and

$$a_\chi(r)$$

is the additional inward support generated by the radial structure of the latency field.

This changes the interpretation of outer-disk dynamics immediately. In the standard picture, the missing centripetal support is evidence for missing gravitating mass. In the finite-capacity picture, it is evidence that the baryonic gravitational response has been incompletely computed because the substrate burden sourced by the baryons has been ignored.

The key requirement is regime discipline. The added term must not destroy the successful inner-galaxy Newtonian branch. It must recover ordinary dynamics in the high-acceleration regime and become important only in the low-acceleration outer disk. That is exactly the kind of branch behavior the FCLET canon already enforces elsewhere: standard limits survive where burden is weak, while finite-capacity descendants become dynamically visible where load accumulates coherently over large scales or long baselines.

The baryon-driven finite-capacity alternative therefore has three exact targets:

1. it must preserve the Newtonian inner-disk regime;
2. it must generate approximately flat outer rotation curves;
3. it must recover the observed baryon-locked scaling of the asymptotic velocity.

If all three are achieved from one latency-gradient branch, then the galactic missing-mass problem is absorbed into the finite-capacity substrate response of visible matter itself.

2.4 Scope of the Present Construction

The purpose of the present paper is not to present one more phenomenological interpolation formula. Its purpose is to derive the galactic dark-matter-mimicry branch from the canonical FCLET architecture and lock that branch to the rest of the program.

We proceed in four steps.

First, we construct the baryon-sourced galactic burden profile. A realistic disk galaxy is treated as an extended realized system whose stellar and gaseous content load the substrate radially. This defines $x(r)$and therefore $\chi(r)$.

Second, we derive the effective radial support term generated by the latency gradient. The additional inward acceleration is not guessed. It is written as the weak-field galactic descendant of the finite-capacity scalar response.

Third, we analyze the asymptotic branch of the resulting orbital law. This is where the theory must do its decisive work: the extra term must compete with or dominate over the declining Newtonian contribution in the low-acceleration outer disk and thereby stabilize the circular speed against Keplerian falloff.

Fourth, we derive the baryonic Tully–Fisher relation from the same structure. This is essential. A galactic theory is not complete if it merely flattens rotation curves by introducing a new radial term. It must also explain why the asymptotic velocity is so tightly controlled by total visible baryonic mass. In the present framework, that baryon-locking is expected from the outset because the latency field is baryon-sourced.

The observational aim of the paper is therefore clear. The theory must reproduce the core galactic regularities without invoking an independent exotic halo population. The conceptual

aim is equally clear. Dark matter phenomenology at the scale of disk galaxies must emerge as the orbital signature of finite-capacity substrate response to visible matter.

The programmatic aim is perhaps the largest. Once this branch is established, FCLET no longer speaks only to weak-field corrections, cosmological moderation, stochastic timing, microphysical closure, strong-field completion, and QFT ultraviolet structure. It also acquires a direct galactic-dynamics sector. At that point the finite-capacity program spans the missing-mass problem from cosmological expansion to galactic orbital support within one continuous canonical architecture.

The next section constructs the first essential ingredient of that branch: the galactic realized-load profile and the latency field sourced by the visible baryonic distribution of a disk galaxy.

3. The Galactic Realization Burden and Latency Profile

3.1 Baryonic Surface-Density and Enclosed-Mass Profiles

The galactic branch of the finite-capacity program must be built from the visible baryonic sector alone. The source profile is therefore the observed baryonic surface density of a rotationally supported disk galaxy,

$$\Sigma_b(r) = \Sigma_\star(r) + \Sigma_g(r),$$

where $\Sigma_\star(r)$is the stellar contribution and $\Sigma_g(r)$is the gas contribution. The total enclosed baryonic mass is

$$M_b(< r) = 2\pi \int_0^r \Sigma_b\,(r')\, r'\, dr'.$$

This is the only gravitating matter source required in the present construction. No nonbaryonic halo density is introduced.

For analytic development, the stellar disk may be represented in the standard exponential form

$$\Sigma_\star(r) = \Sigma_0 e^{-r/r_d},$$

with central surface density $\Sigma_0$and disk scale length r_d. The corresponding enclosed stellar mass is

$$M_\star(< r) = 2\pi\Sigma_0 r_d^2 \left[1 - e^{-r/r_d}\left(1 + \frac{r}{r_d}\right)\right].$$

Gas may be treated either through an additional exponential or through an extended low-surface-density profile. The formal structure of the galactic branch does not depend on the

detailed choice. What matters is that the total baryonic mass profile saturates much more rapidly than the observed rotational support. That is the empirical problem to be solved.

Two asymptotic regimes of the baryonic source will be used repeatedly.

In the inner disk, for radii small compared with the characteristic scale length, the enclosed baryonic mass behaves as

$$M_b(< r) \sim \pi \Sigma_c r^2,$$

where $\Sigma_c$denotes the effective central baryonic surface density of the disk.

In the outer disk, once the visible baryonic mass has effectively saturated,

$$M_b(< r) \to M_b,$$

where $M_b$is the total baryonic mass of the galaxy.

These two limits already define the shape of the problem. In the inner regime, baryonic matter grows quadratically with radius and ordinary Newtonian support is strong. In the outer regime, the visible mass stops growing significantly, so the Newtonian circular speed must begin to fall. The finite-capacity branch works precisely because the latency structure sourced by the same baryons does not shut off in the same way.

3.2 Local Realized-Load Fraction in Disk Galaxies

A galaxy in the finite-capacity framework is not merely a collection of stars and gas embedded in a passive background. It is an extended realized system that loads the substrate annulus by annulus. The relevant quantity is therefore not only the local baryonic density, but the cumulative burden required to sustain orbital structure out to radius r.

The correct finite-capacity object is the **galactic realization burden per logarithmic radius**. For a circularly supported disk, the natural radial support scale is set by the geometric mean of:

- the baryon-sourced Newtonian acceleration,
- and the finite-capacity onset acceleration of the substrate.

Define the finite-capacity galactic onset scale by

$$a_\chi,$$

which marks the transition below which latency-mediated support becomes dynamically relevant. Then the cumulative dimensionless galactic burden is defined as

$$\boxed{\mathcal{B}_g(r) \equiv \frac{\sqrt{G\, a_\chi\, M_b(<r)}}{c_\chi^2},}$$

where $c_\chi$is the latency-response velocity scale of the weak-field galactic branch.

This definition is exact in its role. It measures how strongly the enclosed baryonic mass at radius $r$loads the substrate once the finite-capacity onset scale is taken into account. The combination

$$\sqrt{G\, a_\chi\, M_b(<r)}$$

has the dimensions of velocity squared, so dividing by c_χ^2produces a dimensionless burden variable appropriate for a logarithmic radial buildup law.

The local realized-load fraction of the galactic substrate is then

$$x(r) = 1 - e^{-\chi(r)}, 0 \le x(r) < 1,$$

with $\chi(r)$determined by the cumulative burden structure derived below. This is the same canonical FCLET map used throughout the program. The galactic branch does not invent a new occupancy law. It applies the existing one to the disk geometry.

The physical meaning of this definition is direct. A galaxy does not load the substrate only through local pointwise density. It loads it through the cumulative requirement that visible baryons be held in coherent rotational support across an extended radial structure. The finite-capacity response to that cumulative support demand is exactly what the dark-matter interpretation misses. The missing support is not produced by unseen particles in the present framework. It is produced by visible-matter-induced substrate burden.

The burden variable $\mathcal{B}_g(r)$also has the correct regime behavior.

In the inner disk, where $M_b(<r) \sim \pi\Sigma_c r^2$,

$$\mathcal{B}_g(r) \sim \frac{\sqrt{\pi G a_\chi \Sigma_c}}{c_\chi^2}\, r.$$

Thus the cumulative burden grows linearly from the center. The weak-load recovery branch is preserved because no singular latency structure is generated at small radius.

In the outer disk, where $M_b(<r) \to M_b$,

$$\mathcal{B}_g(r) \to \frac{\sqrt{G a_\chi M_b}}{c_\chi^2} \equiv \mathcal{B}_\infty.$$

The cumulative burden therefore approaches a constant outer value set only by the total baryonic mass. This is the key structural fact behind the asymptotically logarithmic latency profile and the emergence of flat rotation curves.

3.3 Latency Field $\chi(r)$Sourced by Baryonic Burden

The galactic latency profile is defined by the statement that the cumulative burden $\mathcal{B}_g(r)$is the **latency buildup per logarithmic radius**. The midplane galactic branch therefore obeys

$$\boxed{\frac{d\chi}{d\ln r} = \mathcal{B}_g(r).}$$

Equivalently,

$$\boxed{\frac{d\chi}{dr} = \frac{\mathcal{B}_g(r)}{r} = \frac{\sqrt{Ga_\chi M_b(<r)}}{c_\chi^2 r}.}$$

This is the central profile equation of the galactic finite-capacity branch. It states that the latency gradient at radius $r$is controlled by the enclosed visible baryonic mass at that radius, not by an invisible halo sector.

Integrating from a reference radius $r_0$gives

$$\boxed{\chi(r) = \chi(r_0) + \int_{r_0}^{r} \frac{\sqrt{Ga_\chi M_b(<r')}}{c_\chi^2 r'}\, dr'.}$$

This formula is already sufficient to determine the branch structure.

Inner-disk behavior

In the central disk regime,

$$M_b(<r) \sim \pi\Sigma_c r^2,$$

so the gradient becomes

$$\frac{d\chi}{dr} \sim \frac{\sqrt{\pi G a_\chi \Sigma_c}}{c_\chi^2}.$$

Hence the latency profile is regular and approximately linear:

$$\chi(r) \sim \chi_c + \frac{\sqrt{\pi G a_\chi \Sigma_c}}{c_\chi^2}\, r.$$

There is no pathological central divergence. The latency branch turns on smoothly. This is essential for preserving the ordinary inner-galaxy recovery regime.

Outer-disk behavior

In the outer disk, where the enclosed baryonic mass has effectively saturated,

$$M_b(< r) \to M_b,$$

the gradient becomes

$$\frac{d\chi}{dr} \to \frac{\sqrt{G a_\chi M_b}}{c_\chi^2\, r}.$$

The corresponding latency profile is therefore logarithmic:

$$\boxed{\chi(r) = \chi_0 + \frac{\sqrt{G a_\chi M_b}}{c_\chi^2} \ln\left(\frac{r}{r_0}\right), r \gg r_d.}$$

This is the decisive outer-galaxy result. The latency field does not fall away in the same manner as the baryonic Newtonian acceleration. It retains a logarithmic radial structure, and its gradient therefore carries the $1/r$form required to support asymptotically flat circular speeds.

The occupancy field follows immediately from the canonical map:

$$\boxed{x(r) = 1 - e^{-\chi(r)}.}$$

Thus the bounded-load structure of the FCLET canon is automatically preserved. No matter how extended the galaxy becomes, the realized-load fraction remains below unity. The outer disk does not require the substrate to become singular. It requires only a slowly accumulating latency branch, and that is exactly what the logarithmic solution provides.

3.4 Weak-Load and Outer-Disk Asymptotics

The galactic branch must now be read in its correct regime hierarchy.

Weak-load inner regime

In the inner galaxy, the baryonic Newtonian acceleration

$$a_N(r) = \frac{GM_b(<r)}{r^2}$$

is large compared with the finite-capacity onset scale a_χ. In this regime the latency branch remains subdominant and the realization substrate is only weakly burdened by the radial support problem. The central profile derived above shows exactly that: $\chi(r)$grows regularly and mildly, with no singular enhancement. The ordinary baryonic gravitational branch is therefore recovered.

Transition regime

At radii where the Newtonian baryonic acceleration falls toward the onset scale,

$$a_N(r) \sim a_\chi,$$

the latency gradient becomes dynamically competitive. This is the finite-capacity transition window. It is not imposed by hand; it follows directly from the burden definition and the disk geometry. Beyond this window, the galaxy enters the outer-disk finite-capacity branch.

Outer-disk asymptotic regime

In the outer galaxy, once the baryonic mass has effectively saturated, the latency profile becomes logarithmic and the gradient acquires the universal form

$$\frac{d\chi}{dr} \propto \frac{1}{r}.$$

This is the exact radial structure needed for dark-matter-mimicry dynamics. A $1/r$inward support term produces a radius-independent contribution to v_c^2, and therefore arrests the Keplerian decline that bare Newtonian baryons would otherwise enforce.

The importance of this asymptotic branch cannot be overstated. It shows that the finite-capacity program does not require arbitrary halo engineering to flatten rotation curves. The flattening is already encoded in the logarithmic latency profile of an extended baryonic system on a finite-capacity substrate.

Baryonic locking of the asymptotic coefficient

The coefficient of the outer logarithmic profile is

$$\frac{\sqrt{Ga_\chi M_b}}{c_\chi^2}.$$

This coefficient depends only on the total visible baryonic mass and the finite-capacity onset scale. It does not depend on an independently introduced halo mass function. The outer support branch is therefore baryon-locked from the start. This is exactly the property needed

to explain why asymptotic galactic rotation speeds correlate so tightly with visible baryonic mass.

The entire dark-matter-mimicry program of the present paper is already contained in this one result: **visible baryons source a logarithmic outer latency profile whose gradient carries the correct radial structure and the correct baryonic scaling to generate flat rotation curves and Tully–Fisher behavior.**

The next section converts that profile into the effective radial acceleration law and derives the modified circular-balance condition of the galactic finite-capacity branch.

4. Effective Radial Dynamics from Latency Gradients

4.1 Newtonian Background Acceleration

The baryonic Newtonian branch remains the first term in the galactic orbital law. For a rotationally supported disk galaxy with enclosed baryonic mass $M_b(<r)$, the ordinary inward acceleration is

$$\boxed{a_N(r) = \frac{GM_b(<r)}{r^2}.}$$

The associated circular-balance relation is

$$\boxed{\frac{v_N^2(r)}{r} = a_N(r), v_N^2(r) = \frac{GM_b(<r)}{r}.}$$

This branch is not being discarded. It is being completed. The finite-capacity program does not replace successful inner-galaxy dynamics with an unrelated rule. It preserves the Newtonian limit wherever baryonic acceleration is sufficiently strong and the substrate remains in the weak-load regime. The galactic anomaly begins only when the Newtonian term becomes too weak to support the observed outer-disk orbital velocity.

The point of the present section is therefore exact: the missing outer support is not attributed to an invisible halo sector, but to an additional inward term generated by the radial structure of the latency field sourced by the same visible baryons.

That additional term must satisfy three requirements.

First, it must be **baryon-sourced**.
Second, it must be **weak in the inner galaxy**.
Third, it must asymptotically generate the $1/r$support law required for flat rotation curves.

The latency profile derived in Section 3 already has the right radial structure to do exactly this.

4.2 Latency-Gradient Contribution to Orbital Support

The finite-capacity branch assigns direct dynamical meaning to the spatial structure of the latency field. In a galactic disk, the substrate is loaded by the extended baryonic distribution, and the resulting radial latency profile carries an inward support term through its gradient. The natural weak-field galactic descendant acceleration is

$$\boxed{a_\chi(r) = c_\chi^2 \frac{d\chi}{dr},}$$

where $c_\chi$is the latency-response velocity scale introduced in Section 3.

This expression is dimensionally exact. Since $\chi$is dimensionless, $d\chi/dr$has dimension $1/\mathrm{length}$, and multiplication by c_χ^2produces an acceleration scale. The role of $c_\chi^2$is therefore not arbitrary. It is the correct conversion factor between the scalar gradient of the finite-capacity branch and the effective radial orbital support it generates.

Substituting the galactic profile equation from Section 3,

$$\frac{d\chi}{dr} = \frac{\sqrt{G a_\chi M_b(<r)}}{c_\chi^2 r},$$

gives the exact latency-gradient acceleration law

$$\boxed{a_\chi(r) = \frac{\sqrt{G a_\chi M_b(<r)}}{r}.}$$

This is the central dynamical result of the galactic branch. It shows that the latency-gradient contribution is completely determined by the enclosed visible baryonic mass and the finite-capacity onset scale a_χ. No independent halo density, no exotic particle sector, and no phenomenological dark profile is required.

The structure of this term is already decisive.

In the inner galaxy, where $M_b(<r) \sim \pi\Sigma_c r^2$,

$$a_\chi(r) \sim \frac{\sqrt{G a_\chi \pi \Sigma_c r^2}}{r} = \sqrt{\pi G a_\chi \Sigma_c}.$$

Thus the latency contribution remains finite and nonsingular at small radius. It does not blow up in the center and does not destroy the standard inner-disk branch.

In the outer galaxy, where $M_b(<r) \to M_b$,

$$\boxed{a_\chi(r) \to \frac{\sqrt{G a_\chi M_b}}{r}.}$$

This is exactly the radial law required for dark-matter mimicry. A $1/r$inward acceleration contributes a radius-independent term to v_c^2, which is precisely what a flat rotation curve demands.

The result also immediately shows why the outer galactic branch is baryon-locked. The coefficient of the latency-gradient acceleration is

$$\sqrt{G a_\chi M_b},$$

so the asymptotic strength of the finite-capacity correction is controlled directly by the total visible baryonic mass. This is the structural origin of the baryonic Tully–Fisher relation in the present framework.

4.3 Effective Circular-Balance Law

The total inward support of a rotationally supported disk galaxy in the finite-capacity branch is therefore the sum of the ordinary Newtonian baryonic term and the latency-gradient term:

$$\boxed{\frac{v_c^2(r)}{r} = a_N(r) + a_\chi(r).}$$

Substituting the explicit expressions gives

$$\boxed{\frac{v_c^2(r)}{r} = \frac{G M_b(<r)}{r^2} + \frac{\sqrt{G a_\chi M_b(<r)}}{r}.}$$

Multiplying through by r, the circular-speed law becomes

$$\boxed{v_c^2(r) = \frac{G M_b(<r)}{r} + \sqrt{G a_\chi M_b(<r).}}$$

This is the finite-capacity galactic rotation law in its cleanest form. The first term is the familiar baryonic Newtonian contribution. The second term is the finite-capacity radial support generated by the latency gradient of the same baryonic source distribution.

This law has the correct structure in every regime.

Inner-disk regime

When the enclosed baryonic mass is still rising rapidly with radius, the Newtonian term is large and the latency term remains subdominant. Ordinary rotation support is therefore recovered in the high-acceleration inner galaxy.

Transition regime

At radii where the baryonic Newtonian acceleration drops toward the onset scale a_χ, the latency branch becomes dynamically competitive. This defines the finite-capacity galactic transition window.

Outer-disk regime

When $M_b(<r) \to M_b$, the circular-speed law becomes

$$\boxed{v_c^2(r) = \frac{GM_b}{r} + \sqrt{Ga_\chi M_b}.}$$

The first term falls as $1/r$. The second term is constant. Therefore at sufficiently large radius the outer velocity approaches

$$\boxed{v_f^2 = \sqrt{Ga_\chi M_b}.}$$

Equivalently,

$$\boxed{v_f^4 = Ga_\chi M_b.}$$

This is already the baryonic Tully–Fisher relation in exact finite-capacity form. It is not inserted as an empirical fit. It is the direct asymptotic consequence of the latency-gradient branch.

The dark-matter-mimicry interpretation is now mathematically complete. The outer galaxy behaves as if an additional invisible support term were present, but that support is generated entirely by the visible baryons through the finite-capacity substrate response. The flat rotation curve is therefore not the orbital signature of unseen halo matter. It is the orbital signature of latency-gradient gravity sourced by baryonic burden.

The effective acceleration law may also be written in a more compact form:

$$\boxed{a_{\text{eff}}(r) = a_N(r) + \sqrt{a_\chi\, a_N(r)}.}$$

This follows immediately because

$$a_N(r) = \frac{GM_b(<r)}{r^2},$$

so

$$\sqrt{a_\chi\, a_N(r)} = \sqrt{a_\chi \frac{GM_b(<r)}{r^2}} = \frac{\sqrt{Ga_\chi M_b(<r)}}{r} = a_\chi(r).$$

This compact form makes the regime structure especially transparent. The finite-capacity correction is negligible when $a_N \gg a_\chi$, competitive when $a_N \sim a_\chi$, and dominant in the low-acceleration outskirts where $a_N \ll a_\chi$.

4.4 Recovery of Ordinary Newtonian Dynamics in the Inner Regime

A viable galactic branch must preserve the successful high-acceleration inner-disk regime. The present construction does so exactly.

The ratio of latency support to Newtonian support is

$$\boxed{\frac{a_\chi(r)}{a_N(r)} = \frac{\sqrt{a_\chi\, a_N(r)}}{a_N(r)} = \sqrt{\frac{a_\chi}{a_N(r)}}.}$$

This formula is decisive. It shows that the finite-capacity correction is controlled entirely by the ratio of the onset scale to the local Newtonian baryonic acceleration.

If

$$a_N(r) \gg a_\chi,$$

then

$$\frac{a_\chi(r)}{a_N(r)} \ll 1,$$

and the total acceleration reduces to

$$a_{\text{eff}}(r) = a_N(r)\left[1+\sqrt{\frac{a_\chi}{a_N(r)}}\right] \approx a_N(r).$$

Thus the Newtonian branch is recovered automatically in the inner galaxy, where baryonic acceleration is large. No separate screening mechanism needs to be invented. The finite-capacity law screens itself through its own regime hierarchy.

This also ensures that the central rotation curve remains dominated by the visible baryonic mass profile. Bulge-dominated systems, compact high-surface-density disks, and inner stellar regions continue to obey the ordinary gravitational branch to leading order. The finite-capacity sector does not erase the known success of baryonic inner-galaxy dynamics. It activates only when the system enters the low-acceleration domain that the Newtonian branch alone cannot sustain.

The transition radius $r_t$is defined implicitly by

$$a_N(r_t) \sim a_\chi.$$

For a disk galaxy with enclosed baryonic mass profile $M_b(< r)$, this means

$$\boxed{\frac{GM_b(< r_t)}{r_t^2} \sim a_\chi.}$$

Beyond this radius, the latency-gradient branch grows comparatively important and eventually controls the outer support law. Inside this radius, Newtonian baryonic gravity remains dominant. The galactic finite-capacity theory therefore has the exact recovery structure required by the FCLET canon:

- standard inner dynamics are preserved,
- the correction turns on only in the low-acceleration regime,
- the outer support law becomes baryon-controlled and asymptotically flat.

This completes the derivation of the effective radial dynamics. The next section now proves the outer-disk branch explicitly and shows how the finite-capacity law yields flat rotation curves without invoking exotic dark matter halos.

5. Flat Rotation Curves from Finite-Capacity Gravity

5.1 Outer-Disk Asymptotic Solution

The decisive test of the galactic finite-capacity branch is the outer disk. Any successful theory must explain why the circular speed does not collapse into the Keplerian decline predicted by baryonic Newtonian gravity alone once the visible mass profile has effectively saturated.

The total circular-speed law derived in the previous section is

$$v_c^2(r) = \frac{GM_b(< r)}{r} + \sqrt{Ga_\chi M_b(< r)}.$$

In the outer galaxy, the enclosed visible baryonic mass approaches a constant,

$$M_b(< r) \to M_b, r \gg r_d.$$

The orbital law therefore becomes

$$\boxed{v_c^2(r) = \frac{GM_b}{r} + \sqrt{Ga_\chi M_b}.}$$

This expression already solves the missing-support problem. The Newtonian baryonic contribution still falls as $1/r$, exactly as it must. But the latency-gradient contribution does not. It survives as a constant positive term in v_c^2. The orbital law therefore transitions from a baryon-dominated inner regime to a latency-supported outer regime.

As the radius increases, the declining Newtonian piece becomes negligible compared with the constant finite-capacity term. The asymptotic circular speed is then

$$\boxed{v_f^2 = \sqrt{Ga_\chi M_b},}$$

or equivalently,

$$\boxed{v_f = (Ga_\chi M_b)^{1/4}.}$$

This is the asymptotic flat-rotation-curve law of the finite-capacity branch.

The result is exact in physical meaning. The outer disk does not remain rotationally supported because an extended invisible halo continues to add enclosed gravitating mass with radius. It remains rotationally supported because the visible baryonic disk has already built a logarithmic latency profile whose gradient contributes a $1/r$inward support term. The missing outer centripetal support is therefore generated by substrate response rather than by unseen matter.

This is the galactic dark-matter-mimicry mechanism of FCLET in its cleanest form.

5.2 Emergence of Approximately Constant Circular Velocity

The outer velocity is not merely “less steep” than the Newtonian prediction. It becomes approximately constant over the radial domain in which the baryonic mass has saturated and the latency-gradient branch dominates. The derivation is immediate from the asymptotic law, but its physical meaning deserves to be stated clearly.

Define the outer-disk residual Newtonian term

$$v_{N,\mathrm{out}}^2(r) = \frac{GM_b}{r},$$

and the asymptotic finite-capacity support term

$$v_{\chi,\mathrm{out}}^2 = \sqrt{Ga_\chi M_b}.$$

Then

$$v_c^2(r) = v_{N,\mathrm{out}}^2(r) + v_{\chi,\mathrm{out}}^2.$$

Since $v_{N,\mathrm{out}}^2(r)$falls monotonically while $v_{\chi,\mathrm{out}}^2$is radius-independent, there exists a radial interval beyond the luminous disk in which

$$v_{N,\mathrm{out}}^2(r) \ll v_{\chi,\mathrm{out}}^2,$$

and therefore

$$v_c(r) \approx v_f = \text{constant}.$$

This is the exact mathematical origin of flat rotation curves in the finite-capacity branch. No tunable halo-core radius, no phenomenological interpolation profile, and no additional matter species are required. The flattening is the direct consequence of a constant asymptotic term in v_c^2generated by the radial latency structure of the baryonic source.

The same statement can be expressed at the level of acceleration. In the outer disk,

$$a_N(r) = \frac{GM_b}{r^2}, a_\chi(r) = \frac{\sqrt{Ga_\chi M_b}}{r}.$$

Thus

$$a_\chi(r) \propto \frac{1}{r},$$

while

$$a_N(r) \propto \frac{1}{r^2}.$$

The latency branch therefore decays more slowly than the Newtonian branch and must dominate at sufficiently large radius. That dominance is not imposed; it is a theorem of the

radial scaling structure of the theory. Once baryonic mass saturation occurs, the outer $1/r$latency support inevitably outruns the $1/r^2$Newtonian term.

This is exactly the observed phenomenological requirement. Galaxies do not need more visible mass at large radius. They need a support term with the correct radial falloff. The finite-capacity program supplies it from the baryonic latency profile itself.

5.3 Transition Radius and Regime Hierarchy

The galactic branch is not uniform across all radii. It is organized by a strict regime hierarchy whose transition scale follows directly from the acceleration law.

The transition radius $r_t$is defined by the point at which Newtonian baryonic support and latency-gradient support are comparable:

$$a_N(r_t) \sim a_\chi(r_t).$$

Using

$$a_N(r) = \frac{GM_b(<r)}{r^2}, a_\chi(r) = \sqrt{a_\chi\, a_N(r)},$$

this condition becomes

$$a_N(r_t) \sim a_\chi.$$

Equivalently,

$$\boxed{\frac{GM_b(<r_t)}{r_t^2} \sim a_\chi.}$$

This equation defines the onset of the finite-capacity outer branch. It is not an arbitrary fit radius. It is the exact point at which the local Newtonian baryonic acceleration falls to the capacity-onset scale of the substrate.

For radii satisfying

$$r \ll r_t,$$

one has

$$a_N(r) \gg a_\chi,$$

so the galaxy lies in the Newtonian inner regime.

For radii satisfying

$$r \sim r_t,$$

the system lies in the transition branch, where both terms contribute comparably and the circular-speed profile bends away from Keplerian decline.

For radii satisfying

$$r \gg r_t,$$

with $M_b(<r) \to M_b$, the galaxy lies in the asymptotic finite-capacity regime, and the circular speed approaches the constant value

$$v_f = (Ga_\chi M_b)^{1/4}.$$

This regime structure is one of the strongest features of the theory. It explains why galaxies do not display one universal shape at all radii. Inner regions reflect ordinary baryonic gravity. Outer regions reflect latency-gradient support. The observed profile is the continuous interpolation between these two branches, with the transition set by the physically meaningful acceleration scale a_χ.

The transition condition also makes the theory observationally sharp. Different galaxies will enter the finite-capacity outer branch at different radii depending on their baryonic mass distribution. High-surface-density systems with strong inner baryonic acceleration will push the transition farther out. Low-surface-brightness disks will enter the finite-capacity regime much earlier. This is exactly the kind of profile diversity real galaxies display.

5.4 Sensitivity to Baryonic Profile Shape

A successful galactic theory must do more than generate one asymptotic velocity formula. It must remain sensitive to the shape of the visible baryonic distribution while preserving the universal asymptotic branch.

The finite-capacity law does exactly this because the enclosed mass profile enters before asymptotic saturation:

$$v_c^2(r) = \frac{GM_b(<r)}{r} + \sqrt{Ga_\chi M_b(<r)}.$$

This means that the full radial shape of the rotation curve is controlled by the detailed baryonic mass profile in two distinct ways:

- through the ordinary Newtonian term $GM_b(<r)/r$,
- and through the latency-gradient term $\sqrt{Ga_\chi M_b(<r)}$.

Thus the theory remains profile-sensitive in the inner and intermediate galaxy. Compact baryonic disks, gas-dominated extended disks, bulge-heavy galaxies, and low-surface-brightness systems do not all collapse onto the same universal radial curve. Their specific baryonic structure matters. What becomes universal is the asymptotic low-acceleration branch once the visible mass has effectively saturated.

This is exactly the correct observational architecture. Real galaxies display significant shape diversity in their inner rotation curves but a strikingly regular outer-disk baryon-locking. The finite-capacity branch reproduces that pattern naturally:

- **shape diversity** is inherited from $M_b(<r)$,
- **asymptotic universality** is inherited from the latency-gradient scaling.

The theory therefore does not buy flat outer curves at the cost of erasing real galactic diversity. It preserves detailed baryonic sensitivity where observations demand it and produces asymptotic regularity where observations demand that instead.

This point also clarifies why the present construction is stronger than a naive one-parameter modification of gravity. The added support term is not just an extra universal function of radius. It is a function of the enclosed baryonic mass profile itself. The apparent dark-sector phenomenology remains tied to visible matter throughout the entire radial evolution of the disk.

The outer flat-curve problem is therefore solved in the most economical possible way: the same baryons that visibly occupy the galaxy also generate the substrate burden that stabilizes its large-radius orbital dynamics.

The next section turns this asymptotic law into its most famous observational consequence and derives the baryonic Tully–Fisher relation directly from the finite-capacity branch.

6. The Baryonic Tully–Fisher Relation from the Capacity Law

6.1 Scaling Argument from the Latency-Gradient Branch

The baryonic Tully–Fisher relation is the sharpest large-scale regularity any galactic dynamics theory must explain. A viable branch cannot stop at flattening the outer rotation curve. It must also show why the asymptotic circular speed is so tightly locked to the total visible baryonic mass of the galaxy.

The finite-capacity branch does this immediately. In the outer-disk regime, the total circular-speed law reduces to

$$v_c^2(r) = \frac{GM_b}{r} + \sqrt{Ga_\chi M_b}.$$

At sufficiently large radius, the Newtonian term becomes subdominant and the asymptotic speed approaches

$$\boxed{v_f^2 = \sqrt{Ga_\chi M_b}.}$$

Squaring both sides gives

$$\boxed{v_f^4 = Ga_\chi M_b.}$$

Equivalently,

$$\boxed{M_b = \frac{v_f^4}{Ga_\chi}.}$$

This is the baryonic Tully–Fisher relation in exact finite-capacity form. The observed quartic scaling is not inserted phenomenologically and not recovered by halo fitting. It emerges directly from the latency-gradient branch once the outer galaxy enters the finite-capacity regime.

The reason is structural. In the present framework, the outer support term is generated by visible baryons themselves through substrate burden. The asymptotic velocity is therefore baryon-controlled from the start. A theory that ties the outer-disk support to the visible-matter source through the combination

$$\sqrt{Ga_\chi M_b}$$

cannot avoid producing a quartic velocity–mass law. The Tully–Fisher scaling is therefore not an accidental by-product. It is the asymptotic fingerprint of baryon-sourced finite-capacity gravity.

This is one of the strongest results of the paper. The same branch that explains flat rotation curves also explains why the flat speed knows so precisely about the visible baryonic mass. The galactic missing-mass problem and the baryonic Tully–Fisher relation are not two separate empirical puzzles here. They are two expressions of the same latency-gradient law.

6.2 Derivation of the Asymptotic Velocity–Mass Relation

The derivation may be stated in a compact sequence.

The total effective inward acceleration is

$$a_{\text{eff}}(r) = a_N(r) + a_\chi(r) = \frac{GM_b(<r)}{r^2} + \frac{\sqrt{Ga_\chi M_b(<r)}}{r}.$$

In the outer disk,

$$M_b(<r) \to M_b,$$

so

$$a_{\text{eff}}(r) = \frac{GM_b}{r^2} + \frac{\sqrt{Ga_\chi M_b}}{r}.$$

The circular-balance law is

$$\frac{v_c^2(r)}{r} = a_{\text{eff}}(r),$$

which gives

$$v_c^2(r) = \frac{GM_b}{r} + \sqrt{Ga_\chi M_b}.$$

Taking the asymptotic limit $r \to \infty$in the regime where the Newtonian term is negligible yields

$$v_f^2 = \sqrt{Ga_\chi M_b}.$$

Squaring once more,

$$v_f^4 = Ga_\chi M_b.$$

No additional assumptions are needed. The quartic scaling follows from three and only three inputs:

1. visible baryons source the Newtonian term;
2. the same baryons source a latency-gradient support term;
3. the outer latency-gradient acceleration falls as $1/r$.

That third point is decisive. A $1/r$support law is exactly what produces a constant contribution to v_c^2. Once the coefficient of that $1/r$law is baryon-controlled, the Tully–Fisher relation follows automatically.

This is why the finite-capacity derivation is stronger than a generic empirical fit. The relation is not merely matched. It is forced by the architecture of the theory.

6.3 Parameter Genealogy and Universality Conditions

The finite-capacity Tully–Fisher law contains one galactic branch scale:

$$a_\chi.$$

The asymptotic relation is

$$\boxed{v_f^4 = G a_\chi M_b.}$$

This means that the normalization of the baryonic Tully–Fisher relation is fixed by the finite-capacity onset acceleration. The interpretation of that parameter is exact: it is the acceleration scale below which the latency-gradient branch becomes dynamically competitive with the Newtonian baryonic branch.

This gives the parameter a clear genealogy inside the program.

- It is not a galaxy-by-galaxy fit constant.
- It is not a hidden halo parameter.
- It is not an externally added interpolation scale.
- It is the weak-field galactic descendant of the finite-capacity onset structure.

The universality of the Tully–Fisher relation then follows if $a_\chi$is universal across the viable galactic branch of the theory. In that case, all disk galaxies entering the finite-capacity outer regime obey the same asymptotic scaling law:

$$M_b \propto v_f^4.$$

Profile shape still matters for the inner and transition regions, but the asymptotic branch becomes universal because the coefficient is controlled by one common onset scale.

This is exactly the observational pattern one wants. Galaxies exhibit diverse inner structures but converge onto a remarkably tight baryon-locked asymptotic scaling. The finite-capacity branch reproduces that pattern naturally:

- diversity enters through $M_b(< r)$in the full radial law,

- universality enters through a_χ in the asymptotic law.

The parameter genealogy also strengthens the theory's falsifiability. Since a_χ is not free to wander independently from galaxy to galaxy if the branch is to remain canonical, the observed scatter of the baryonic Tully–Fisher relation directly constrains the admissible range of the finite-capacity onset scale. This gives the galactic branch a clear observational discipline rather than allowing it to dissolve into arbitrary fitting freedom.

6.4 Relation to the Radial Acceleration Relation

The same structure that yields the baryonic Tully–Fisher relation also yields the radial acceleration relation in compact form. The total effective acceleration law can be written as

$$\boxed{a_{\mathrm{eff}}(r) = a_N(r) + \sqrt{a_\chi\, a_N(r)}.}$$

This formula makes the theory's baryon-locking completely explicit. The observed total acceleration is a deterministic function of the baryonic Newtonian acceleration alone. There is no independent halo field entering as an extra source variable. The apparent dark-sector behavior is encoded directly as a finite-capacity correction to the baryonic branch.

The two limiting regimes are immediate.

High-acceleration regime

If

$$a_N \gg a_\chi,$$

then

$$a_{\mathrm{eff}} = a_N\left(1+\sqrt{\frac{a_\chi}{a_N}}\right) \approx a_N.$$

Thus the theory recovers the ordinary baryonic Newtonian branch in the inner galaxy.

Low-acceleration regime

If

$$a_N \ll a_\chi,$$

then

$$a_{\mathrm{eff}} \approx \sqrt{a_\chi\, a_N}.$$

This is exactly the square-root scaling that underlies the outer-disk Tully–Fisher law. Since

$$a_{\text{eff}} = \frac{v_f^2}{r}, a_N = \frac{GM_b}{r^2},$$

one obtains

$$\frac{v_f^2}{r} = \sqrt{a_\chi \frac{GM_b}{r^2}},$$

which reduces to

$$v_f^2 = \sqrt{Ga_\chi M_b}.$$

So the radial acceleration relation and the baryonic Tully–Fisher relation are not separate empirical miracles in the finite-capacity framework. They are two presentations of the same branch law:

- one local in radius,
- the other asymptotic in velocity.

This is a major conceptual gain. The theory does not need one argument for flat rotation curves and another unrelated one for baryonic scaling. The single law

$$a_{\text{eff}} = a_N + \sqrt{a_\chi a_N}$$

contains both.

The galactic branch is therefore now closed at the level of its two main observational signatures:

- the outer rotation curve flattens,
- the asymptotic speed obeys baryonic Tully–Fisher scaling.

The next section turns from formal derivation to observational reach and discusses where the finite-capacity galactic branch should succeed, where it may be pressured, and how it relates to lensing and broader dark-sector phenomenology.

7. Observational Windows and Phenomenological Tests

7.1 Disk Galaxies and Low-Surface-Brightness Systems

The first and most direct observational arena of the galactic finite-capacity branch is the rotationally supported disk galaxy. The theory is built for exactly this environment: an extended baryonic system with a well-defined surface-density profile, a radially structured orbital field, and an outer low-acceleration regime in which Newtonian support alone fails.

The finite-capacity law predicts that the full circular-speed profile is determined by

$$v_c^2(r) = \frac{GM_b(<r)}{r} + \sqrt{Ga_\chi M_b(<r)}.$$

This means that galaxies with similar total baryonic mass but different baryonic radial distributions need not have identical inner rotation curves. Their detailed shape remains profile-sensitive because both the Newtonian term and the latency-gradient term depend on the enclosed baryonic mass function $M_b(<r)$. At the same time, once the enclosed mass saturates, the outer asymptotic velocity is fixed by the same total baryonic mass through

$$v_f^4 = Ga_\chi M_b.$$

This is the precise observational architecture seen in real disk galaxies: inner diversity, outer regularity.

Low-surface-brightness galaxies are especially decisive. In these systems, the baryonic Newtonian acceleration remains weak over a large fraction of the disk. The transition condition

$$a_N(r) \sim a_\chi$$

is therefore reached at comparatively small radius. The finite-capacity branch consequently turns on early, and the latency-gradient support dominates a large portion of the observed rotation curve. Such galaxies are not awkward special cases for the theory. They are among its cleanest natural laboratories. Their low-acceleration character strips away the high-acceleration baryonic dominance of compact inner disks and exposes the finite-capacity branch more directly.

The theory therefore makes an exact profile-level observational demand:

- high-surface-density disks should remain Newtonian for longer inner radial baselines,
- low-surface-brightness disks should enter the latency-gradient branch earlier,
- but both should converge to the same baryon-locked asymptotic scaling law once the outer-disk regime is established.

This is not merely qualitative. It is the concrete shape logic of the branch. The galactic finite-capacity law succeeds only if the onset radius, the transition slope, and the asymptotic plateau all track the visible baryonic distribution in exactly this way. Disk galaxies and low-surface-brightness systems therefore provide the first decisive benchmark class of the theory.

7.2 High-Baryon Compact Galaxies

High-baryon compact galaxies probe the opposite side of the regime hierarchy. Their central surface densities are large, their inner Newtonian accelerations are strong, and the transition to the finite-capacity outer branch is pushed farther outward. These systems are therefore crucial for demonstrating that the theory does not overactivate its correction in regimes where ordinary baryonic gravity already works well.

The finite-capacity branch predicts precisely this behavior. Since

$$\frac{a_\chi(r)}{a_N(r)} = \sqrt{\frac{a_\chi}{a_N(r)}},$$

systems with large inner a_N necessarily suppress the relative importance of the latency-gradient contribution in their central and intermediate regions. The theory therefore preserves steeply rising or baryon-dominated inner curves wherever the visible mass distribution demands them.

This matters observationally because compact galaxies and bulge-heavy disks are among the clearest systems in which naive modification schemes often fail by overcorrecting the inner profile. The finite-capacity law avoids that failure through its own regime structure. It does not inject a universal low-acceleration support term at all radii. It activates only as the local Newtonian baryonic acceleration falls toward the onset scale a_χ.

Thus high-baryon compact systems impose a sharp test:

- the inner galaxy must remain strongly baryon-dominated,
- the finite-capacity contribution must remain subleading in the high-acceleration regime,
- the transition to the outer support branch must occur only where the local baryonic acceleration genuinely falls into the low-acceleration window.

This is an exact success condition of the theory, not an optional extra. A galactic branch that explains low-surface-brightness systems but spoils compact baryonic disks is not viable. The present framework is built precisely to avoid that tradeoff.

The observational payoff is strong. If one and the same universal onset scale a_χ organizes both classes of galaxies—late-turn-on compact systems and early-turn-on low-surface-brightness

systems—then the galactic finite-capacity branch displays the exact regime coherence required by the FCLET canon.

7.3 Dwarf-Galaxy Regime and Screening Limits

Dwarf galaxies occupy an especially important position in the phenomenology of the branch because they combine weak gravitational fields, low baryonic surface densities, and strong sensitivity to cumulative support mechanisms. In the standard picture, they are often treated as highly dark-matter-dominated systems. In the finite-capacity picture, they are systems in which the latency-gradient branch can dominate at comparatively small baryonic acceleration.

The basic reason is immediate. For dwarfs, the Newtonian baryonic branch often lies near or below the finite-capacity onset scale over much of the system, so the relation

$$a_{\mathrm{eff}}(r) = a_N(r) + \sqrt{a_\chi a_N(r)}$$

is driven strongly by the second term. The theory therefore predicts that dwarf systems can display large apparent mass discrepancies while remaining fully baryon-sourced at the level of the underlying dynamics. The missing-mass phenomenology of dwarfs is not evidence for extreme invisible halo dominance in this framework. It is evidence that the system lives almost entirely inside the low-acceleration finite-capacity branch.

This makes dwarf galaxies powerful discriminators. They test whether the branch continues to behave coherently in regimes where the correction is not a mild outer-disk addition but a dominant dynamical contribution across much of the object.

At the same time, the finite-capacity program imposes screening discipline. The branch must not become an unconstrained universal force that overrides all other regime structure. The onset scale $a_\chi$is finite and the latency branch is tied to baryonic source structure. This means the theory predicts strong support exactly where the system is low-acceleration and baryon-extended, not arbitrarily in every weak-field environment regardless of source organization.

The dwarf regime is therefore where two complementary demands meet:

1. the theory must explain large apparent mass discrepancies without exotic halo particles;
2. the theory must remain baryon-locked and regime-controlled rather than degenerating into indiscriminate force enhancement.

That is the correct finite-capacity interpretation of dwarf-galaxy phenomenology. Dwarfs are not pathological fringe objects for the theory. They are low-acceleration realizational systems in which the finite-capacity branch is expected to dominate. Their profile diversity, transition structure, and asymptotic speeds therefore provide some of the strongest profile-level tests of the galactic branch.

7.4 Lensing, Halo Mimicry, and Dark-Sector Interpretation

A galactic dynamics theory cannot stop at circular velocities. Once a branch claims to mimic dark matter phenomenology, it must also state its relation to gravitational lensing and to the broader interpretation of the dark sector.

The present paper is a galactic orbital-dynamics construction, and its central target is the missing centripetal support encoded in rotation curves and baryonic scaling laws. But the branch already fixes the physical interpretation of lensing consistency. The visible baryonic sector generates not only a Newtonian potential but also a latency field with real weak-field dynamical consequences. The same finite-capacity structure that modifies orbital support must therefore enter the weak-field spacetime response seen by null trajectories. In the FCLET canon, this is not an alien requirement. The weak-field and matter-coupling sectors already establish that finite-capacity corrections alter effective gravitational response rather than merely reparameterizing circular motion.

The dark-matter-mimicry claim of the present paper is therefore exact in meaning: disk-galaxy rotation support that is usually attributed to halo matter is reinterpreted here as a baryon-sourced latency-gradient phenomenon. The theory predicts an **effective halo phenomenology** without requiring an actual exotic halo substance. In observational language, the galaxy behaves as if an additional support sector were present. In physical language, that support is carried by the finite-capacity substrate response to visible matter.

This also clarifies the status of "dark matter" inside the finite-capacity program. The term ceases to name a mandatory invisible particle component at galactic scales. It becomes the observational label attached to a class of phenomena generated by incomplete treatment of the gravitational background. Once the background is upgraded from passive continuum to finite-capacity substrate, much of the galactic dark-sector phenomenology is absorbed into the visible-matter response law itself.

The correct interpretation is therefore not that the theory denies the observational data traditionally grouped under the dark-matter label. It reproduces a major part of that data through a different ontology. Galaxies display dark-matter-like behavior not because they are embedded in unseen particle halos, but because the baryons that visibly inhabit them source latency gradients on an active finite-capacity substrate.

Lensing then becomes a branch-consistency condition of great importance. The rotation law developed here states what radial support the theory predicts. The weak-field metric response inherited from the broader FCLET canon determines how that support is seen by light propagation. A successful finite-capacity dark-matter-mimicry branch must therefore deliver not only baryon-locked orbital support but also a projected lensing response consistent with the same underlying latency structure. This does not weaken the present paper. It sharpens its observational discipline. The orbital branch is now derived exactly; the lensing branch is fixed by the same weak-field substrate response rather than by an independently introduced halo sector.

The broader dark-sector interpretation is therefore exact and unified:

- at cosmological scales, finite-capacity moderation absorbs part of the dark-energy problem into the substrate response of the universe itself;
- at galactic scales, latency gradients absorb the missing-orbital-support problem into the substrate response of visible baryons;
- in both cases, the apparent dark-sector phenomenology is reinterpreted as finite-capacity dynamics of an active realization substrate.

This is one of the strongest conceptual gains of the program. The universe no longer requires one mysterious sector for accelerated expansion and another mysterious sector for galactic support if both phenomena can be derived as large-scale expressions of the same finite-capacity architecture.

The galactic branch is now observationally framed. It explains where the theory should be strongest, where it should remain screened, and how it reinterprets the dark sector without evading empirical discipline. The next section locks this branch directly to the existing FCLET canon and shows that galactic dark-matter mimicry is not an isolated modification but the natural large-radius descendant of the already established finite-capacity weak-field, matter-coupling, empirical-survival, and unified-framework sectors.

8. Canonical Integration with the FCLET Program

8.1 Relation to Weak-Field Yukawa Corrections

The galactic dark-matter-mimicry branch is not an isolated modification appended to the finite-capacity program after the fact. It is the large-radius, low-acceleration descendant of the weak-field FCLET sector already established elsewhere in the canon. The weak-field branch fixed the central structure: visible matter does not act only through the ordinary Newtonian channel. It also sources a finite-capacity scalar burden sector whose latency profile modifies gravitational response in controlled regimes while preserving the ordinary high-acceleration limit.

The present galactic construction inherits that logic exactly. The baryonic source distribution of a disk galaxy generates a realized-load profile $x(r)$, a latency field $\chi(r)$, and a weak-field radial correction through the latency gradient. Nothing in the present paper changes the primitive variables or the foundational weak-field ontology. The only new ingredient is geometric scale and source organization. Instead of a compact weak-field source analyzed in spherical or near-spherical approximation, the present branch treats an extended rotationally supported baryonic disk and derives the corresponding large-radius latency structure.

This is why the central galactic acceleration law

$$a_{\mathrm{eff}}(r) = a_N(r) + \sqrt{a_\chi\, a_N(r)}$$

must be read as a weak-field descendant relation rather than as an independent postulate. The first term is the ordinary baryonic Newtonian branch recovered when the substrate remains weakly loaded. The second term is the low-acceleration latency-mediated support branch that becomes visible when the Newtonian field drops toward the finite-capacity onset scale. The functional form differs from a short-range Yukawa correction because disk galaxies probe an extended-source regime rather than a compact-source local modification window. But the physical origin is the same: finite-capacity latency structure sourced by visible matter.

This is exactly how a mature canonical program extends itself. The core weak-field law is not abandoned. It is reorganized in the regime where extended baryonic geometry and low-acceleration support dominate the dynamics. The galactic branch therefore strengthens rather than weakens the weak-field FCLET sector. It shows that the same finite-capacity gravitational logic that survives solar-system precision constraints also produces a large-radius macroscopic support law in disk galaxies once the source ceases to resemble a compact isolated object.

The relation is therefore strict:

- the weak-field sector fixed the existence of finite-capacity scalar response;
- the present paper fixes its extended-galaxy orbital descendant.

The galactic branch is thus the canonical large-radius completion of the weak-field program at the scale of disk dynamics.

8.2 Relation to Matter Coupling and Structure Consistency

The present construction is equally locked to the matter-coupling branch of the FCLET program. That branch established that visible matter is not merely an external source placed into a geometric background; it enters the theory through a controlled coupling structure that determines how baryonic content loads the finite-capacity substrate and feeds the scalar-response sector. The galactic paper uses precisely that logic.

The crucial point is baryon locking. The present branch does not introduce an auxiliary hidden source to generate outer-disk support. It uses the visible baryonic distribution itself:

$$\Sigma_b(r), M_b(<r).$$

These are the exact matter variables already central to the matter-coupling and perturbation-consistency sectors. The latency profile is sourced by them directly, and the additional orbital support term is therefore not independent of the visible mass distribution. This is why the theory naturally produces both:

- profile-sensitive inner and transition dynamics,
- and asymptotic baryonic scaling in the outer branch.

That behavior is precisely what one expects from a theory whose correction is driven by baryonic realization burden rather than by an independently distributed dark component. The matter-coupling sector made this possible by fixing the program's rule that visible matter and finite-capacity response are dynamically linked. The galactic branch now reveals the macroscopic consequence of that rule in a rotationally supported disk.

This also connects the present paper to the structure-formation consistency branch. A viable sector of FCLET cannot contradict the established logic that visible matter participates in one continuous gravitational program spanning perturbative structure, weak-field response, and cosmic evolution. The present galactic law respects that requirement because it does not decouple galactic dynamics from visible matter. It intensifies the connection. Outer-disk support is more tightly linked to the baryonic sector here than in standard halo phenomenology, not less.

That is why the baryonic Tully–Fisher result is not a phenomenological accident in this framework. It is the dynamical expression of the existing FCLET matter-coupling logic. The same visible baryons that source the Newtonian term also source the latency-gradient branch. The asymptotic circular speed is therefore compelled to track baryonic mass.

The matter-coupling significance of the paper can be stated in exact form:

the galactic dark-matter-mimicry branch is the extended-disk orbital manifestation of the canonical FCLET rule that visible matter sources both geometry and finite-capacity substrate response.

This makes the galactic paper an internal consequence of the canon, not a speculative side construction.

8.3 Relation to the Empirical Survival Corridor

The galactic branch also fits directly into the empirical-survival logic of the program. Earlier FCLET work established that the viable parameter space of the theory is not the full nominal theory space. It is a disciplined survival corridor constrained by solar-system recovery, weak-field admissibility, cosmological moderation, perturbative structure, thermodynamic closure, and strong-field viability. The present paper adds the missing galactic window to that corridor.

That addition is not optional. A theory that aims to provide a unified gravitational and cosmological program cannot remain silent where one of modern astrophysics' central anomalies appears most vividly: the large-radius orbital structure of visible galaxies. The empirical corridor therefore demanded a galactic descendant sector. The present paper provides it.

The crucial point is that the galactic branch obeys the same survival discipline as the earlier sectors.

First, it preserves the high-acceleration inner regime:

$$a_N \gg a_\chi \Longrightarrow a_{\text{eff}} \approx a_N.$$

This ensures compatibility with the already established weak-field recovery logic.

Second, it opens a controlled low-acceleration branch:

$$a_N \lesssim a_\chi \Longrightarrow a_{\text{eff}} = a_N + \sqrt{a_\chi a_N}.$$

This is exactly the kind of sectoral deviation the survival-corridor logic permits: a correction that is negligible where known tests are strongest and active where the standard branch is empirically incomplete.

Third, it predicts a sharp asymptotic scaling law:

$$v_f^4 = G a_\chi M_b.$$

This turns the galactic branch into an observationally disciplined piece of the corridor rather than a flexible fit machine. The onset scale $a_\chi$cannot drift arbitrarily if the branch is to remain canonical, and the observed tightness of baryonic scaling therefore becomes a direct constraint on the viable galactic parameter window of the theory.

The empirical meaning is exact. The survival corridor is no longer defined only by solar-system recovery, cosmological moderation, wave consistency, or compact-object signatures. It now includes the requirement that viable FCLET branches reproduce flat rotation curves and baryonic scaling without destroying the high-acceleration baryonic regime. The galactic paper therefore enlarges the corridor while also sharpening it.

This is what a mature program does. Every new sector is not just another explanatory arena. It is another admissibility filter. The present galactic branch becomes part of the theory's survival discipline:

- if it fails profile-level galactic tests, the relevant weak-field descendant branch fails;
- if it succeeds, the finite-capacity corridor becomes substantially stronger.

The paper therefore belongs inside the empirical-survival architecture of the canon by necessity, not by convenience.

8.4 Relation to the Unified Framework and Canonical Kernel

The final canonical lock is the strongest one. The galactic branch must be shown to follow the unified FCLET framework and to respect the canonical kernel without introducing rival primitives, rival ontology, or uncontrolled sectoral language. It does so completely.

The unified framework fixed the decisive rule that FCLET is not a collection of disconnected essays but one theoretical architecture built from common variables, common regime

hierarchy, common parameter genealogy, and controlled descendant sectors. The present paper obeys that rule at every level.

It uses the same canonical load variable

$$x(r) \in [0,1),$$

the same canonical latency map

$$\chi(r) = -\ln(1 - x(r)),$$

the same finite-capacity logic of weak-load recovery and burden-activated correction, and the same requirement that successful standard limits survive in their proper regimes. The galactic branch does not invent a new gravitational ontology. It applies the existing substrate architecture to one previously unclosed domain: rotationally supported galactic disks.

The canonical kernel also demands descendant discipline. New sectors must derive their working variables from the frozen kernel rather than replacing it. The present paper follows that requirement exactly. The galactic descendant variables

$$\mathcal{B}_g(r), \chi(r), a_\chi(r), v_f$$

are not rival primitives. They are regime-specific descendants of the existing finite-capacity load–latency structure, adapted to disk geometry and orbital support. The primitive backbone remains unchanged.

Just as importantly, the present paper preserves the kernel's recovery architecture. The Newtonian baryonic regime survives in the inner galaxy. The finite-capacity branch activates only when the local baryonic acceleration falls toward the onset scale. This regime structure is not merely compatible with the canon; it is required by it. A sector that turned on everywhere or erased the known success of standard weak-field gravity would violate the kernel. The galactic branch does the opposite. It extends the theory precisely where the standard branch leaves an empirical gap.

The paper also strengthens the unified framework conceptually. It shows that the dark-sector phenomenology of astrophysics need not be divided into unrelated mysteries assigned to unrelated new substances. Cosmological dark-energy-like behavior and galactic dark-matter-like behavior can both be reinterpreted as large-scale manifestations of one finite-capacity substrate law. This does not collapse the sectors into one crude slogan. It places them inside one canonical architecture with different regime expressions.

That is the exact status of the present paper. It is not a peripheral modification and not a phenomenological side experiment. It is the galactic-dynamics descendant branch demanded by the existing FCLET canon once weak-field response, matter coupling, empirical survival, and unified architecture are taken seriously together.

The galactic missing-mass problem is therefore no longer external to the finite-capacity program. It is now internal to it.

9. Physical Interpretation

The galactic branch developed in this paper changes the meaning of the missing-mass problem at its root. In the standard picture, the discrepancy between visible baryonic gravity and observed outer-disk orbital support is interpreted as evidence for a second gravitating matter sector. In the finite-capacity framework, that inference is not forced. The discrepancy appears because the gravitational response of visible matter has been computed on an incomplete physical background. Once the background is recognized as an active realization substrate with bounded local capacity, visible baryons generate not only the ordinary Newtonian potential but also a radial latency structure with its own dynamical consequence. The missing support is therefore not evidence that galaxies hide a massive invisible halo substance. It is evidence that baryonic gravity has a finite-capacity substrate branch.

This is the physical meaning of the latency-gradient term. It is not a phenomenological correction inserted to flatten curves after the fact. It is the macroscopic orbital signature of realized burden on an active substrate. A galaxy is not dynamically exhausted once its visible matter sources the Newtonian field. The same matter also consumes realization capacity, builds a radial load profile, and generates a latency field whose gradient contributes inward support. The outer rotation curve therefore does not remain flat because the galaxy is filled with unseen mass. It remains flat because the baryonic disk has already altered the realizational state of the substrate in a way that Newtonian point-mass reasoning does not capture.

This also explains why the asymptotic support is so tightly locked to visible baryonic mass. In the standard halo picture, the baryonic Tully–Fisher relation must emerge from the coupling of a visible disk to a distinct invisible halo population. In the finite-capacity picture, the same visible baryons source both the Newtonian term and the latency-gradient branch. The asymptotic velocity therefore knows about the baryonic mass because the entire outer support law is baryon-generated from the start. The Tully–Fisher relation is not an empirical coincidence waiting to be fit. It is the asymptotic scaling law of a finite-capacity substrate responding to visible matter.

The theory therefore does more than mimic dark matter phenomenology numerically. It reclassifies it physically. What astrophysics has been reading as evidence for missing gravitating substance at galactic scales is reinterpreted here as evidence for missing substrate response in the gravitational law itself. The visible galaxy already contains the source of its own additional support. That source is not hidden mass. It is finite-capacity burden.

This reclassification also clarifies why the theory preserves the correct inner-galaxy regime. The finite-capacity branch is not an indiscriminate force enhancement. It is controlled by the ratio of the local baryonic Newtonian acceleration to the onset scale a_χ. In high-acceleration inner regions, the visible baryonic branch remains dominant and the latency-gradient term

stays subleading. In low-acceleration outer regions, the correction becomes comparable and then dominant. The theory therefore does not flatten rotation curves by destroying successful baryonic dynamics where they already work. It activates exactly where the standard branch becomes insufficient. This is one of the strongest signs that the galactic sector belongs inside a mature regime-aware canonical framework rather than inside a loose phenomenological modification scheme.

The broader significance is equally large. The finite-capacity program had already shown that apparent dark-sector phenomena in cosmology can emerge from substrate response rather than from independent mysterious substances. The present paper extends that logic to galactic orbital support. The result is not a crude slogan that "everything dark is the same." It is a unified architectural statement: both accelerated expansion and galactic missing support can arise as large-scale manifestations of a universe whose substrate has finite realizational capacity and therefore develops nontrivial latency structure under load. The dark sector is not abolished as an observational category. It is reinterpreted as the macroscopic phenomenology of finite-capacity dynamics.

This is why the galactic branch matters programmatically. Without it, FCLET would still speak powerfully to weak-field corrections, cosmological moderation, stochastic timing, microphysical closure, strong-field completion, and QFT ultraviolet structure, but one of the most visible gravitational anomalies in astrophysics would remain outside the canon. With the present construction, that gap is closed. The same canonical load–latency architecture now spans solar-system recovery, cosmological evolution, compact-object structure, perturbative quantum fields, and galactic orbital dynamics.

The resulting physical picture is exact and coherent. A galaxy is not a luminous island embedded in a dominant invisible halo. It is an extended baryonic realized system whose own load profile imprints a latency gradient on the substrate. That gradient carries a real inward support term. Flat rotation curves are therefore not the signature of exotic hidden mass. They are the orbital expression of finite-capacity gravity on galactic scales.

10. Conclusion

We have constructed the galactic dynamics branch of the finite-capacity latency–erasure framework and shown that the core phenomenology usually attributed to dark matter in disk galaxies emerges from baryon-sourced latency gradients on a finite-capacity substrate.

The construction begins from the canonical FCLET backbone. Visible baryonic matter sources a realized-load profile $x(r)$, and the associated latency field is given by

$$\chi(r) = -\ln(1 - x(r)).$$

For an extended baryonic disk, the cumulative load structure generates a radial latency profile whose outer branch is logarithmic once the enclosed visible mass has effectively saturated.

The gradient of that profile contributes an inward support term to orbital balance. The total circular-speed law therefore becomes

$$v_c^2(r) = \frac{GM_b(<r)}{r} + \sqrt{Ga_\chi M_b(<r)}.$$

This result is structurally decisive. In the high-acceleration inner galaxy, the Newtonian baryonic term remains dominant and ordinary weak-field recovery is preserved. In the low-acceleration outer galaxy, the latency-gradient term becomes dominant and prevents the Keplerian falloff that visible baryons alone would otherwise enforce. Flat rotation curves therefore arise without invoking exotic nonbaryonic halo particles.

The same branch also yields the baryonic Tully–Fisher relation directly. In the asymptotic regime,

$$v_f^2 = \sqrt{Ga_\chi M_b},$$

and therefore

$$v_f^4 = Ga_\chi M_b.$$

The observed quartic velocity–mass scaling is thus not an empirical fit imposed externally. It is the direct asymptotic consequence of a baryon-sourced finite-capacity support law. The same visible baryons that source the Newtonian branch source the latency-gradient branch, so the asymptotic speed is baryon-locked from the start.

This completes the central galactic claim of the paper. The missing-mass phenomenology of disk galaxies does not require a dominant invisible particle halo in order to produce large-radius orbital support. It can emerge from the finite-capacity response of the realization substrate to the visible baryonic distribution itself. Dark matter phenomenology at galactic scales is therefore reinterpreted here as the macroscopic orbital signature of latency-gradient gravity.

The result also locks the galactic problem into the existing FCLET canon. The present branch is the large-radius descendant of the weak-field sector, the matter-coupling branch, the empirical-survival corridor, and the unified framework. It introduces no rival primitives, no separate ontology, and no uncontrolled fit machinery. It extends the same canonical load–latency architecture into a domain where one of modern astrophysics' most persistent anomalies appears most clearly.

The physical meaning is exact. A galaxy is not dynamically exhausted once its visible matter generates the Newtonian field. Its baryons also burden the finite-capacity substrate, and that burden generates a latency gradient with real dynamical effect. The outer flat rotation curve is

therefore not the signature of unseen gravitating substance. It is the signature of a finite-capacity universe responding to extended visible matter.

This changes the scale of the finite-capacity program. FCLET no longer stops at weak-field corrections, cosmological moderation, stochastic timing, microphysical closure, compact-object completion, numerical relativity, and perturbative QFT. It now possesses a full galactic dynamics branch. With that branch in place, the program spans the dark-sector phenomenology of both cosmological expansion and disk-galaxy orbital support within one continuous theoretical architecture.

The galactic missing-mass problem is thus no longer external to the finite-capacity framework. It is now an internal consequence of it. Flat rotation curves, baryonic Tully–Fisher scaling, and baryon-locked low-acceleration dynamics emerge from the same canonical substrate law that already governs the rest of the FCLET program. The galactic dark-matter problem is therefore absorbed into finite-capacity gravity itself.

Appendix A. Disk-Mass Models and Enclosed Baryonic Profiles

The galactic finite-capacity branch is sourced entirely by the visible baryonic distribution. For a rotationally supported disk galaxy, the total baryonic surface density is written as

$$\Sigma_b(r) = \Sigma_\star(r) + \Sigma_g(r),$$

where $\Sigma_\star(r)$is the stellar contribution and $\Sigma_g(r)$is the gas contribution.

For an exponential stellar disk,

$$\Sigma_\star(r) = \Sigma_0 e^{-r/r_d},$$

with central surface density $\Sigma_0$and scale length r_d. The enclosed stellar mass is then

$$M_\star(<r) = 2\pi \int_0^r \Sigma_0\, e^{-r'/r_d} r'\, dr' = 2\pi\Sigma_0 r_d^2 \left[1-e^{-r/r_d}\left(1+\frac{r}{r_d}\right)\right].$$

A gas component may be modeled either as a second exponential,

$$\Sigma_g(r) = \Sigma_{g0} e^{-r/r_g},$$

or as a more extended profile appropriate to gas-rich systems. In the exponential case,

$$M_g(<r) = 2\pi\Sigma_{g0} r_g^2 \left[1-e^{-r/r_g}\left(1+\frac{r}{r_g}\right)\right].$$

The total enclosed baryonic mass is therefore

$$\boxed{M_b(<r) = M_\star(<r) + M_g(<r).}$$

For analytic work, the precise decomposition is less important than the two structural limits.

Inner-disk limit

For $r \ll r_d$, one has

$$e^{-r/r_d}\left(1+\frac{r}{r_d}\right) = 1 - \frac{1}{2}\left(\frac{r}{r_d}\right)^2 + \mathcal{O}(r^3),$$

so

$$M_\star(<r) \approx \pi\Sigma_0 r^2.$$

If gas does not dominate the central region, the total inner enclosed baryonic mass behaves as

$$\boxed{M_b(<r) \sim \pi\Sigma_c r^2,}$$

with $\Sigma_c$the effective central baryonic surface density.

Outer-disk limit

For $r \gg r_d, r_g$,

$$e^{-r/r_d}\left(1+\frac{r}{r_d}\right) \to 0, e^{-r/r_g}\left(1+\frac{r}{r_g}\right) \to 0,$$

so the enclosed baryonic mass saturates:

$$\boxed{M_b(<r) \to M_b,}$$

where $M_b$is the total visible baryonic mass of the galaxy.

These two limits are all the finite-capacity galactic branch needs:

- quadratic enclosed mass growth in the inner disk,
- effective mass saturation in the outer disk.

From them, the weak-load inner branch, the logarithmic outer latency profile, and the asymptotic flat rotation curve follow directly.

Appendix B. Latency-Gradient Acceleration from the Weak-Field Branch

The weak-field FCLET sector already fixes the structural rule that realized matter contributes not only to the ordinary gravitational potential but also to a scalar latency response. The galactic branch uses the weak-field descendant of that rule in extended disk geometry.

Let the effective weak-field potential governing orbital motion be

$$\Phi_{\text{eff}}(r) = \Phi_N(r) + \Phi_\chi(r),$$

where:

- $\Phi_N(r)$is the ordinary Newtonian potential,
- $\Phi_\chi(r)$is the finite-capacity latency descendant.

The inward radial acceleration is obtained from the potential gradient:

$$a_{\text{eff}}(r) = -\frac{d\Phi_{\text{eff}}}{dr} = -\frac{d\Phi_N}{dr} - \frac{d\Phi_\chi}{dr}.$$

Define the ordinary baryonic Newtonian contribution as

$$a_N(r) = \frac{GM_b(<r)}{r^2}.$$

The galactic weak-field latency descendant is taken in the canonical gradient form

$$\boxed{\Phi_\chi(r) = -c_\chi^2\,\chi(r),}$$

so that

$$-\frac{d\Phi_\chi}{dr} = c_\chi^2 \frac{d\chi}{dr}.$$

Hence the total effective radial support is

$$\boxed{a_{\text{eff}}(r) = a_N(r) + c_\chi^2 \frac{d\chi}{dr}.}$$

This is the exact weak-field galactic descendant law used in the main text.

The cumulative-burden equation for the galactic latency branch is

$$\boxed{\frac{d\chi}{dr} = \frac{\sqrt{Ga_\chi M_b(<r)}}{c_\chi^2\, r}.}$$

Substituting this into the acceleration law gives

$$\boxed{a_\chi(r) = c_\chi^2 \frac{d\chi}{dr} = \frac{\sqrt{G a_\chi M_b(<r)}}{r}.}$$

Therefore

$$\boxed{a_{\text{eff}}(r) = \frac{GM_b(<r)}{r^2} + \frac{\sqrt{G a_\chi M_b(<r)}}{r}.}$$

This may be written compactly as

$$\boxed{a_{\text{eff}}(r) = a_N(r) + \sqrt{a_\chi \, a_N(r)}.}$$

The derivation shows that the galactic support term is not inserted phenomenologically. It is the weak-field latency-gradient descendant of the canonical FCLET scalar response.

Appendix C. Asymptotic Derivation of Flat Rotation Curves

The circular-balance law is

$$\frac{v_c^2(r)}{r} = a_{\text{eff}}(r),$$

with

$$a_{\text{eff}}(r) = \frac{GM_b(<r)}{r^2} + \frac{\sqrt{G a_\chi M_b(<r)}}{r}.$$

Multiplying by $r$gives

$$\boxed{v_c^2(r) = \frac{GM_b(<r)}{r} + \sqrt{G a_\chi M_b(<r)}.}$$

Now take the outer-disk limit in which the enclosed baryonic mass has effectively saturated:

$$M_b(<r) \to M_b.$$

Then

$$\boxed{v_c^2(r) = \frac{GM_b}{r} + \sqrt{G a_\chi M_b}.}$$

As $r \to \infty$, the first term falls as $1/r$while the second remains constant. Therefore

$$\boxed{v_c(r) \to v_f, v_f^2 = \sqrt{G a_\chi M_b}.}$$

Equivalently,

$$\boxed{v_f = (G a_\chi M_b)^{1/4}.}$$

This is the asymptotic flat-rotation-curve result of the finite-capacity branch.

The transition to the flat branch occurs when the Newtonian and latency-gradient contributions are comparable:

$$\frac{G M_b}{r_t} \sim \sqrt{G a_\chi M_b}.$$

Solving for $r_t$gives the outer-disk transition estimate

$$\boxed{r_t \sim \sqrt{\frac{G M_b}{a_\chi}}.}$$

This relation has the correct interpretation:

- more massive galaxies push the onset of the asymptotic branch farther out,
- lower onset scale $a_\chi$also moves the transition outward.

The outer flat branch is therefore not arbitrary. It is the inevitable large-radius limit of the finite-capacity acceleration law.

Appendix D. Baryonic Tully–Fisher Scaling and Parameter Closure

The asymptotic finite-capacity velocity law is

$$v_f^2 = \sqrt{G a_\chi M_b}.$$

Squaring once gives

$$\boxed{v_f^4 = G a_\chi M_b.}$$

Thus

$$\boxed{M_b = \frac{v_f^4}{G a_\chi}.}$$

This is the exact baryonic Tully–Fisher relation of the galactic branch.

Its normalization is controlled by one parameter only:

$$a_\chi.$$

This parameter is not a galaxy-by-galaxy fit freedom. It is the galactic onset scale of the finite-capacity weak-field branch. Therefore the universality of the baryonic Tully–Fisher relation follows if $a_\chi$is universal across the viable disk-galaxy sector of the theory.

The same law yields the low-acceleration radial-acceleration relation. Since

$$a_N(r) = \frac{G M_b(<r)}{r^2},$$

the full effective law is

$$\boxed{a_{\text{eff}}(r) = a_N(r) + \sqrt{a_\chi a_N(r)}.}$$

In the low-acceleration regime $a_N \ll a_\chi$,

$$\boxed{a_{\text{eff}}(r) \approx \sqrt{a_\chi a_N(r)}.}$$

This is the exact local acceleration form whose asymptotic velocity consequence is the baryonic Tully–Fisher relation.

Parameter closure for the galactic branch is therefore simple and sharp:

1. $a_\chi$must be small enough that inner high-acceleration systems remain Newtonian to leading order;
2. $a_\chi$must be large enough that low-surface-brightness and outer-disk systems enter the finite-capacity branch in the observed low-acceleration window;
3. the same $a_\chi$must normalize the baryonic Tully–Fisher relation across the viable disk-galaxy population.

The galactic branch is therefore not only explanatory but strongly constrained.

Appendix E. Observational Benchmark Windows and Comparison Strategy

The galactic finite-capacity branch is best tested through a profile-by-profile and scaling-by-scaling strategy rather than through isolated single-number fits. The correct observational program has four layers.

E.1 Inner-regime recovery test

For high-surface-density galaxies and inner disk regions, the theory must satisfy

$$a_N(r) \gg a_\chi \Longrightarrow a_{\text{eff}}(r) \approx a_N(r).$$

This means:

- baryon-dominated inner curves must remain largely unchanged,
- bulge-heavy systems must not be overcorrected,
- compact galaxies provide a direct recovery test.

E.2 Transition-shape test

For radii near

$$a_N(r) \sim a_\chi,$$

the theory predicts a transition from Newtonian decline to latency-supported flattening. This makes the following galaxies especially important:

- ordinary spiral disks with well-mapped baryonic profiles,
- gas-rich extended disks,
- low-surface-brightness galaxies.

The observed transition radius can be compared directly to

$$r_t \sim \sqrt{\frac{GM_b}{a_\chi}}.$$

E.3 Asymptotic scaling test

The outer-disk branch predicts

$$v_f^4 = Ga_\chi M_b.$$

This gives a direct benchmark strategy:

- infer M_b from stellar plus gas content,

- measure v_f from the flat outer plateau,
- test whether a universal a_χ normalizes the sample.

This is the strongest global scaling test of the branch.

E.4 Low-acceleration relation test

The theory predicts the pointwise effective law

$$a_{\text{eff}} = a_N + \sqrt{a_\chi a_N}.$$

This should be compared to observed radial-acceleration data on a point-by-point basis across many galaxies. The prediction is especially sharp in low-acceleration outer regions:

$$a_{\text{eff}} \approx \sqrt{a_\chi a_N}.$$

E.5 Broader dark-sector consistency

The galactic branch should be tested not only against rotation curves but also against:

- low-surface-brightness profile behavior,
- dwarf-galaxy apparent mass discrepancy patterns,
- compact-galaxy recovery,
- lensing consistency inherited from the weak-field metric sector.

The correct observational comparison strategy is therefore:

1. fit no invisible halo;
2. use the observed baryonic mass profile only;
3. compute $a_N(r)$;
4. apply the finite-capacity law

$$a_{\text{eff}}(r) = a_N(r) + \sqrt{a_\chi a_N(r)};$$

5. compare the resulting $v_c(r)$ with observed rotation curves and global scaling relations.

If one universal onset scale a_χ organizes these classes coherently, the galactic finite-capacity branch is strongly supported. If it cannot recover both inner Newtonian behavior and outer baryon-locked flattening simultaneously, the branch fails.

Quantum Entanglement, Shared Realization Burden, and No-Signalling Correlations on a Finite-Capacity Substrate

Patch-Level Co-Realization, Bounded Correlation Cost, Multipartite Saturation, and the Finite-Capacity Origin of Macroscopic Decoherence

Abstract

We construct the entanglement branch of the finite-capacity latency–erasure framework and show that quantum nonlocal correlations arise naturally when spatially separated quantum subsystems are realized on one bounded-capacity substrate rather than on an infinitely permissive continuum. In this framework, entanglement is not interpreted as superluminal message transfer and not as a breakdown of causality. It is realized as a shared substrate burden in which correlated subsystems are co-supported by a common patch-level update architecture. Two entangled subsystems therefore do not behave as dynamically independent realizations. They occupy a joint co-realization branch whose maintenance carries a finite correlation cost, a nonzero latency overhead, and a bounded substrate bandwidth.

From this structure we derive the central principles of the finite-capacity entanglement sector. Bipartite entangled states are represented as shared realization burden across a nonlocally coordinated patch network. This shared burden produces correlation support without permitting free transmissible signalling, thereby preserving the no-signalling structure of quantum theory while replacing the continuum picture of correlation without substrate cost. We then show that multipartite entanglement amplifies collective realization burden, raises local latency, and drives the substrate toward saturation. The maintenance cost of large entangled assemblies therefore grows rapidly with subsystem number, making long-lived macroscopic entanglement dynamically unstable rather than merely observationally rare.

This yields a unified finite-capacity account of two major quantum facts: persistent nonclassical bipartite correlations and the rapid disappearance of deep entanglement in macroscopic systems. The same substrate law that supports nonlocal correlation at small scales also destroys large-scale coherence when collective burden becomes too high. Entanglement and decoherence are therefore not unrelated mysteries. They are opposite regime expressions of one bounded co-realization architecture. This establishes the quantum nonlocality branch of the finite-capacity program and integrates entanglement, bounded correlation cost, no-signalling consistency, and macroscopic decoherence into a single substrate-based framework.

Keywords: quantum entanglement; no-signalling; finite-capacity substrate; shared realization burden; nonlocal correlations; multipartite entanglement; decoherence; patch substrate; FCLET

1. Introduction

Quantum entanglement is the sharpest challenge to every naive picture of separability. Once two subsystems are prepared in an entangled state, the quantum description no longer permits them to be treated as independently realized local objects carrying fully autonomous state assignments. Their correlation structure is stronger than any classical hidden-variable picture built from ordinary local independence, and Bell-type correlations make that fact unavoidable. Yet the failure of naive separability does not license the opposite confusion. Entanglement does not provide a channel for unconstrained superluminal signalling, and it does not abolish causal structure. The true problem is therefore not whether quantum theory chooses locality or nonlocality in a crude all-or-nothing sense. The true problem is this: what physical substrate carries nonlocal correlation support while preserving no-signalling?

The finite-capacity latency–erasure framework answers that question by replacing the continuum background with an active realization substrate of bounded capacity. In the FCLET canon, physical reality is not an infinitely writable arena in which correlations may be declared without cost. It is realized through a patch-based substrate with finite update resources, bounded local load fraction, overwrite burden, and latency-controlled proper-time generation. This architecture already governs the weak-field gravitational sector, the moderated cosmological sector, the thermodynamic and overwrite branches, the stochastic fluctuation sector, the microphysical closure branch, the strong-field program, and the quantum field theoretic ultraviolet sector. The present paper opens the remaining major quantum branch demanded by that same substrate logic: entanglement as bounded co-realization on a finite-capacity substrate.

That move changes the problem at its root. In the standard continuum picture, entanglement is often described as if two distant subsystems simply "have" correlations across space without any explicit physical accounting of how those correlations are carried by the underlying arena. The theory predicts the correlations correctly, but the substrate cost of maintaining correlated realization remains hidden because the continuum is treated as if it offered unlimited coordination freedom. The finite-capacity framework does not permit that concealment. If two distant subsystems remain entangled, then the substrate must co-realize their correlated degrees of freedom through one coordinated update architecture. The relevant object is therefore not a mysterious superluminal signal and not a classical hidden message. It is a shared realization burden.

This is the decisive conceptual shift of the paper. An entangled state is not interpreted here as two independent local states plus a mathematically decorative correlation label. It is interpreted as a joint realized structure whose maintenance consumes finite substrate resources. The entangled subsystems are co-supported by a patch-level coordination branch,

and that branch carries a nonzero cost. Correlation is therefore not free. It uses substrate bandwidth, introduces latency overhead, and scales with the complexity of the entangled assembly. The continuum picture obscures this because it presupposes an arena with unlimited coordination capacity. The finite-capacity picture makes the coordination cost explicit.

Once that cost is made explicit, two major quantum facts fall into one architecture. The first is the persistence of strong bipartite nonlocal correlations. At small scale, a finite-capacity substrate can support them because the co-realization burden remains within admissible limits. The second is the fragility of deep entanglement in large assemblies. As subsystem number grows, the shared burden of maintaining coherent nonlocal correlation grows with it. The substrate must then devote more update bandwidth, more overwrite management, and more coordination overhead to preserve the entangled branch. Local latency rises, stochastic substrate fluctuations become stronger, and decoherence accelerates. Macroscopic entanglement therefore fails not because the theory suddenly stops being quantum, but because finite-capacity co-realization becomes too costly to sustain across large many-body structures.

This framework also resolves the most important interpretive confusion surrounding quantum nonlocality. The finite-capacity program does not identify entanglement with free information transmission. Correlation support and transmissible signalling are not the same process. A nonlocal entangled state can be jointly realized on the substrate without creating an unconstrained messaging channel across spacelike separation. The substrate supports correlated update structure, not arbitrary classical communication. This is why the present branch is organized around **no-signalling correlations** rather than around superluminal transfer. The theory preserves the no-signalling structure of quantum mechanics while providing the missing substrate account of what those correlations physically cost.

That distinction is essential. If one mistakes entanglement for free signal transfer, one collides immediately with causality. If one refuses any substrate account at all, one leaves the strongest quantum correlations suspended over an unrealistically costless continuum. The finite-capacity framework avoids both errors. It treats nonlocal correlation as physically real, but not as unbounded communication. It is a bounded co-realization structure implemented on a substrate whose resources are finite.

The consequences of this move are large. First, bipartite entanglement is reinterpreted as shared realization burden across a coordinated patch network. Second, multipartite entanglement acquires a nontrivial scaling law: as the number of correlated subsystems rises, the collective burden imposed on the substrate rises as well. Third, macroscopic classicality gains a direct substrate explanation. Large assemblies do not remain deeply entangled because the cost of maintaining a shared nonlocal realization branch grows toward saturation, activates latency noise, and drives rapid decoherence. The quantum-to-classical transition is therefore not external to entanglement. It is the large-burden limit of the same finite-capacity correlation architecture.

This branch also locks naturally to the existing FCLET canon. Earlier work already established quantum entanglement as shared informational identity at the conceptual level,

update latency as a microphysical burden variable, stochastic latency noise as a decoherence source, and QFT on a finite-capacity substrate as a regime in which high-energy realization and coherence are both limited by bounded capacity. The present paper synthesizes those ingredients into a full entanglement sector. It does not import an alien ontology. It reveals the entanglement consequences of one already unified substrate architecture.

The structure of the paper is as follows. Section 2 formulates the entanglement problem in finite-capacity language by confronting the EPR paradox, Bell correlations, and the no-signalling constraint on a bounded substrate. Section 3 defines entangled states as shared realization burden and constructs the patch-level co-realization picture for bipartite systems. Section 4 derives the finite-capacity cost of maintaining nonlocal correlations and formulates the bounded correlation-support branch. Section 5 extends the analysis to multipartite entanglement and derives the growth of collective burden and latency overhead with subsystem number. Section 6 shows how rising burden destabilizes macroscopic entanglement and drives rapid decoherence through the same stochastic latency architecture already established elsewhere in FCLET. Section 7 proves that the branch preserves no-signalling while supporting genuine nonlocal correlations. Section 8 locks the entanglement sector to the existing FCLET canon, including the microphysical, stochastic, thermodynamic, and unified-framework branches. The concluding sections state the physical meaning of the result.

The outcome is decisive. Quantum nonlocality is not mystical action at a distance and not a violation of causal structure. It is the substrate-level reality that correlated quantum subsystems can occupy a shared co-realization branch on a finite-capacity patch network. That branch has a real maintenance cost, a bounded coordination bandwidth, and a regime-dependent stability limit. Small entangled systems survive because their shared burden is supportable. Macroscopic deep entanglement collapses because the burden of maintaining it drives the substrate toward saturation and activates decoherence. Entanglement and classicality are therefore not separate worlds. They are neighboring regimes of one finite-capacity reality.

2. EPR, Bell Correlations, and the Need for a Finite-Capacity Substrate Description

2.1 The EPR Paradox and the Crisis of Naive Locality

The entanglement problem entered physics in its most forceful form through the EPR paradox. The decisive point of that paradox is not merely that quantum theory predicts correlations between distant systems. The decisive point is that those correlations remain exact even when the subsystems are separated so strongly that any naive picture of independent local realization becomes untenable. Once two subsystems are prepared in a joint state, the quantum description refuses to decompose them into two fully autonomous local realities. Measurement outcomes remain correlated because the state itself is joint.

In a continuum picture that treats space as a passive container, this creates an immediate crisis. If the two systems are truly independent local realities after separation, then the observed correlations seem too strong. If the correlations are retained, then one is tempted to

imagine some form of hidden superluminal influence. The standard quantum formalism avoids both mistakes operationally by assigning a joint state and by refusing to interpret that state as classical local independence. But the underlying arena is still usually left unexamined. The continuum is treated as if it can sustain arbitrarily strong cross-region correlation structure without any physical account of how the substrate bears that burden.

The finite-capacity framework rejects that omission. The EPR problem is not merely a conceptual puzzle about measurement. It is a direct signal that naive locality mistakes the physical status of separated subsystems. Two systems that remain entangled are not two independently realized objects connected afterward by an abstract probabilistic rule. They are one co-realized structure distributed across more than one location on the substrate. The relevant question is therefore not whether one part of the pair sends a free message to the other. The relevant question is how one finite-capacity substrate maintains a joint realization branch across spatially separated patches.

That is the precise point at which the entanglement branch of FCLET begins. The paradox is not resolved by denying the correlations, and not by promoting them into unconstrained signalling. It is resolved by refusing the assumption that separated quantum subsystems must already be fully independent realizations. In the present framework, they are not. Their joint state is a shared realization burden carried by a coordinated substrate architecture. The classical intuition of naive locality fails because it assumes two realizations where the substrate is still carrying one.

2.2 Bell Correlations and the Limits of Classical Hidden-Variable Pictures

Bell's theorem sharpens the EPR problem into a definitive structural result. The theorem shows that no theory built from ordinary local hidden-variable independence can reproduce the full set of quantum correlations observed in entangled systems. The problem is therefore not a gap in experimental control or an epistemic lack of access to deeper local variables. It is the inadequacy of the classical locality template itself.

This matters enormously for the finite-capacity program. FCLET cannot simply dress a classical hidden-variable picture in new language and declare the entanglement problem solved. The entanglement branch must preserve the observed strength of nonlocal correlations while refusing both naive local independence and unconstrained superluminal communication. That is exactly the branch constructed here.

The key move is to reinterpret what Bell correlations are telling us physically. They are not telling us that arbitrary messages are being transmitted faster than light. They are telling us that the joint state of an entangled system cannot be decomposed into two separately maintained local realities with only classical coordination. The substrate must therefore support a stronger structure than ordinary local independence. In the finite-capacity framework, that stronger structure is a co-realized branch of the patch substrate.

Let an entangled bipartite state be written schematically as

$$|\Psi_{AB}\rangle \neq |\psi_A\rangle \otimes |\psi_B\rangle.$$

This is not merely a symbolic statement about Hilbert-space nonfactorization. It is a substrate statement. The nonfactorizable state means that the realization burden of subsystem $A$and the realization burden of subsystem Bcannot be assigned independently. The two subsystems occupy one joint burden sector. Their observable correlations are therefore not added afterward by classical comparison. They are already present because the substrate has not separated them into two independent realized threads.

This is the precise FCLET reinterpretation of Bell's lesson. Classical locality fails because it assumes separable hidden realization. Quantum entanglement violates that assumption because the underlying realized structure remains joint. The correct replacement is not a return to classical hidden variables, and not a surrender to mystical nonlocality, but a finite-capacity account in which correlated subsystems share a coordinated realization branch.

Bell correlations are therefore not an embarrassment for the finite-capacity substrate. They are exactly the kind of signal one expects when a bounded patch architecture is supporting a joint state whose burden cannot be factorized into independent local loads.

2.3 No-Signalling as a Non-Negotiable Constraint

The entanglement branch stands or falls on one exact requirement: it must preserve no-signalling. A finite-capacity reinterpretation of nonlocal correlation that turns entanglement into free transmissible communication would destroy the causal discipline of the theory and collapse immediately into inconsistency. That is not what FCLET does.

The distinction between correlation support and transmissible information is absolute. An entangled pair can occupy a shared co-realization branch on the substrate without granting either party an unconstrained signalling channel. The reason is simple. The substrate does not expose the hidden coordination structure as freely writable classical data. It maintains joint consistency of the correlated branch, but that maintenance is not equivalent to user-controlled message injection.

This can be stated in operational terms. Let $A$and Bdenote two distant subsystems prepared in an entangled state. Let $a$and $b$denote measurement settings, and let $P(\alpha, \beta \mid a, b)$denote the joint outcome distribution. No-signalling requires

$$\sum_{\beta} P(\alpha, \beta \mid a, b) = \sum_{\beta} P(\alpha, \beta \mid a, b')$$

for all settings b, b', and similarly on the opposite side,

$$\sum_{\alpha} P(\alpha, \beta \mid a, b) = \sum_{\alpha} P(\alpha, \beta \mid a', b)$$

for all a, a'. The local marginal statistics cannot be changed by the distant choice of measurement basis.

The finite-capacity substrate preserves this because the shared realization burden controls only the joint correlation architecture, not the free local marginal output channel. The substrate coordinates consistency of the entangled branch, but it does not allow one observer to rewrite distant local statistics at will. The co-realized branch is therefore constrained in exactly the right way: it is strong enough to sustain Bell correlations, but not free enough to become a signalling medium.

This distinction also reveals why continuum language is so often misleading. When one hears that "the measurement here instantly affects the state there," the phrase tempts one into thinking that a message has travelled. In the finite-capacity framework, that is the wrong picture. Nothing needs to propagate as a free classical signal across a passive background. The two subsystems already occupy one coordinated branch of the substrate. What changes at measurement is not that a superluminal packet is launched, but that the joint branch is resolved under a shared consistency rule already carried by the substrate.

That is why no-signalling is non-negotiable and fully preserved here. FCLET supports nonlocal correlations through bounded co-realization, not through unrestricted transmission. The theory therefore keeps the strongest empirical content of entanglement while refusing the false dilemma between classical separability and faster-than-light messaging.

2.4 Finite-Capacity Substrate Logic as the Correct Arena

The entanglement problem cannot be solved inside the wrong arena. If one begins with an infinitely permissive continuum, then one is forced to choose between two inadequate pictures: either entangled subsystems are secretly independent after all, which Bell rules out, or the theory contains unexplained nonlocal correlation without any substrate cost. The finite-capacity program rejects both options by replacing the arena itself.

The correct arena is a patch-based substrate with finite local update rate, bounded realized-load fraction, and latency-controlled realization. In that arena, a quantum state is not merely an abstract vector floating above physical implementation. It is a realized branch carried by actual substrate resources. Entanglement therefore has a physical meaning that the continuum picture obscures: it is a co-realized branch whose maintenance consumes finite coordination bandwidth.

This gives the branch its exact governing principle:

$$\text{entanglement} \implies \text{shared realization burden.}$$

A pair of entangled subsystems does not correspond to two unrelated local update threads. It corresponds to one joint branch of the substrate whose realization cost is distributed across separated patches. Because the substrate is finite-capacity, that distributed branch cannot be

free. It carries maintenance cost, latency overhead, and a bounded correlation-support capacity. This is the missing physical content of nonlocal correlation.

The finite-capacity arena also explains why the problem of macroscopic entanglement must be treated dynamically rather than mystically. If entanglement consumes substrate coordination resources, then increasing the number of correlated subsystems must increase the burden of maintaining the branch. Small entangled systems can remain stably supported because their shared burden remains modest. Large multipartite assemblies drive the substrate toward saturation, amplify latency overhead, and activate stochastic decoherence. This is not an afterthought. It is the exact many-body consequence of finite-capacity co-realization.

The arena is therefore now fixed. The continuum is retained only as an effective descriptive shell where burden is weak and coordination cost is negligible. The true physical support of entanglement is the bounded patch substrate. That substrate carries three non-negotiable properties simultaneously:

genuine nonlocal correlation support,
no free signalling,
finite coordination cost.

Any entanglement sector that lacks one of these three is incomplete. The finite-capacity branch contains all three from the start because they are not patched together afterward; they are consequences of one substrate law.

The next section builds that law explicitly by formulating entangled states as shared realization burden and by constructing the patch-level co-realization picture for bipartite systems.

3. Entangled States as Shared Realization Burden

3.1 Patch Substrate and Co-Realized Quantum States

The finite-capacity entanglement branch begins from a simple but decisive rule: a realized quantum state is not a freely existing abstract object detached from physical implementation. It is a burden-bearing configuration carried by the substrate. When the state is factorizable, that burden can be decomposed into independent local realization channels. When the state is entangled, it cannot.

Let the substrate consist of local patches P_i, each with bounded update capacity, bounded realized-load fraction, and finite residual coordination bandwidth. A quantum subsystem localized or effectively supported on a set of patches does not merely occupy geometric position. It occupies update budget, overwrite budget, and coherence-maintenance budget within that patch ensemble. A pair of noninteracting product states may therefore be written schematically as

$$|\Psi_{\mathrm{prod}}\rangle = |\psi_A\rangle \otimes |\psi_B\rangle,$$

with separate realization costs

$$\mathcal{B}_{\text{prod}} = \mathcal{B}_A + \mathcal{B}_B,$$

up to small background and environmental dressing terms. In such a case, the substrate can maintain the two subsystems through effectively independent update branches.

An entangled state is different in kind, not merely in notation. For a bipartite entangled state

$$|\Psi_{AB}\rangle \neq |\psi_A\rangle \otimes |\psi_B\rangle,$$

the realization burden is not separable:

$$\boxed{\mathcal{B}_{AB} \neq \mathcal{B}_A + \mathcal{B}_B.}$$

Instead, the substrate must support a joint co-realization branch,

$$\boxed{\mathcal{B}_{AB} = \mathcal{B}_A + \mathcal{B}_B + \mathcal{B}_{\text{corr}},}$$

where $\mathcal{B}_{\text{corr}} > 0$is the irreducible correlation-support burden carried by the shared branch itself.

This is the first central law of the entanglement sector. The nonfactorizability of the state becomes nonfactorizability of realization cost. Entanglement is therefore not just a statement about amplitudes in Hilbert space. It is a statement about how the substrate must allocate its finite resources. A product state consumes local realization budget only. An entangled state consumes local realization budget plus nonlocal coordination burden.

The continuum picture obscures this because it permits perfect correlation support without any explicit accounting of substrate cost. The finite-capacity framework does not. The co-realized state must be maintained by a real coordination structure distributed across patches, and that structure consumes finite capacity.

This immediately clarifies the ontological status of entanglement. The two subsystems are not independent local realizations mysteriously coordinated later. They are already members of one shared realized branch. The substrate cost of that shared branch is what classical locality misses and what the finite-capacity program makes explicit.

3.2 Shared Update Structure for Bipartite Entanglement

To turn this into a dynamical picture, the substrate must be given a coordination rule. The minimal rule is that entangled subsystems are maintained through a shared update architecture rather than through two disconnected local threads.

Let subsystem Abe supported on patch family $\mathcal{P}_A$and subsystem Bon patch family $\mathcal{P}_B$. For a product state, the substrate may update the two families through independent local realization sequences:

$$\mathcal{U}_{\mathrm{prod}} = \mathcal{U}_A \oplus \mathcal{U}_B.$$

For an entangled state, this decomposition fails. The update architecture must include a joint coordination branch,

$$\boxed{\mathcal{U}_{AB} = \mathcal{U}_A \oplus \mathcal{U}_B \oplus \mathcal{U}_{\mathrm{corr}},}$$

where $\mathcal{U}_{\mathrm{corr}}$is the finite-capacity coordination structure that preserves the joint correlation content of the state.

This term is not a message channel. It is a consistency-support branch. Its task is not to transmit arbitrary classical symbols from one subsystem to the other. Its task is to preserve the nonfactorizable structure of the joint realized state across separated substrate regions. That is the correct finite-capacity meaning of nonlocal correlation.

The cost of maintaining $\mathcal{U}_{\mathrm{corr}}$is encoded in the correlation burden $\mathcal{B}_{\mathrm{corr}}$, and the corresponding additional latency overhead is denoted

$$\chi_{\mathrm{corr}}.$$

The total local latency associated with the entangled branch is then

$$\boxed{\chi_{AB} = \chi_A + \chi_B + \chi_{\mathrm{corr}},}$$

under the coarse-grained descendant approximation in which the correlation-support latency is treated additively at branch level. The additive form is not the exact microscopic law; it is the correct sector-level descendant representation of shared co-realization cost.

The physical meaning is exact. Entanglement does not merely change the statistics of joint measurement outcomes. It increases the burden of maintaining the realized quantum branch. A substrate supporting an entangled pair must devote resources not only to $A$and not only to B, but also to the coherence of their joint support structure.

This immediately yields the correct asymmetry between product and entangled states:

- for product states, the substrate cost is approximately local and separable;
- for entangled states, the substrate cost includes a positive nonlocal coordination sector.

That extra sector is what the finite-capacity program identifies as the physical support of quantum nonlocality.

3.3 Correlation Support without Superluminal Signalling

The existence of a shared coordination burden does not imply unrestricted signal transfer. This distinction must be made exact at the level of substrate structure.

Let $\mathcal{U}_{\mathrm{corr}}$denote the joint coordination branch supporting an entangled pair. The purpose of this branch is to maintain admissible joint consistency of the realized state, not to provide either local subsystem with arbitrary control over distant marginal statistics. The substrate therefore distinguishes between:

correlation maintenanceandmessage transmission.

This distinction can be encoded operationally by writing the joint realization branch as

$$\mathcal{R}_{AB} = \mathcal{R}_A \cup \mathcal{R}_B \cup \mathcal{R}_{\mathrm{corr}},$$

with the condition that the correlation sector constrains joint outcomes but does not allow free unilateral rewriting of local marginal distributions. In probabilistic terms, the substrate supports a joint law

$$P(\alpha, \beta \mid a, b),$$

but does not allow observer $A$to manipulate $P_B(\beta \mid b)$through arbitrary choice of a, nor observer $B$to manipulate $P_A(\alpha \mid a)$through arbitrary choice of b. The substrate carries correlation support, not free command signalling.

In the finite-capacity picture, this is why no-signalling survives automatically. The coordination burden $\mathcal{B}_{\mathrm{corr}}$is not a writable communication channel. It is a maintenance channel for the joint realized state. Its finite capacity is used to preserve correlation structure, not to carry unrestricted user-controlled messages.

The distinction may be stated sharply:

Entanglement support ≠ transmissible classical bandwidth.

This statement is central. Without it, the finite-capacity branch would collapse into a signalling theory and violate causality. With it, the branch captures exactly what quantum theory empirically requires: strong nonlocal correlations without free superluminal communication.

The continuum picture fails because it leaves the support of the correlation unexplained. A crude signalling picture fails because it turns correlation into messaging. The finite-capacity branch succeeds because it gives the correlation a real physical support cost while preserving the operational no-signalling structure.

This is the precise sense in which nonlocality becomes intelligible inside FCLET. The theory does not eliminate the nonlocal character of the correlation. It gives that correlation a bounded substrate implementation.

3.4 Entanglement as Bounded Co-Realization Cost

The previous subsections define the qualitative structure. The next step is to write the minimal quantitative law of entanglement burden.

Let $\mathcal{E}_{AB}$ denote an entanglement measure normalized so that

$$\mathcal{E}_{AB} = 0 \text{for product states,} \mathcal{E}_{AB} > 0 \text{for entangled states.}$$

The finite-capacity descendant law is that the irreducible correlation burden scales monotonically with the degree of entanglement:

$$\boxed{\mathcal{B}_{\mathrm{corr}} = \kappa_E \, \mathcal{E}_{AB},}$$

to leading order in the bipartite branch, where κ_E is the substrate correlation-cost coefficient. This is the minimal linear descendant form. More generally, one may allow nonlinear dressing,

$$\mathcal{B}_{\mathrm{corr}} = \kappa_E \, F(\mathcal{E}_{AB}), F(0) = 0, F'(\mathcal{E}) > 0,$$

but the monotonic principle is non-negotiable: stronger entanglement costs more substrate burden.

The associated correlation latency overhead is then

$$\boxed{\chi_{\mathrm{corr}} = -\ln(1 - x_{\mathrm{corr}}),}$$

where x_{corr} is the correlation-support fraction of the local patch capacity budget. In the weak-burden bipartite regime,

$$x_{\mathrm{corr}} \ll 1,$$

this reduces to

$$\chi_{\mathrm{corr}} \approx x_{\mathrm{corr}} \propto \mathcal{B}_{\mathrm{corr}}.$$

Thus lightly entangled small systems can be supported with small additional latency overhead. This is why microscopic bipartite entanglement is readily sustainable. The substrate cost is real, but still modest.

The decisive point is that the cost is bounded. The patch substrate does not provide infinite correlation-support bandwidth. Therefore there exists a regime in which

$$x_{\mathrm{corr}} \to 1^{-},$$

and the latency overhead diverges:

$$\chi_{\mathrm{corr}} \to +\infty.$$

This is the finite-capacity saturation law of the entanglement sector. Deep enough shared correlation, especially across increasingly large composite systems, drives the substrate toward a regime where maintaining the co-realized branch becomes dynamically unstable.

That instability is not yet the full macroscopic decoherence result; it is the burden law that prepares it. The present section therefore establishes the exact core statement of the bipartite branch:

entanglement is a real substrate burden, not a free abstract relation.

That burden is finite for small systems, bounded by finite-capacity support, and costly in proportion to the degree of shared quantum correlation.

This closes the first construction step of the entanglement sector. The next section builds on it by deriving the explicit finite-capacity cost of nonlocal coordination and formulating the bounded correlation-support branch of the theory.

4. Patch-Level Coordination and Correlation Bandwidth

4.1 Correlation Support on a Finite-Capacity Substrate

The entanglement branch becomes physically sharp only when shared realization burden is translated into a concrete substrate support law. That law must answer one exact question: how much finite-capacity coordination bandwidth is required to maintain a nonfactorizable quantum state across separated patches?

The finite-capacity answer begins with the residual coordination budget available to the entangled branch. Let the patch families supporting subsystems $A$and Bsit inside a larger coordination-support region $\mathcal{P}_{AB}$. That region already carries a background burden from local realization, environmental activity, and baseline substrate load. Denote the corresponding deterministic background latency by

$$\bar{\chi}_{AB}.$$

Then the available coordination bandwidth of the branch is

$$\boxed{\Gamma_{\mathrm{avail}}^{(AB)} = \Gamma_{\star} e^{-\bar{\chi}_{AB}},}$$

where $\Gamma_\star$ is the bare microphysical update rate of the substrate. This quantity is not a signalling speed. It is the residual substrate capacity available for maintaining the joint correlation structure of the entangled pair.

The required correlation-support rate is a function of the entanglement content of the state and of the complexity of the coordination footprint over which the joint branch must be maintained. Introduce the entanglement measure $\mathcal{E}_{AB}$ and a dimensionless coordination-footprint factor $\mathcal{G}_{AB} \geq 1$. The minimal descendant law is

$$\boxed{\Gamma_{\mathrm{req}}^{(AB)} = \gamma_E \, F(\mathcal{E}_{AB}) \, \mathcal{G}_{AB},}$$

where:

- γ_E is the elementary substrate cost scale of entanglement support,
- $F(\mathcal{E}_{AB})$ is a monotonic function with $F(0) = 0$,
- $\mathcal{G}_{AB}$ measures how many coordinated patch relations the substrate must maintain to preserve the branch.

This formula carries an important physical statement. The burden of bipartite entanglement does not depend on geometric distance alone. In clean bipartite support, $\mathcal{G}_{AB}$ can remain of order unity even across large separations because the substrate is maintaining one joint correlation branch rather than propagating a classical message through every intermediate point in the continuum sense. The relevant cost is the complexity of the support architecture, not naive path length in a passive background.

The finite-capacity support fraction of the correlation branch is therefore

$$\boxed{x_{\mathrm{corr}}^{(AB)} = \frac{\Gamma_{\mathrm{req}}^{(AB)}}{\Gamma_{\mathrm{avail}}^{(AB)}} = \frac{\gamma_E \, F(\mathcal{E}_{AB}) \, \mathcal{G}_{AB}}{\Gamma_\star e^{-\bar{\chi}_{AB}}}.}$$

This is the exact correlation-support analogue of the ordinary FCLET load fraction. The entangled branch is physically admissible only when

$$\boxed{0 \leq x_{\mathrm{corr}}^{(AB)} < 1.}$$

If this inequality fails, the substrate does not possess enough residual coordination bandwidth to sustain the entangled branch coherently.

The associated correlation latency is then

$$\boxed{\chi_{\mathrm{corr}}^{(AB)} = -\ln\left(1 - x_{\mathrm{corr}}^{(AB)}\right).}$$

This is the second central law of the entanglement sector. Entanglement is not merely a formal correlation label. It consumes a definite fraction of the substrate's residual coordination bandwidth and therefore generates a real latency overhead.

This already explains two otherwise disconnected quantum facts:

- small entangled systems are easy to sustain because $x_{\mathrm{corr}}^{(AB)} \ll 1$,
- heavily burdened or structurally complex entangled branches become unstable because $x_{\mathrm{corr}}^{(AB)} \to 1^{-}$.

The continuum theory hides this because it treats coordination support as costless. The finite-capacity branch makes the cost explicit.

4.2 Bounded Nonlocal Coordination Cost

The total burden of an entangled pair is not exhausted by the local burdens of the two subsystems. It contains an irreducible nonlocal coordination sector. At branch level, the total co-realization burden may therefore be written as

$$\boxed{\mathcal{B}_{AB}^{\mathrm{tot}} = \mathcal{B}_A + \mathcal{B}_B + \mathcal{B}_{\mathrm{corr}}^{(AB)},}$$

with

$$\mathcal{B}_{\mathrm{corr}}^{(AB)} = \kappa_E \, F(\mathcal{E}_{AB}) \, \mathcal{G}_{AB}.$$

This law is exact in interpretation. The correlation sector is not a decorative extra. It is the finite-capacity cost of maintaining the nonfactorizable branch itself.

Because the substrate is bounded, this cost is also bounded. The coordination branch cannot be increased without consequence. Define the residual correlation-support bandwidth margin by

$$\boxed{\mathcal{W}_{\mathrm{corr}}^{(AB)} = \Gamma_{\mathrm{avail}}^{(AB)} - \Gamma_{\mathrm{req}}^{(AB)}.}$$

The entangled pair is stably supportable only when

$$\boxed{\mathcal{W}_{\mathrm{corr}}^{(AB)} > 0.}$$

When the margin is large, the substrate supports the entangled branch easily. When the margin shrinks, the branch becomes increasingly latency-loaded and vulnerable to stochastic degradation. When the margin collapses to zero, the branch is driven to the edge of finite-capacity support.

This is the correct finite-capacity meaning of bounded nonlocal coordination. The substrate supports nonlocal correlation, but not without cost and not with infinite reserve capacity. Quantum nonlocality is therefore real but resource-limited.

This boundedness also explains why long-distance bipartite entanglement remains possible in the theory without turning into arbitrary signalling. A simple Bell pair with modest $\mathcal{E}_{AB}$and uncomplicated coordination footprint $\mathcal{G}_{AB} \sim 1$can remain supportable even when the subsystems are spatially far apart, because the substrate is not paying the cost of classical message transport through the continuum picture. It is paying the cost of maintaining one correlated branch. Distance matters only insofar as it changes the coordination footprint or environmental burden, not because the theory mistakes entanglement for broadcast transmission.

The finite-capacity branch therefore avoids both familiar errors:

- it does not reduce entanglement to a classical hidden-variable relation with zero coordination cost,
- and it does not inflate entanglement into an infinite-bandwidth superluminal channel.

Instead it gives the branch an exact physical status:

$$\boxed{\text{entanglement} = \text{bounded nonlocal coordination on a finite-capacity substrate.}}$$

4.3 Latency Overhead of Entangled State Maintenance

Once the correlation-support fraction is defined, the latency overhead of entangled-state maintenance follows immediately. The total branch latency of a bipartite entangled state is the sum of:

- the local support latency of subsystem A,
- the local support latency of subsystem B,
- the irreducible coordination latency of the entangled branch itself.

At the sector level this gives

$$\boxed{\chi_{AB} = \chi_A + \chi_B + \chi_{\mathrm{corr}}^{(AB)}.}$$

The corresponding effective branch proper-time law is

$$\boxed{d\tau_{AB} = e^{-\chi_{AB}}dt = e^{-(\chi_A+\chi_B+\chi_{\mathrm{corr}}^{(AB)})}dt.}$$

This formula is crucial. It shows that entanglement does not merely correlate outcomes; it modifies the realized temporal support conditions of the branch. The more substrate coordination the joint state requires, the more latency overhead the branch acquires.

This has immediate dynamical meaning.

If the pair is weakly burdened and the environment is quiet, then

$$x_{\mathrm{corr}}^{(AB)} \ll 1, \chi_{\mathrm{corr}}^{(AB)} \approx x_{\mathrm{corr}}^{(AB)} \ll 1,$$

so the additional latency overhead is small and the entangled state remains stable over long timescales.

If the pair is heavily burdened or embedded in a noisy or overloaded background, then

$$x_{\mathrm{corr}}^{(AB)} \lesssim 1, \chi_{\mathrm{corr}}^{(AB)} \gg 1,$$

so the branch proper-time support slows substantially and the state becomes increasingly exposed to stochastic latency fluctuations. The branch is still quantum, but it is no longer cheaply sustainable.

This is the direct bridge to decoherence. A large $\chi_{\mathrm{corr}}^{(AB)}$ does not automatically mean the state has decohered, but it means the entangled branch is maintaining itself close to the capacity edge of the substrate. In that regime:

- overwrite overhead grows,
- stochastic latency fluctuations increase,
- phase stability weakens,
- and the branch becomes dynamically fragile.

Thus the finite-capacity program does not treat entanglement and decoherence as unrelated chapters. The same coordination overhead that supports the entangled branch also prepares its destabilization when burden becomes too large.

The key point is exact:
entanglement consumes latency budget.
That consumption is mild for small systems and severe for heavily loaded or structurally complex ones. The fragility of large-scale entanglement is therefore built directly into the substrate law.

4.4 Regime Hierarchy for Bipartite Correlation Support

The bipartite branch is not uniform. It is organized by a strict finite-capacity regime hierarchy. This hierarchy is the entanglement analogue of the weak-field/strong-field and infrared/ultraviolet regime logic already familiar from the rest of FCLET.

Transparent correlation regime

In the simplest and most stable branch,

$$x_{\mathrm{corr}}^{(AB)} \ll 1, \chi_{\mathrm{corr}}^{(AB)} \ll 1.$$

Here the entangled state carries only a small correlation burden relative to the residual coordination bandwidth of the substrate. Bipartite Bell-type correlations are stably supportable, the branch proper time is only weakly dressed, and environmental stochasticity remains subdominant. This is the natural regime of clean microscopic entanglement experiments.

Loaded but stable bipartite regime

When the correlation burden grows but remains comfortably below the substrate ceiling,

$$x_{\mathrm{corr}}^{(AB)} \lesssim 1 \mathrm{with} \mathcal{W}_{\mathrm{corr}}^{(AB)} > 0,$$

the entangled state remains supportable, but the coordination overhead is no longer negligible. The branch acquires noticeable latency dressing, coherence maintenance becomes more expensive, and stochastic degradation becomes more relevant over long observation times. The state is still genuinely entangled, but its maintenance cost is dynamically significant.

Saturation-adjacent bipartite regime

As the branch approaches the support ceiling,

$$x_{\mathrm{corr}}^{(AB)} \to 1^{-}, \chi_{\mathrm{corr}}^{(AB)} \to +\infty, \mathcal{W}_{\mathrm{corr}}^{(AB)} \to 0^{+},$$

the entangled pair approaches the edge of finite-capacity stability. In this regime, the substrate must devote nearly all available coordination bandwidth to preserving the branch. Latency overhead becomes large, stochastic fluctuations are amplified, and the state becomes dynamically fragile. This is the saturation edge of bipartite nonlocal support.

Nonadmissible correlation regime

If one formally demands

$$x_{\mathrm{corr}}^{(AB)} \geq 1,$$

the branch is no longer physically supportable on the finite-capacity substrate. The continuum picture may still write the entangled state algebraically, but the substrate cannot realize it as a stable co-maintained branch. This is not a philosophical statement. It is the exact finite-capacity exclusion condition of the entanglement sector.

These four regimes already reveal the central physical meaning of the branch:

- bipartite entanglement is real and stably supportable,
- it is not costless,
- it becomes latency-loaded near the support ceiling,
- and finite capacity imposes a genuine upper bound on correlation maintenance.

This regime hierarchy is what the continuum theory cannot express because it has no notion of coordination burden. In FCLET, the branch is exact because the substrate has finite capacity and the co-realization cost can therefore be written explicitly.

The next section extends this logic beyond bipartite states and derives the growth of collective burden, latency overhead, and saturation tendency in multipartite entanglement.

5. Multipartite Entanglement and Substrate Saturation

5.1 Scaling of Shared Realization Burden with Subsystem Number

The decisive weakness of continuum entanglement language is that it hides the scaling cost of correlation maintenance. A bipartite Bell pair may be sustained with modest substrate burden, but a many-body entangled assembly is not merely "more of the same." Once the number of subsystems grows, the coordination structure required to preserve a genuinely shared quantum branch grows with it. In a finite-capacity substrate, that growth cannot remain dynamically free.

Let an N-partite entangled state be denoted schematically by

$$|\Psi_{1\cdots N}\rangle,$$

with local subsystem burdens $\mathcal{B}_i$ and total realized burden

$$\mathcal{B}_N^{\mathrm{tot}} = \sum_{i=1}^{N} \mathcal{B}_i + \mathcal{B}_{\mathrm{corr}}^{(N)}.$$

The central object is therefore the multipartite correlation burden $\mathcal{B}_{\mathrm{corr}}^{(N)}$. This is not the sum of independent pair costs unless the state factorizes into disconnected bipartite sectors. For a genuinely multipartite entangled branch, the substrate must maintain a nonseparable coordination architecture across the entire correlated assembly.

Introduce a multipartite entanglement functional $\mathcal{E}_N$ satisfying

$\mathcal{E}_N = 0$ for fully separable states, $\mathcal{E}_N > 0$ for genuinely multipartite entangled states.

The minimal finite-capacity descendant law is then

$$\boxed{\mathcal{B}_{\mathrm{corr}}^{(N)} = \kappa_N \, F_N(\mathcal{E}_N) \, \mathcal{G}_N,}$$

where:

- κ_N is the branch-level cost coefficient,
- $F_N(\mathcal{E}_N)$ is monotonic in the degree of multipartite entanglement,
- $\mathcal{G}_N$ is the coordination-footprint factor of the N-body branch.

The crucial fact is that $\mathcal{G}_N$ grows with subsystem number. In the simplest pairwise coordination picture, one already expects

$$\mathcal{G}_N \sim \frac{N(N-1)}{2},$$

because the number of pair relations grows quadratically. In a genuinely nonfactorizable multipartite branch, the cost can grow even faster because the substrate is not merely supporting pairwise links but a higher-order consistency structure across the full correlated assembly. The exact microscopic law need not be fixed here in order to establish the decisive branch result:

$$\boxed{\frac{d\mathcal{B}_{\mathrm{corr}}^{(N)}}{dN} > 0, \frac{d^2\mathcal{B}_{\mathrm{corr}}^{(N)}}{dN^2} \geq 0 \text{ for the genuinely multipartite branch.}}$$

That is the scaling law that matters physically. The correlation burden grows at least superlinearly once the branch is truly collective. The finite-capacity substrate therefore does not treat an N-body entangled state as a trivial extension of one Bell pair. It treats it as a rapidly more expensive co-realization structure.

This is the exact place where macroscopic entanglement ceases to look mysterious. Large entangled assemblies are not rare because nature "forgets quantum mechanics" at large scale. They are rare because maintaining a deeply shared correlation branch on a bounded substrate becomes rapidly more expensive as subsystem number grows.

5.2 Growth of Local Latency under Multipartite Entanglement

Once the multipartite correlation burden is defined, the latency law follows immediately. The branch support fraction of an N-body entangled assembly is

$$\boxed{x_{\mathrm{corr}}^{(N)} = \frac{\Gamma_{\mathrm{req}}^{(N)}}{\Gamma_{\mathrm{avail}}^{(N)}},}$$

with required coordination rate

$$\Gamma_{\mathrm{req}}^{(N)} = \gamma_N \, F_N(\mathcal{E}_N) \, \mathcal{G}_N,$$

and available residual coordination bandwidth

$$\Gamma_{\mathrm{avail}}^{(N)} = \Gamma_\star e^{-\bar{\chi}_N},$$

where $\bar{\chi}_N$ is the background latency of the region supporting the multipartite branch.

Hence

$$\boxed{x_{\mathrm{corr}}^{(N)} = \frac{\gamma_N \, F_N(\mathcal{E}_N) \, \mathcal{G}_N}{\Gamma_\star e^{-\bar{\chi}_N}}.}$$

The corresponding correlation-support latency is

$$\boxed{\chi_{\mathrm{corr}}^{(N)} = -\ln\left(1 - x_{\mathrm{corr}}^{(N)}\right).}$$

This formula is the many-body generalization of the bipartite branch. Its physical content is stronger because the scaling factor $\mathcal{G}_N$ now grows with subsystem number. Even if the elementary local burden per subsystem remains modest, the collective coordination burden of the entangled branch drives the correlation-support fraction upward as N increases.

For weak multipartite burden,

$$x_{\mathrm{corr}}^{(N)} \ll 1,$$

one has the linear descendant approximation

$$\chi_{\mathrm{corr}}^{(N)} \approx x_{\mathrm{corr}}^{(N)}.$$

But as the number of entangled subsystems grows, the support fraction rises and the latency becomes nonlinear. Once

$$x_{\mathrm{corr}}^{(N)} \lesssim 1,$$

the logarithmic structure of the finite-capacity law becomes decisive and the branch latency increases sharply.

The exact branch statement is therefore:

$$\boxed{N \uparrow \Longrightarrow \mathcal{G}_N \uparrow \Longrightarrow x_{\mathrm{corr}}^{(N)} \uparrow \Longrightarrow \chi_{\mathrm{corr}}^{(N)} \uparrow.}$$

The substrate meaning of multipartite entanglement is thus clear. A larger entangled assembly is not simply a bigger quantum state. It is a more latency-loaded branch of the realization substrate.

This is why the many-body regime differs qualitatively from the bipartite regime. Bipartite entanglement can remain cheap enough that its correlation latency is small. Multipartite entanglement drives branch latency upward even when each individual subsystem is locally benign, because the true cost lies in the shared coordination structure rather than in the local state labels alone.

The branch proper-time law now becomes

$$\boxed{d\tau_N = e^{-\chi_N} dt = e^{-(\sum_i \chi_i + \chi_{\mathrm{corr}}^{(N)})} dt.}$$

As $\chi_{\mathrm{corr}}^{(N)}$grows, the realized temporal support of the collective branch becomes increasingly burdened. This does not yet mean immediate collapse. It means the branch is moving toward the regime in which stochastic destabilization and saturation become unavoidable.

5.3 Collective Correlation Cost and Finite-Capacity Overhead

The many-body branch reveals a property absent from continuum descriptions: collective entanglement carries an irreducible overhead even when no subsystem individually approaches local saturation. The overhead is not located in one particle or one patch alone. It is a property of the shared coordination architecture itself.

The total branch cost of an N-body entangled assembly may be written as

$$\boxed{\mathcal{C}_N = \sum_{i=1}^{N} \mathcal{C}_i + \mathcal{C}_{\mathrm{corr}}^{(N)},}$$

where $\mathcal{C}_i$ are local realization costs and $\mathcal{C}_{\mathrm{corr}}^{(N)}$ is the collective coordination overhead. The essential point is that $\mathcal{C}_{\mathrm{corr}}^{(N)}$ is not eliminable by redistributing the branch across more subsystems. On the contrary, for a genuinely entangled many-body state it is strengthened by the very fact that more subsystems must remain jointly supported.

This allows the branch to be characterized by an overhead ratio

$$\boxed{\mathcal{R}_N \equiv \frac{\mathcal{C}_{\mathrm{corr}}^{(N)}}{\sum_{i=1}^{N} \mathcal{C}_i}.}$$

For small N, one may have

$$\mathcal{R}_N \ll 1,$$

and the branch behaves much like a lightly dressed local system. But for large N, the coordination overhead can become comparable to or larger than the sum of local realization costs:

$$\mathcal{R}_N \gtrsim 1.$$

This is the finite-capacity signature of collective nonlocality. The branch is no longer dominated by the cost of maintaining its components individually. It is dominated by the cost of maintaining them jointly.

The physical consequence is exact. Once the overhead ratio grows, the entangled branch becomes increasingly sensitive to any background burden, overwrite activity, or latency fluctuation already present in the substrate. The many-body branch is therefore not merely a larger coherent state. It is a more fragile one because it sits closer to the substrate's correlation-support ceiling.

The same point may be expressed dynamically through the residual coordination margin

$$\boxed{\mathcal{W}_N = \Gamma_{\mathrm{avail}}^{(N)} - \Gamma_{\mathrm{req}}^{(N)}.}$$

As N rises, $\Gamma_{\mathrm{req}}^{(N)}$ rises through the growth of $\mathcal{G}_N$, and therefore

$$\boxed{N \uparrow \Longrightarrow \mathcal{W}_N \downarrow.}$$

A large entangled assembly is thus not just more expensive. It is closer to the edge at which stable co-realization ceases to be supportable.

This is the exact finite-capacity meaning of collective entanglement overhead:

- nonlocal coordination cost grows faster than local realization cost,

- residual support margin shrinks with subsystem number,
- and the branch becomes increasingly vulnerable even before complete saturation is reached.

The continuum picture cannot express this because it assigns no explicit resource cost to correlation support. The finite-capacity picture makes the many-body penalty unavoidable.

5.4 Saturation Tendency in Large Entangled Assemblies

The final consequence of the multipartite branch is saturation tendency. Because the substrate is finite-capacity, the growth of coordination burden cannot continue indefinitely without driving the branch toward its support ceiling.

The saturation condition is

$$\boxed{x_{\mathrm{corr}}^{(N)} \to 1^{-},}$$

equivalently,

$$\boxed{\chi_{\mathrm{corr}}^{(N)} \to +\infty,}$$

or in bandwidth language,

$$\boxed{\mathcal{W}_N \to 0^{+}.}$$

This is the precise finite-capacity criterion for the loss of stable multipartite support. It does not mean that the state algebraically ceases to exist in Hilbert space. It means the substrate can no longer maintain it as a coherent realized branch with finite overhead.

The physical signature of this approach to saturation is threefold.

First, the branch latency becomes large. Realized proper-time support of the collective branch slows sharply.

Second, stochastic vulnerability rises. A branch near its capacity ceiling is far more sensitive to latency noise, overwrite irregularity, and environmental perturbation than a lightly burdened branch.

Third, coherence lifetime collapses. Even before the exact saturation edge is reached, the combination of large coordination overhead and growing stochasticity drives the branch into rapid decoherence.

This gives the entanglement sector its exact many-body conclusion:

$$\boxed{\text{deep multipartite entanglement} \implies \text{rapid approach to substrate saturation.}}$$

That statement does not deny the existence of controlled many-body entanglement in laboratory systems. It explains why such states are difficult, fragile, and strongly scale-limited. Small or carefully engineered assemblies can remain below the correlation-support ceiling. Large, uncontrolled, macroscopic assemblies cannot. Their branch overhead rises too quickly and the substrate drives them toward latency-loaded instability.

This is the finite-capacity origin of the quantum-to-classical transition at the level of entanglement architecture. Classical macroscopic systems are not nonquantum in principle. They are systems for which the substrate cost of maintaining a deeply shared nonlocal branch is overwhelmingly too high.

The next section now turns this saturation tendency into its direct physical consequence and derives macroscopic decoherence as the large-burden limit of finite-capacity entanglement support.

6. Macroscopic Decoherence from Finite-Capacity Burden

6.1 Why Macroscopic Systems Do Not Remain Deeply Entangled

The disappearance of deep entanglement in macroscopic systems is not a peripheral inconvenience of laboratory practice. It is one of the most basic structural facts any serious quantum ontology must explain. A finite-capacity substrate explains it directly.

The preceding section established the central scaling law of the entanglement branch: as the number of correlated subsystems grows, the collective coordination burden grows with it, the residual support margin shrinks, and the correlation-support latency rises sharply. This immediately changes the status of a macroscopic entangled assembly. Such an assembly is not merely a larger version of a Bell pair. It is a branch whose realization cost is dominated by the burden of maintaining global coherence across many degrees of freedom at once.

A macroscopic object contains an enormous number of potentially interacting or environmentally exposed constituents. If such a system were required to remain in a deeply entangled global branch, the substrate would have to sustain a nonseparable coordination structure across a vast patch ensemble. That demand does not scale linearly in a benign way. It drives the co-realization burden upward until the branch enters a latency-loaded regime in which coherence maintenance becomes dynamically unstable.

This is the exact finite-capacity reason macroscopic systems do not persist as long-lived deeply entangled objects. The obstacle is not that the formal quantum state space suddenly disappears at large scale. The obstacle is that the substrate cost of maintaining a globally entangled realization branch becomes overwhelming. The state remains kinematically writable in abstract Hilbert space, but it ceases to be dynamically sustainable as a low-latency realized branch on a bounded substrate.

The theory therefore resolves the apparent contrast between microscopic nonclassicality and macroscopic classicality without introducing a discontinuous law of nature. The same substrate supports both. Small entangled branches survive because their coordination cost remains supportable. Macroscopic branches fail because the shared burden required to

preserve them pushes the substrate toward saturation. The distinction is one of regime, not one of metaphysical category.

This is why the finite-capacity framework does not need to speak of "mysterious collapse" as an unexplained primitive. What disappears at large scale is not the formal possibility of quantum superposition. What disappears is the substrate's ability to sustain a deeply shared co-realization branch without rapid degradation.

6.2 Burden Amplification, Latency Noise, and Rapid Decoherence

The transition from fragile entanglement to effective classicality is driven by a precise dynamical chain. Collective burden amplifies coordination overhead. Coordination overhead amplifies branch latency. Large latency amplifies susceptibility to stochastic substrate fluctuations. Those fluctuations randomize phase relations and destroy off-diagonal coherence. Macroscopic decoherence is therefore the dynamical consequence of burden amplification on a finite-capacity substrate.

Let the total branch latency of an N-partite entangled system be

$$\chi_N = \sum_{i=1}^{N} \chi_i + \chi_{\mathrm{corr}}^{(N)}.$$

The realized proper-time support of the branch is then

$$d\tau_N = e^{-\chi_N} dt.$$

Now decompose the total latency into deterministic and stochastic parts,

$$\chi_N = \bar{\chi}_N + \delta\chi_N.$$

The deterministic part $\bar{\chi}_N$carries the collective burden of maintaining the branch. The stochastic part $\delta\chi_N$carries the noise inherited from overwrite activity, patch irregularity, environmental coupling, and finite-response fluctuation of the substrate.

For a coherent superposition of macroscopically distinct branch components, the relative phase accumulation is controlled by realized proper time. A fluctuation in $\delta\chi_N$therefore produces a fluctuation in branch phase. The larger the deterministic burden $\bar{\chi}_N$, the more latency-loaded the branch becomes, and the more strongly its coherent phase structure is exposed to substrate noise. In other words, burden amplification does not merely slow the branch. It makes the branch fragile.

The finite-capacity decoherence law therefore takes the same structural form as in the QFT descendant sector, but now with collective branch quantities. For two macroscopic branch

components $A$and $B$with effective energy gap ΔE_{AB}, the noise-averaged off-diagonal density-matrix element obeys

$$\langle \rho_{AB}(t) \rangle = \rho_{AB}(0)\, e^{-i\Delta E_{AB} e^{-\bar{\chi}_N} t} e^{-\Gamma_{AB}^{(N)}(t)},$$

with decoherence kernel

$$\Gamma_{AB}^{(N)}(t) = \frac{(\Delta E_{AB})^2 e^{-2\bar{\chi}_N}}{2} \int_0^t d\, t_1 \int_0^t d\, t_2\, C_{\chi_N}(t_1, t_2),$$

where

$$C_{\chi_N}(t_1, t_2) = \langle \delta\chi_N(t_1) \delta\chi_N(t_2) \rangle.$$

This formula makes the many-body logic exact. The decoherence rate is not controlled only by the nominal energy gap of the branch components. It is controlled by that gap together with the collective latency state of the substrate supporting the entangled assembly. Macroscopic systems decohere quickly because both factors grow in the wrong direction for long-lived coherence:

- effective branch distinctions become large,
- collective burden raises the noise-sensitive latency structure,
- and the substrate correlation-support margin collapses.

In a Markovian descendant approximation, one may write

$$C_{\chi_N}(t - t') \approx 2 D_{\chi_N} \delta(t - t'),$$

so that

$$\Gamma_{AB}^{(N)}(t) = (\Delta E_{AB})^2 e^{-2\bar{\chi}_N} D_{\chi_N}\, t.$$

The corresponding decoherence rate is

$$\boxed{\gamma_{AB}^{(N)} = (\Delta E_{AB})^2 e^{-2\bar{\chi}_N} D_{\chi_N}.}$$

The notation makes the central physical fact explicit: the effective noise strength $D_{\chi_N}$is not a fixed microscopic constant. It is a collective descendant of branch burden. As the number of coordinated subsystems rises, the branch becomes more latency-loaded and more

stochastically unstable. Rapid decoherence is therefore not an accidental environmental nuisance. It is the expected large-N consequence of finite-capacity co-realization.

This is why macroscopic coherence lifetimes collapse so quickly. They are not suppressed by one mechanism alone. They are suppressed by the joint action of growing branch burden, rising latency overhead, shrinking coordination margin, and amplified stochastic destabilization.

6.3 Relation to the Stochastic Branch of FCLET

The decoherence mechanism derived here is not a new auxiliary sector invented solely to rescue the entanglement branch. It is the direct many-body descendant of the stochastic FCLET branch already established elsewhere in the program.

Earlier FCLET work fixed the existence of latency noise, overwrite-driven fluctuation, and patch-level irregularity as intrinsic properties of a finite-capacity realization substrate. That sector already showed that realized timing is not perfectly smooth and that finite-capacity evolution carries an irreducible stochastic component. The present paper uses exactly that sector, but now in the language of nonlocal correlation maintenance.

The relation is strict. The same stochastic latency fluctuation field that perturbs realized proper time in other FCLET branches now perturbs the phase stability of an entangled co-realization branch. The many-body entanglement problem does not therefore require a second noise ontology. It requires only that the pre-existing stochastic substrate sector be evaluated on a branch whose collective burden is much larger. That is the entire source of the scale transition.

This continuity is one of the strongest features of the theory. It means that microscopic decoherence-like effects, QFT phase diffusion, and macroscopic entanglement loss all descend from one canonical stochastic architecture. The substrate does not need one kind of fluctuation for clocks, another for propagators, and a third for cats or macroscopic superpositions. It carries one latency-noise sector whose physical consequences vary by regime.

The entanglement branch therefore slots naturally into the canon:

- the microphysical branch fixes the patch substrate,
- the entanglement branch fixes the co-realization burden of correlated states,
- the stochastic branch fixes the unavoidable fluctuation content of the substrate,
- the present section shows how large branch burden makes that fluctuation fatal to macroscopic coherence.

This is exactly how a unified program should behave. The theory does not pile disconnected explanatory stories on top of one another. It uses one substrate law repeatedly, with different branches revealing different consequences of the same underlying architecture.

6.4 Classicality as Saturation-Driven Correlation Loss

The final physical meaning of the entanglement branch is now clear. Classicality is not a separate ontological domain imposed from outside quantum theory. It is the large-burden, saturation-driven regime in which deeply shared nonlocal correlation can no longer be maintained on a finite-capacity substrate.

Let the effective correlation-support fraction of an N-partite branch be

$$x_{\mathrm{corr}}^{(N)}.$$

When

$$x_{\mathrm{corr}}^{(N)} \ll 1,$$

the branch is lightly burdened, the correlation latency is small, the residual coordination margin is large, and coherent entanglement survives.

When

$$x_{\mathrm{corr}}^{(N)} \lesssim 1,$$

the branch becomes latency-loaded, the residual margin collapses, and stochastic fluctuations begin to erase off-diagonal coherence rapidly.

The approach to classicality is therefore the approach to correlation saturation. The substrate is no longer able to maintain one deeply entangled branch across the full many-body assembly. The system falls into dynamically robust local or quasi-local sectors whose mutual coherence has been destroyed. This is what classical appearance means in the finite-capacity framework: not the death of quantum law, but the failure of large-scale nonlocal co-realization under bounded capacity.

This interpretation is exact and powerful because it unifies three facts that are usually treated separately:

- small systems can remain strongly entangled,
- large systems decohere rapidly,
- no discontinuous classical postulate is needed.

All three follow from one branch law. Small systems remain far from the substrate's correlation-support ceiling. Large systems drive the branch toward that ceiling. As the ceiling is approached, latency overhead and stochastic fragility destroy coherent nonlocal support. Classicality is therefore the stable low-correlation-loss endpoint of saturation-driven entanglement breakdown.

This is also why the theory preserves no-signalling while still explaining why the macroscopic world does not look Bell-correlated at human scale. The branch never grants free signalling to begin with. It grants bounded nonlocal correlation support. That support is cheap enough for microscopic systems and too expensive for macroscopic ones. Classicality is therefore not the denial of nonlocal quantum structure. It is the regime in which finite-capacity burden prevents that structure from remaining globally sustained.

The next section turns from saturation-driven decoherence to the final logical safeguard of the branch and shows explicitly how finite-capacity entanglement preserves no-signalling and causal discipline while still supporting genuine nonlocal correlation.

7. No-Signalling, Causality, and the Structure of Nonlocal Correlations

7.1 Why Entanglement Does Not Permit Free Message Transfer

The finite-capacity entanglement branch supports genuine nonlocal correlation, but it does not convert that support into a free communication channel. This distinction is absolute and foundational. If entanglement were equivalent to unrestricted signal transfer, the branch would violate the causal discipline of the program and collapse into inconsistency. It does not. The substrate supports correlation consistency, not arbitrary classical messaging.

The reason is structural. An entangled state is realized as a joint branch of the substrate, not as two independent local realizations exchanging editable symbols after the fact. The coordination sector $\mathcal{U}_{\mathrm{corr}}$maintains the consistency of the shared realized state, but it does not expose that shared branch as a user-controlled channel through which one observer can freely encode and send classical information to the other. The substrate preserves the branch; it does not surrender it as a writable message bus.

This can be stated in operational form. Let $A$and Bdenote two distant parties sharing an entangled state. Observer Amay choose a local measurement setting a, and observer Bmay choose a local measurement setting b. Let the outcomes be $\alpha$and β. The substrate supports a joint distribution

$$P(\alpha, \beta \mid a, b),$$

but the marginal distribution seen locally by A,

$$P_A(\alpha \mid a) = \sum_{\beta} P(\alpha, \beta \mid a, b),$$

must be independent of b, and similarly the marginal seen by B,

$$P_B(\beta \mid b) = \sum_{\alpha} P(\alpha, \beta \mid a, b),$$

must be independent of a. This is not an optional empirical convenience. It is the exact condition that distinguishes nonlocal correlation support from signalling.

The finite-capacity substrate enforces this because the correlation burden $\mathcal{B}_{\mathrm{corr}}$maintains only the compatibility structure of the joint branch. It does not allow either observer to rewrite the local branch statistics at the distant location by unilateral choice. The local measurement operation is a branch-resolution action applied to one local realization sector. It is not a command packet injected into the global substrate.

This is why entanglement remains nonclassical without becoming a communication paradox. The substrate supports more than classical local independence, but less than arbitrary writable superluminal control. That intermediate structure is exactly what quantum theory empirically demands and exactly what the finite-capacity framework provides.

The correct statement is therefore sharp:

Entanglement permits nonlocal correlation support, not free message transfer.

That is the first causal safeguard of the branch.

7.2 Correlation Support versus Transmissible Information

The distinction between correlation support and transmissible information must be formulated more precisely, because much of the confusion surrounding quantum nonlocality comes from collapsing these two into one.

A correlation-supported branch means that the substrate maintains a joint realized state whose outcome structure cannot be factorized into independent local realizations. A transmissible-information channel means that one local agent can, by controlled action, alter the distant local output statistics in a way that encodes freely chosen classical symbols. The first is what entanglement requires. The second is what no-signalling forbids.

In the finite-capacity framework, these two structures are different because they consume substrate resources differently.

The correlation-supported branch uses coordination burden

$$\mathcal{B}_{\mathrm{corr}},$$

and coordination bandwidth

$$\Gamma_{\mathrm{req}}^{(AB)},$$

to preserve a nonfactorizable realized state. But this burden is spent on branch consistency, not on local-message programmability. The substrate keeps the joint state coherent; it does not provide either party a classical control interface to the distant subsystem.

This difference may be written schematically at the level of channel capacity. Let

$$\mathcal{K}_{\mathrm{corr}}$$

denote the nonlocal correlation-support capacity of the branch, and let

$$\mathcal{K}_{\mathrm{sig}}$$

denote the freely transmissible classical signalling capacity. The finite-capacity entanglement branch enforces

$$\boxed{\mathcal{K}_{\mathrm{corr}} > 0, \mathcal{K}_{\mathrm{sig}} = 0}$$

for a pure entanglement-support channel in the absence of an additional classical communication layer.

This is one of the most important equations in the paper. It says the substrate genuinely supports nonlocal correlation but does not convert that support into signal bandwidth. The branch is therefore stronger than classical locality and weaker than unconstrained message transport. That is exactly the correct structural location of quantum entanglement.

The continuum picture often obscures this because it speaks only in terms of formal state vectors and measured correlations, while a crude hidden-message picture obscures it from the opposite side by imagining that correlation must be mediated as if it were a classical packet. The finite-capacity framework avoids both errors. It gives the correlation a real physical support cost, but refuses to confuse that cost with message capacity.

This is also why Bell correlations do not threaten causality inside FCLET. The substrate is not transporting classical content from one measurement station to the other at arbitrary speed. It is maintaining a shared realized branch whose joint statistics are stronger than classical local independence but still subject to the strict no-signalling condition on local marginals.

The correct causal lesson is therefore exact:

> Correlation architecture and information architecture are not the same structure.

Entanglement belongs to the first. Classical messaging belongs to the second. The finite-capacity substrate supports the first without yielding the second.

7.3 Compatibility with Causal Structure

The preservation of no-signalling is not enough by itself. The branch must also be compatible with the causal structure already established elsewhere in the FCLET canon. In particular, it must coexist with:

- the latency-based realization of proper time,
- the weak-field and strong-field causal branches,
- the QFT descendant sector,
- and the gravitational-wave consistency sector.

The entanglement branch satisfies this exactly because it does not alter causal propagation cones for ordinary transmissible disturbances. The branch introduces no new free-propagating superluminal degree of freedom. It introduces only a bounded co-realization structure for states that are already jointly prepared on the substrate. The support of entanglement therefore does not compete with the propagation law of ordinary signals. The two belong to different categories.

This can be stated in a clean FCLET form. Let

$$\mathcal{C}_{\mathrm{prop}}$$

denote the causal structure governing propagating physical disturbances, and let

$$\mathcal{C}_{\mathrm{corr}}$$

denote the support structure of entangled nonlocal correlations. The finite-capacity branch requires

$$\boxed{\mathcal{C}_{\mathrm{corr}} \neq \mathcal{C}_{\mathrm{prop}},}$$

while also requiring that

$$\boxed{\mathcal{C}_{\mathrm{corr}} \text{ does not enlarge } \mathcal{C}_{\mathrm{prop}} \text{ into a signalling cone.}}$$

In words: the existence of nonlocal correlation support does not modify the propagation law of ordinary transmissible effects.

This is why the branch remains compatible with causal discipline. The substrate already supports many structures that are not identical to propagating classical disturbances. Static constraints, global branch consistency, and realized-load bookkeeping are not “signals” in the ordinary sense, yet they are real features of the substrate. Entanglement support belongs to that same category. It is a real global or distributed support structure without being a propagating local message.

The consequence is immediate. Relativistic causal order remains intact for operations that transmit usable information, energy-bearing signals, or freely controllable physical disturbances. Entanglement correlations remain stronger than local hidden-variable independence, but they do not open a second operational causal channel. The branch therefore preserves the empirical structure of relativistic causality while giving quantum correlation the substrate support it lacks in a costless continuum picture.

This also protects the program from internal contradiction with its own QFT sector. The same finite-capacity theory that dynamically suppresses ultraviolet propagators and preserves no-signalling in the entanglement branch is not torn between two incompatible notions of causality. It has one causal law for transmissible effects and one bounded coordination law for nonlocal quantum correlation support. These are distinct but compatible sectors of one substrate architecture.

The exact conclusion is therefore:

FCLET entanglement is nonlocal in correlation, not superluminal in propagation.

That is the second causal safeguard of the branch.

7.4 Finite-Capacity Reinterpretation of Nonlocality

The entanglement branch now allows nonlocality itself to be reinterpreted in exact finite-capacity language.

In the standard continuum picture, nonlocality appears almost magical because the arena is treated as passive and costless. One either leaves the correlations uninterpreted, or one imagines hidden causal processes that immediately threaten no-signalling and relativistic order. Both approaches fail because the continuum picture provides no middle category between local independence and signal transfer.

The finite-capacity framework provides that middle category. Nonlocality is not interpreted as the ability to send arbitrary messages outside the causal propagation structure. It is interpreted as the ability of a bounded substrate to maintain one shared realized branch across spatially separated patches. That branch has a real maintenance cost, a finite coordination bandwidth, and a strict no-signalling boundary. Nonlocality is therefore no longer mysterious action at a distance. It is bounded co-realization on a finite-capacity substrate.

This reinterpretation is exact because it unifies every result derived so far:

- entangled states are nonseparable because their realization burden is nonseparable;
- Bell correlations are supported because the substrate maintains a joint branch rather than two independent local ones;
- no-signalling is preserved because the correlation-support channel is not a writable message channel;

- multipartite entanglement becomes fragile because coordination burden scales upward with subsystem number;
- macroscopic classicality emerges because large-scale co-realization drives the substrate toward saturation and stochastic breakdown.

These are not separate explanatory patches. They are all manifestations of one substrate law.

The finite-capacity reinterpretation of nonlocality may therefore be summarized in one statement:

$$("Quantum\ nonlocality\ is\ the\ bounded, non-signalling\ co \\ -realization\ of\ a\ shared\ branch\ on\ a\ finite-capacity\ patch\ substrate.")$$

That is the correct replacement for both naive locality and mystical nonlocality. The theory does not deny the full force of entanglement correlations. It gives them physical support. It does not confuse that support with unconstrained communication. It limits it through finite capacity. And it does not need a second classicality postulate to explain why large systems lose deep entanglement. It derives that loss from the scaling of correlation burden itself.

The entanglement sector is therefore now causally closed. It supports genuine quantum nonlocal correlations, preserves no-signalling, remains compatible with the broader FCLET causal architecture, and explains why nonlocal support is cheap at small scale and unsustainable at macroscopic scale.

The next section locks this branch directly to the existing FCLET canon and shows that the present entanglement construction is not an isolated interpretive move but the natural quantum-nonlocal descendant of the microphysical, stochastic, thermodynamic, QFT, and unified-framework sectors of the program.

8. Canonical Integration with the Existing FCLET Program

8.1 Relation to Quantum Entanglement as Shared Informational Identity

The present paper does not introduce entanglement into the finite-capacity program from outside. It develops, hardens, and completes a line that was already structurally present in the canon: entangled systems do not behave as two fully independent realized objects, but as one shared informational branch. The earlier conceptual formulation identified that fact at the level of meaning. The present paper translates it into substrate dynamics.

That translation is exact. What earlier appeared as shared informational identity now appears here as shared realization burden. The shift is not a change of ontology. It is a sectoral completion. The same nonfactorizability that defines entanglement at the Hilbert-space level is re-expressed here as nonfactorizability of substrate cost:

$$\mathcal{B}_{AB} \neq \mathcal{B}_A + \mathcal{B}_B.$$

This is the decisive canonical move. Entanglement is no longer described only by abstract joint-state language. It is assigned a definite finite-capacity burden structure, a coordination-support budget, and a latency overhead. In this way, the present paper does not compete with the earlier entanglement paper. It operationalizes it.

This is exactly how the FCLET canon matures. Conceptual sector papers establish the ontological direction of a branch. Later sector papers convert that direction into descendant variables, regime laws, and explicit substrate mechanics. The present entanglement paper is that second-stage completion. It takes the claim that entanglement reflects shared realized structure and writes the finite-capacity support law that makes that claim physically exact.

The consequence is large. The earlier conceptual statement that entangled subsystems share informational identity is now tied directly to:

- patch-level co-realization,
- bounded coordination bandwidth,
- nonzero correlation-support cost,
- and the saturation instability of large entangled assemblies.

The branch is therefore no longer only interpretive. It is dynamical, finite-capacity, and canonically anchored.

8.2 Relation to Update Latency and Microphysical Closure

The entanglement branch is also a direct descendant of the microphysical closure and update-latency sectors of the program. Those sectors established the core substrate facts that make the present paper possible:

- physical realization proceeds through finite-capacity patches,
- every sustained physical branch consumes update resources,
- local burden is bounded,
- and latency is the canonical response of the substrate to rising realization load.

The present entanglement construction uses exactly those facts and extends them into the nonlocal quantum domain. A bipartite or multipartite entangled state is not treated as a formal relation floating above the substrate. It is treated as a realized branch that must be maintained through a shared update architecture:

$$\mathcal{U}_{AB} = \mathcal{U}_A \oplus \mathcal{U}_B \oplus \mathcal{U}_{\mathrm{corr}}.$$

This is nothing other than the entanglement-sector descendant of the microphysical update law. The same substrate that must refresh ordinary local states must also refresh the shared correlation structure of an entangled branch. The difference is that local state maintenance can

be approximately separable, while entangled-state maintenance cannot. That is why the present paper introduces the irreducible correlation burden $\mathcal{B}_{\mathrm{corr}}$: it is the nonlocal descendant of update cost.

This immediately locks the paper to the update-latency branch. The correlation-support latency

$$\chi_{\mathrm{corr}} = -\ln(1 - x_{\mathrm{corr}})$$

is not an auxiliary new variable. It is the exact same latency logic already established in the canonical kernel, now applied to the branch cost of nonlocal quantum support. Entanglement therefore does not sit outside the latency architecture of FCLET. It is one of its most refined expressions.

The relation to microphysical closure is equally strict. The microphysical branch already denied that physical reality is a free continuum with unlimited refresh capacity. The present paper shows what that denial means for quantum correlation. Once update resources are finite, entanglement can no longer be treated as costless global coordination. It becomes a branch whose support burden is explicit, finite, and scale-sensitive. This is why the entanglement paper belongs naturally inside the microphysical canon: it is the nonlocal quantum consequence of finite patch realizability.

The programmatic meaning is exact:

- microphysical closure fixed the finite substrate,
- update latency fixed the cost of sustained realization,
- the present paper fixes the cost of sustaining nonlocal realization.

That is one continuous architecture, not three disconnected ideas.

8.3 Relation to Latency Noise and Decoherence-Like Effects

The present paper is also tightly locked to the stochastic branch of FCLET. Earlier work already established that the finite-capacity substrate carries irreducible latency noise generated by overwrite activity, patch irregularity, and finite-response fluctuation. It also established that this latency noise can suppress coherence-like structures in realized systems. The current entanglement paper does not invent a new decoherence source. It identifies the precise entanglement-sector target of the already existing one.

This continuity is exact. The same stochastic latency field that appears in the timing and decoherence-like branches now acts here on the branch proper-time support of an entangled assembly:

$$d\tau_N = e^{-(\bar{\chi}_N + \delta\chi_N)} dt.$$

Once the entangled branch carries large collective burden, the corresponding stochastic fluctuation $\delta\chi_N$ becomes dynamically decisive. The present paper therefore shows why entanglement loss and macroscopic decoherence are not separate mysteries. They are consequences of one pre-existing stochastic substrate architecture evaluated on a heavy co-realization branch.

This is one of the strongest canonical locks in the paper. Without it, the macroscopic decoherence argument could be mistaken for an ad hoc rescue move appended to the entanglement sector only after the burden law is written down. With it, the logic is exact:

- the stochastic FCLET branch already exists,
- the entanglement branch already carries finite correlation burden,
- large burden amplifies sensitivity to the existing stochastic field,
- therefore macroscopic entanglement destabilizes through the already canonical latency-noise sector.

The result is a full unification of three branches:

1. entanglement as nonseparable shared realization,
2. latency noise as finite-capacity stochastic substrate structure,
3. decoherence as noise-driven loss of heavy nonlocal branch support.

That unification is not rhetorical. It means the theory uses one stochastic ontology across clocks, coherence, QFT phase diffusion, and entanglement loss. This is exactly what a serious unified research framework must do.

8.4 Relation to the Canonical Kernel and Unified Framework

The final canonical lock is the strongest one. The present paper must stand as a legitimate descendant of the frozen FCLET kernel and as an integrated sector of the unified framework. It does so completely.

The canonical kernel fixed the program's primitive backbone:

- bounded realized-load fraction,
- canonical latency map,
- burden-dependent proper-time generation,
- finite-capacity update logic,
- and regime-aware recovery structure.

The present paper changes none of these. It introduces no rival substrate, no rival primitive source hierarchy, and no second ontological arena for quantum nonlocality. Instead, it builds the entanglement sector from exact descendants of the frozen kernel:

- $\mathcal{B}_{\mathrm{corr}}$as correlation burden,
- x_{corr}as correlation-support load fraction,
- χ_{corr}as correlation-support latency,
- $\mathcal{W}_N$as residual coordination margin,
- and $d\tau_N = e^{-\chi_N}dt$as the branch proper-time law.

These are not new primitives. They are the entanglement-sector descendants of the same finite-capacity backbone already used across the rest of the program.

The unified framework required more than symbolic continuity. It required regime discipline. The present paper satisfies that exactly. Small bipartite systems occupy the transparent correlation regime, where burden is light and nonlocal support is stable. Loaded bipartite systems enter a latency-dressed regime. Large multipartite systems approach the correlation-support ceiling and become decoherence-prone. Macroscopic classicality appears as the saturation-driven limit of the same branch. This is textbook FCLET regime logic: one substrate, multiple controlled branches, no uncontrolled discontinuity.

The paper also strengthens the unified framework at a programmatic level. Before this branch, FCLET already contained:

- gravity,
- cosmology,
- thermodynamics,
- stochasticity,
- microphysical closure,
- strong-field completion,
- and quantum field theoretic ultraviolet structure.

With the present construction, the program now contains a fully articulated account of quantum nonlocality. Entanglement is no longer left as a conceptual loose end alongside QFT and decoherence. It is integrated into the same substrate architecture that already governs the rest of the theory.

This changes the scale of the canon. FCLET no longer stops at saying that the substrate is finite-capacity and that quantum phases or propagators are burden-sensitive. It now says how one and the same substrate:

- supports nonlocal quantum correlation,
- forbids no-signalling violation,
- makes large entangled systems expensive,
- and drives macroscopic classicality through saturation and stochastic branch fragility.

That is not a peripheral completion. It is a central one.

The exact status of the present paper is therefore clear:
it is the canonical entanglement and nonlocality descendant of the finite-capacity latency–erasure framework.
It belongs inside the frozen kernel, obeys the unified framework, preserves regime discipline, and completes a quantum branch the program could no longer leave implicit.

9. Physical Interpretation

The entanglement branch developed in this paper changes the meaning of quantum nonlocality at its foundation. In the standard continuum picture, entanglement appears strange because the underlying arena is treated as passive, infinitely permissive, and costless. Correlations are predicted correctly, but the physical support of those correlations remains hidden. The result is a false dilemma. Either one clings to naive local independence and collides with Bell, or one speaks of nonlocality as if the theory had licensed unconstrained action at a distance. The finite-capacity framework rejects both options by replacing the arena itself.

In the present branch, entanglement is not interpreted as superluminal message transfer and not as an inexplicable violation of causality. It is interpreted as the co-realization of a shared quantum branch on a bounded patch substrate. That branch has real physical status. It consumes substrate coordination bandwidth, carries nonzero realization burden, and generates a correlation-support latency overhead. Quantum nonlocality therefore ceases to be a mystical category. It becomes a finite-capacity coordination structure.

This is the central physical meaning of shared realization burden. An entangled state is not merely a formal refusal of tensor-factor separability. It is a statement that the substrate is still carrying one joint branch where classical intuition expected two fully independent realized threads. The problem with naive locality is therefore not that it lacks hidden variables of the right sort. The problem is that it assumes separable realization where the substrate has not separated the branch.

The same framework also clarifies why no-signalling survives. The coordination architecture that supports entanglement is not a writable message bus. It maintains joint consistency of the branch without opening a channel for arbitrary classical symbol transfer. Correlation support and transmissible information are therefore physically distinct structures. This is why Bell correlations can be strong without becoming a signalling paradox. The substrate supports nonlocal correlation but does not license unrestricted controllable messaging.

This distinction is one of the strongest achievements of the branch. It replaces the stale opposition between “local realism” and “spooky action” with a sharper physical picture. What exists is neither classical local independence nor mystical infinite-speed transmission. What exists is bounded co-realization: a distributed support structure that is stronger than classical separability, weaker than free signalling, and exactly tuned to the empirical logic of quantum theory.

The many-body consequence is equally important. Once entanglement is treated as real substrate burden, the fragility of macroscopic coherence ceases to be mysterious. Large entangled assemblies are not unstable because the world stops being quantum at large scale. They are unstable because the substrate cost of maintaining a deeply shared branch grows rapidly with subsystem number. Collective burden amplifies coordination overhead, coordination overhead amplifies latency, and latency amplifies stochastic vulnerability. Macroscopic decoherence is therefore not an external add-on. It is the saturation-driven large-N consequence of the same finite-capacity entanglement law that supports microscopic Bell pairs.

This yields a unified interpretation of two facts that are often kept conceptually separate:

- small systems can remain strongly entangled,
- large systems rapidly look classical.

In the finite-capacity framework, these are not separate mysteries. They are neighboring regimes of one substrate architecture. Small entangled states survive because their shared burden remains supportable. Large entangled states collapse because their coordination burden drives the substrate toward its support ceiling. Classicality is therefore not an alien postulate standing above quantum theory. It is the stable low-correlation endpoint of saturation-driven nonlocal branch failure.

The programmatic significance is equally large. Before this paper, FCLET already possessed a quantum field theoretic descendant branch in which ultraviolet propagation and phase coherence were controlled by finite-capacity burden. With the present construction, the program now possesses a full nonlocal quantum branch as well. Quantum mechanics inside FCLET is no longer limited to propagators, decoherence-like noise, and microphysical burden. It now includes the support law of entanglement itself.

That changes the scale of the framework. The same canonical substrate now governs:

- weak-field gravity,
- cosmological moderation,
- thermodynamic overwrite,
- stochastic timing,
- microphysical realization,
- strong-field completion,

- QFT ultraviolet closure,
- and quantum nonlocal correlation.

The entanglement paper therefore does not ornament the program. It closes a missing central branch.

The physical picture that results is exact and coherent. Reality is not an infinitely writable continuum. It is a finite-capacity realization substrate. Quantum correlations are not exempt from that fact. They consume branch-support resources, they generate latency overhead, and they become fragile when their collective burden approaches saturation. Entanglement is therefore real, nonlocal, no-signalling, bounded, and dynamically costly. Classicality is the regime in which that cost becomes too large to sustain deep global coherence.

That is the physical meaning of the present branch. It does not dilute quantum nonlocality. It explains what supports it, what limits it, and why it fails at macroscopic scale.

10. Conclusion

We have constructed the entanglement branch of the finite-capacity latency–erasure framework and derived quantum nonlocality as bounded co-realization on a finite-capacity patch substrate.

The starting point of the construction is exact. Physical reality is not an infinitely permissive continuum that can sustain nonlocal correlation without cost. It is a bounded-capacity realization substrate whose branches consume finite update budget, finite coordination bandwidth, and finite latency overhead. Once entangled states are interpreted as realized substrate branches rather than as abstract costless relations, their central physical property becomes unavoidable: they carry irreducible shared realization burden.

From that principle we derived the key laws of the branch. A bipartite entangled state does not decompose into two independent local realization costs. It carries an additional correlation-support burden,

$$\mathcal{B}_{\mathrm{corr}} > 0,$$

and a corresponding correlation-support latency,

$$\chi_{\mathrm{corr}} = -\ln(1 - x_{\mathrm{corr}}),$$

where $x_{\mathrm{corr}}$is the fraction of residual coordination capacity consumed by maintaining the entangled branch. Entanglement is therefore not free. It is a bounded substrate cost.

We then showed that this cost does not turn entanglement into a superluminal message channel. The finite-capacity substrate supports nonlocal correlation while preserving no-signalling because correlation maintenance and transmissible information are physically

distinct structures. The branch carries genuine joint consistency of the realized state, but it does not expose that consistency as a freely writable signalling medium. Quantum nonlocality is therefore supported without violating causal discipline.

We further derived the many-body consequence of the same burden law. Multipartite entanglement amplifies coordination overhead, raises branch latency, and shrinks the residual support margin of the substrate. As subsystem number grows, the shared burden of maintaining global coherence rises rapidly and drives the branch toward saturation. Deep macroscopic entanglement therefore becomes dynamically unstable not because quantum law disappears, but because the substrate cost of maintaining a globally shared branch becomes too high.

That saturation tendency yields the final major result of the paper: macroscopic decoherence emerges as the finite-capacity large-burden limit of entanglement support. The same substrate that supports microscopic nonlocal correlations destroys macroscopic coherence when collective burden drives the branch into a latency-loaded, noise-sensitive regime. Entanglement and classicality are therefore not disconnected explanatory domains. They are neighboring regimes of one bounded co-realization architecture.

This establishes the central quantum-nonlocal result of the finite-capacity program. Quantum nonlocality is not mystical action at a distance and not a hidden signalling channel. It is the bounded, no-signalling co-realization of a shared branch on a finite-capacity substrate. Small entangled systems survive because their burden remains supportable. Large entangled assemblies decohere because their burden approaches saturation. Classicality is therefore the dynamically stable endpoint of correlation-support failure at large scale.

The consequences for FCLET are decisive. The framework no longer stops at gravity, cosmology, thermodynamics, stochasticity, microphysical closure, strong-field completion, and QFT ultraviolet structure. It now possesses a fully articulated entanglement sector. The same canonical substrate law that governs realized burden, latency, proper time, stochastic noise, and field-theoretic propagation now also governs the support, limitation, and breakdown of quantum nonlocal correlation.

This changes the scale of the program. FCLET now spans:

- ontological time,
- gravity,
- cosmology,
- thermodynamic irreversibility,
- stochastic fluctuations,
- microphysical realization,
- strong-field dynamics,
- perturbative quantum field theory,

- and quantum entanglement.

The theory therefore no longer leaves the deepest quantum correlation problem outside its canon. It absorbs it into the same finite-capacity architecture that already governs the rest of the program.

Quantum nonlocality is thus no longer external to the finite-capacity framework. It is now an internal consequence of it. Entanglement, no-signalling, multipartite fragility, and macroscopic decoherence emerge from one substrate law. The finite-capacity program now contains its own nonlocal quantum branch, and with it, a unified extension from ontological time and realized burden to the deepest structure of quantum correlation itself.

Appendix A. Patch-Level Co-Realization Map for Bipartite States

The finite-capacity entanglement branch begins from the statement that an entangled bipartite state is not realized as two independent local threads. It is realized as one shared branch distributed across a patch substrate.

Let subsystem Abe supported on patch family $\mathcal{P}_A$and subsystem Bon patch family $\mathcal{P}_B$. A product state is realized through independent local support channels,

$$|\Psi_{\mathrm{prod}}\rangle = |\psi_A\rangle \otimes |\psi_B\rangle,$$

with branch burden

$$\mathcal{B}_{\mathrm{prod}} = \mathcal{B}_A + \mathcal{B}_B.$$

An entangled state is different in structure:

$$|\Psi_{AB}\rangle \neq |\psi_A\rangle \otimes |\psi_B\rangle.$$

Its realized support burden is not separable:

$$\boxed{\mathcal{B}_{AB} = \mathcal{B}_A + \mathcal{B}_B + \mathcal{B}_{\mathrm{corr}}^{(AB)}.}$$

The term $\mathcal{B}_{\mathrm{corr}}^{(AB)}$is the irreducible correlation-support burden required to maintain the nonfactorizable branch. It is not an optional decorative term. It is the exact finite-capacity cost of entanglement support.

At the level of patch updates, the product-state realization map is

$$\mathcal{U}_{\mathrm{prod}} = \mathcal{U}_A \oplus \mathcal{U}_B,$$

while the entangled realization map is

$$\boxed{\mathcal{U}_{AB} = \mathcal{U}_A \oplus \mathcal{U}_B \oplus \mathcal{U}_{\mathrm{corr}}^{(AB)}.}$$

The correlation branch $\mathcal{U}_{\mathrm{corr}}^{(AB)}$ is not a classical messaging channel. It is the shared update structure required to preserve the joint realized branch.

Define the correlation-support fraction

$$x_{\mathrm{corr}}^{(AB)} = \frac{\Gamma_{\mathrm{req}}^{(AB)}}{\Gamma_{\mathrm{avail}}^{(AB)}}, 0 \le x_{\mathrm{corr}}^{(AB)} < 1,$$

where

- $\Gamma_{\mathrm{req}}^{(AB)}$ is the coordination rate needed to support the entangled branch,
- $\Gamma_{\mathrm{avail}}^{(AB)}$ is the residual coordination bandwidth available in the supporting substrate region.

The associated correlation-support latency is

$$\boxed{\chi_{\mathrm{corr}}^{(AB)} = -\ln\left(1 - x_{\mathrm{corr}}^{(AB)}\right).}$$

Thus the full bipartite branch latency is

$$\boxed{\chi_{AB} = \chi_A + \chi_B + \chi_{\mathrm{corr}}^{(AB)}.}$$

The corresponding realized proper-time law of the entangled branch is

$$\boxed{d\tau_{AB} = e^{-\chi_{AB}} dt.}$$

This completes the bipartite co-realization map:

- local burdens support the component subsystems,
- irreducible correlation burden supports the shared branch,
- and branch proper time is dressed by the full latency overhead of that joint support structure.

Appendix B. Bounded Correlation-Cost Functional and Scaling Law

A finite-capacity substrate cannot support entanglement without cost. The minimal correlation-cost law is therefore defined as a monotonic functional of branch entanglement content and coordination footprint.

Let $\mathcal{E}_{AB}$ be a bipartite entanglement measure such that

$$\mathcal{E}_{AB} = 0 \text{for product states,} \mathcal{E}_{AB} > 0 \text{for entangled states.}$$

Let $\mathcal{G}_{AB} \geq 1$ denote the coordination-footprint factor of the branch. Then the minimal finite-capacity descendant cost functional is

$$\boxed{\mathcal{B}_{\mathrm{corr}}^{(AB)} = \kappa_E \, F(\mathcal{E}_{AB}) \, \mathcal{G}_{AB},}$$

where

- κ_E is the elementary substrate cost coefficient,
- $F(\mathcal{E})$ is monotonic with

$$F(0) = 0, F'(\mathcal{E}) > 0.$$

The simplest descendant choice is linear:

$$\boxed{\mathcal{B}_{\mathrm{corr}}^{(AB)} = \kappa_E \, \mathcal{E}_{AB} \, \mathcal{G}_{AB}.}$$

The required correlation-support rate is then

$$\boxed{\Gamma_{\mathrm{req}}^{(AB)} = \gamma_E \, F(\mathcal{E}_{AB}) \, \mathcal{G}_{AB},}$$

with γ_E the substrate update-cost scale of correlation support.

The residual available coordination bandwidth in the supporting region is

$$\boxed{\Gamma_{\mathrm{avail}}^{(AB)} = \Gamma_\star e^{-\bar{\chi}_{AB}},}$$

where $\Gamma_\star$ is the bare patch update rate and $\bar{\chi}_{AB}$ is the deterministic background latency of the supporting region.

Therefore the correlation-support load fraction is

$$\boxed{x_{\mathrm{corr}}^{(AB)} = \frac{\gamma_E \, F(\mathcal{E}_{AB}) \, \mathcal{G}_{AB}}{\Gamma_\star e^{-\bar{\chi}_{AB}}}.}$$

The corresponding support margin is

$$\boxed{\mathcal{W}_{\mathrm{corr}}^{(AB)} = \Gamma_{\mathrm{avail}}^{(AB)} - \Gamma_{\mathrm{req}}^{(AB)}.}$$

Stable bipartite support requires

$$\boxed{\mathcal{W}_{\mathrm{corr}}^{(AB)} > 0.}$$

The saturation boundary occurs when

$$\boxed{\mathcal{W}_{\mathrm{corr}}^{(AB)} \to 0^{+}, x_{\mathrm{corr}}^{(AB)} \to 1^{-}, \chi_{\mathrm{corr}}^{(AB)} \to +\infty.}$$

This yields the exact branch law of finite-capacity entanglement:

- stronger entanglement costs more,
- more complex coordination costs more,
- larger background burden reduces the available support margin,
- and the substrate imposes a hard ceiling on correlation maintenance.

Appendix C. Multipartite Burden Growth and Saturation Threshold

For an N-partite entangled branch,

$$|\Psi_{1\cdots N}\rangle,$$

the total realized burden is

$$\boxed{\mathcal{B}_N^{\mathrm{tot}} = \sum_{i=1}^{N} \mathcal{B}_i + \mathcal{B}_{\mathrm{corr}}^{(N)}.}$$

Let $\mathcal{E}_N$ be a multipartite entanglement functional with

$\mathcal{E}_N = 0$ for fully separable states, $\mathcal{E}_N > 0$ for genuinely multipartite entangled states.

Then the finite-capacity descendant burden law is

$$\boxed{\mathcal{B}_{\mathrm{corr}}^{(N)} = \kappa_N \, F_N(\mathcal{E}_N) \, \mathcal{G}_N,}$$

where $\mathcal{G}_N$ is the coordination-footprint factor of the N-body branch.

In the simplest pairwise scaling model,

$$\mathcal{G}_N \sim \frac{N(N-1)}{2}.$$

In a genuinely collective branch, the exact growth can be stronger, but the decisive structural fact is

$$\boxed{\frac{d\mathcal{G}_N}{dN} > 0, \frac{d^2\mathcal{G}_N}{dN^2} \geq 0.}$$

The required correlation-support rate is

$$\boxed{\Gamma_{\mathrm{req}}^{(N)} = \gamma_N \, F_N(\mathcal{E}_N) \, \mathcal{G}_N,}$$

and the available residual branch-support rate is

$$\boxed{\Gamma_{\mathrm{avail}}^{(N)} = \Gamma_\star e^{-\bar{\chi}_N}.}$$

Thus the branch support fraction is

$$\boxed{x_{\mathrm{corr}}^{(N)} = \frac{\gamma_N \, F_N(\mathcal{E}_N) \, \mathcal{G}_N}{\Gamma_\star e^{-\bar{\chi}_N}}.}$$

The correlation-support latency is

$$\boxed{\chi_{\mathrm{corr}}^{(N)} = -\ln\left(1 - x_{\mathrm{corr}}^{(N)}\right).}$$

The residual coordination margin is

$$\boxed{\mathcal{W}_N = \Gamma_{\mathrm{avail}}^{(N)} - \Gamma_{\mathrm{req}}^{(N)}.}$$

The saturation threshold of the branch is reached when

$$\boxed{x_{\mathrm{corr}}^{(N)} \to 1^-, \chi_{\mathrm{corr}}^{(N)} \to +\infty, \mathcal{W}_N \to 0^+.}$$

This defines the exact finite-capacity instability boundary of many-body entanglement.

A practical saturation threshold $N_{\mathrm{sat}}$is therefore determined implicitly by

$$\boxed{\Gamma_{\mathrm{req}}^{(N_{\mathrm{sat}})} = \Gamma_{\mathrm{avail}}^{(N_{\mathrm{sat}})}.}$$

For $N \ll N_{\mathrm{sat}}$, entangled support remains stable.
For $N \sim N_{\mathrm{sat}}$, the branch becomes latency-loaded and fragile.
For $N > N_{\mathrm{sat}}$, stable coherent co-realization is no longer admissible on the substrate.

This is the exact finite-capacity scaling reason deep macroscopic entanglement is dynamically unstable.

Appendix D. No-Signalling Proof Structure in the Finite-Capacity Branch

The finite-capacity entanglement branch supports nonlocal correlations, but not free signalling. This appendix states that structure explicitly.

Let two observers $A$and Bshare an entangled branch with joint outcome distribution

$$P(\alpha, \beta \mid a, b),$$

where

- $a$and $b$are local measurement settings,
- $\alpha$and $\beta$are local outcomes.

The branch includes a correlation-support sector $\mathcal{U}_{\mathrm{corr}}^{(AB)}$, but this sector preserves only joint branch consistency. It does not expose a free local control interface for rewriting distant marginals.

Therefore the local marginal at $A$is

$$P_A(\alpha \mid a) = \sum_{\beta} P(\alpha, \beta \mid a, b),$$

and finite-capacity support requires

$$\boxed{\sum_{\beta} P(\alpha, \beta \mid a, b) = \sum_{\beta} P(\alpha, \beta \mid a, b')}$$

for all b, b'. Similarly, the marginal at $B$is

$$P_B(\beta \mid b) = \sum_{\alpha} P(\alpha, \beta \mid a, b),$$

and finite-capacity support requires

$$\boxed{\sum_{\alpha} P(\alpha, \beta \mid a, b) = \sum_{\alpha} P(\alpha, \beta \mid a', b)}$$

for all a, a'.

These are exactly the no-signalling conditions.

In the finite-capacity substrate, this follows because the correlation-support burden

$$\mathcal{B}_{\mathrm{corr}}^{(AB)}$$

maintains the nonfactorizable branch but does not add a classical channel capacity

$$\mathcal{K}_{\mathrm{sig}}.$$

The exact branch statement is therefore

$$\boxed{\mathcal{K}_{\mathrm{corr}} > 0, \mathcal{K}_{\mathrm{sig}} = 0.}$$

That is:

- nonlocal correlation support exists,
- free transmissible signalling capacity does not.

Thus entanglement in FCLET preserves:

1. Bell-type nonlocal correlation strength,
2. no-signalling marginals,
3. causal compatibility with the rest of the program.

The branch therefore occupies the correct physical middle ground between naive local separability and unconstrained superluminal messaging.

Appendix E. Macroscopic Decoherence Estimate from Collective Burden

Let an N-partite entangled branch carry total latency

$$\chi_N = \bar{\chi}_N + \delta\chi_N,$$

where

- $\bar{\chi}_N$ is the deterministic collective burden latency,

- $\delta\chi_N$ is the stochastic fluctuation descendant inherited from the FCLET noise branch.

The branch proper-time law is

$$d\tau_N = e^{-\chi_N}dt.$$

Consider two macroscopically distinct branch components A and B with effective energy gap ΔE_{AB}. The noise-averaged off-diagonal density-matrix element obeys

$$\langle\rho_{AB}(t)\rangle = \rho_{AB}(0)e^{-i\Delta E_{AB}e^{-\bar{\chi}_N}t}e^{-\Gamma_{AB}^{(N)}(t)},$$

with decoherence kernel

$$\boxed{\Gamma_{AB}^{(N)}(t) = \frac{(\Delta E_{AB})^2 e^{-2\bar{\chi}_N}}{2}\int_0^t d\,t_1\int_0^t d\,t_2\,C_{\chi_N}(t_1,t_2),}$$

where

$$C_{\chi_N}(t_1,t_2) = \langle\delta\chi_N(t_1)\delta\chi_N(t_2)\rangle.$$

In the short-correlation Markovian descendant limit,

$$C_{\chi_N}(t-t') \approx 2D_{\chi_N}\delta(t-t'),$$

so

$$\boxed{\Gamma_{AB}^{(N)}(t) = (\Delta E_{AB})^2 e^{-2\bar{\chi}_N}D_{\chi_N}\,t.}$$

Hence the effective macroscopic decoherence rate is

$$\boxed{\gamma_{AB}^{(N)} = (\Delta E_{AB})^2 e^{-2\bar{\chi}_N}D_{\chi_N}.}$$

This formula shows the exact finite-capacity scaling logic:

- larger effective branch distinctions raise ΔE_{AB},
- larger collective burden raises $\bar{\chi}_N$,
- heavier coordinated branches amplify the stochastic descendant D_{χ_N},
- and therefore macroscopic entangled branches decohere rapidly.

The classical branch emerges when

$$\boxed{\Gamma_{AB}^{(N)}(t) \gtrsim 1}$$

over the observational timescale of interest. This is the operational finite-capacity condition for saturation-driven loss of macroscopic coherence.

Thus macroscopic classicality is not imposed from outside quantum law. It is the regime in which the collective burden of sustaining deep nonlocal correlation becomes too high for the finite-capacity substrate to maintain coherently.

The Master Experimental Blueprint: Observational Protocols, Benchmark Signals, and Falsification Criteria for the Finite-Capacity Latency–Erasure Theory

From Precision Clocks and Atom Interferometers to Pulsars, Ringdown Echoes, Horizon-Scale Imaging, and Cosmological Survey Windows

Abstract

We construct the unified experimental and observational protocol paper of the finite-capacity latency–erasure framework and convert the full theory program into an explicit falsification architecture. Earlier FCLET papers established the ontology of bounded realization, the canonical latency field, weak-field corrections, matter coupling, moderated cosmology, stochastic latency noise, thermodynamic closure, compact-object completion, binary timing effects, primordial fluctuation structure, numerical strong-field evolution, quantum-field-theoretic ultraviolet completion, galactic dark-matter mimicry, and finite-capacity entanglement. The present paper gathers these sectoral results into one benchmark matrix and states, in operational form, what experimental teams must measure, where they must look, what signal families the theory predicts, and what outcomes would exclude specific branches or the program's canonical core.

We derive a sector-by-sector blueprint covering precision optical clocks, atom interferometers, pulsar timing, compact-object imaging, gravitational-wave ringdown and echo searches, cosmic-microwave-background low-ℓ suppression, galactic rotation benchmarks, and cross-sector parameter consistency. The purpose is not to repeat isolated predictions already given elsewhere, but to organize them into a unified protocol language: observable, instrument class, scaling law, benchmark window, null expectation, finite-capacity deviation, and exclusion threshold. In this way, the finite-capacity framework is no longer presented only as a theoretical architecture. It is presented as a disciplined experimental program.

The paper culminates in a falsification matrix that distinguishes between branch-level failure and core-kernel failure. Some observational outcomes would eliminate particular effective descendants while leaving the canonical backbone intact; others would directly violate the central finite-capacity structure itself. This distinction is essential for theoretical maturity. A

framework becomes scientifically serious not when it merely accumulates explanatory sectors, but when it states clearly how it survives, how it is constrained, and how it can fail. The result is the final Popper-structured capstone of the FCLET program: a master experimental blueprint that translates finite-capacity physics into a unified measurement agenda.

Keywords: falsifiability; experimental blueprint; FCLET; optical clocks; atom interferometry; pulsar timing; ringdown echoes; EHT; CMB; benchmark matrix

1. Introduction

A physical theory reaches maturity only when it stops speaking exclusively in the language of possibility and begins speaking in the language of protocol. Formal consistency, cross-sector closure, and explanatory reach are indispensable, but they are not the final threshold. The final threshold is experimental discipline. A theory must say where its effects should appear, which instruments can resolve them, how large the relevant deviations are expected to be, which benchmark families are allowed, and what result would count as failure. The finite-capacity latency–erasure framework now reaches that threshold.

The FCLET program already spans a broad theoretical architecture. Its earlier branches established the ontology of bounded realized-load fraction, the canonical latency field, the burden-dependent proper-time law, covariant source closure, weak-field gravity, moderated cosmology, stochastic latency fluctuations, thermodynamic irreversibility, matter coupling, compact-object saturation-shell structure, binary timing corrections, primordial perturbation sectors, numerical strong-field evolution, perturbative quantum-field-theoretic ultraviolet completion, galactic dark-matter mimicry, and finite-capacity entanglement. That cumulative structure gives the program unusual breadth. But breadth alone is not enough. A theory of this scale must also tell the world's observers and experimentalists what to do with it.

This paper is written for that exact purpose. It is the master protocol paper of the program. Its role is not to rederive every sector from first principles, and not to restate every formal equation already derived elsewhere. Its role is to transform a multi-branch theoretical framework into a unified experimental blueprint. The question addressed here is direct: if FCLET is taken seriously as a physical architecture, what must be measured, by whom, in which systems, through what observable, on what benchmark scale, and under what exclusion logic?

This question is more demanding than a generic "predictions" section. A mature theory does not merely say that some effect may be seen one day. It organizes its full observational interface. That requires several layers of discipline. First, sectoral observables must be written in instrument-facing language: clock drift, phase shift, secular timing residual, ringdown deformation, echo delay, horizon-scale image anomaly, low-ℓ suppression amplitude, asymptotic galactic velocity relation, and so on. Second, those observables must be embedded in benchmark families rather than in vague claims. Third, the theory must distinguish between soft branch pressure and hard falsification. A single sector's failure does not always kill an

entire research program. But some failures do reach the canonical core. A serious theory must say which is which.

The finite-capacity program is especially suited to this form of organization because its sectors are not disconnected. Earlier papers already established that viable branches of FCLET occupy a narrow corridor rather than the full nominal theory space. The program already contains a benchmark atlas, decisive-island logic, branch-aware inference structure, and explicit falsification criteria in several subdomains. What has been missing until now is a final capstone synthesis that presents the whole measurement agenda at once. That is what this paper provides.

The need for such a synthesis is now unavoidable. Precision atomic clocks probe nonequilibrium latency memory and stochastic timing structure. Atom interferometers probe phase shifts sourced by fluctuations in the effective latency field. Binary pulsars probe scalar-latency radiation and hysteretic timing corrections. Gravitational-wave detectors probe ringdown deformation and saturation-shell echoes. Horizon-scale imaging probes compact-object shadow deviations from classical horizon expectations. Cosmic-microwave-background experiments probe primordial latency fluctuations and low-multipole suppression. Disk-galaxy dynamics probe the galactic latency-gradient branch. These are not speculative appendices scattered around the edges of the program. They are the empirical face of the theory itself. A final unified blueprint must therefore gather them into one operational matrix.

This changes the role of falsifiability inside FCLET. Earlier branches already showed that the theory is not protected by vagueness. It produces sectoral structure, scaling relations, and regime logic. The present paper sharpens that into a final charter. It distinguishes between three levels of observational impact. At the first level, data may disfavor a particular effective descendant while leaving the canonical finite-capacity backbone intact. At the second level, data may force severe narrowing of the admissible parameter corridor. At the third level, data may directly violate the core latency–burden architecture itself and therefore falsify the program at its foundation. These distinctions are essential. Without them, falsification talk becomes theatrical. With them, the theory becomes experimentally disciplined.

The present paper is therefore not defensive and not provisional. It does not present FCLET as a framework waiting indefinitely for future interpretation. It presents FCLET as a theory program ready to be read by instrument teams, timing analysts, waveform modellers, cosmological inference groups, and astronomical observers. It states the full measurement logic of the theory and the explicit routes by which the theory survives, narrows, or fails.

The structure of the paper follows that purpose. Section 2 formulates the experimental logic of the finite-capacity program and defines the benchmark philosophy governing all sectors. Section 3 gathers the precision-laboratory signatures, especially optical-clock hysteresis and atom-interferometric phase shifts. Section 4 turns to compact-binary and pulsar timing observables. Section 5 organizes strong-field and horizon-scale signatures, including compact-object imaging deviations. Section 6 treats gravitational-wave observables, with special emphasis on ringdown modification and saturation-shell echo searches in current and future detector classes. Section 7 collects cosmological signatures, especially low-ℓ

suppression and primordial-latency observables. Section 8 adds galactic and dark-sector phenomenology, tying the rotation-curve branch and baryonic scaling laws into the broader benchmark architecture. Section 9 assembles the full FCLET benchmark matrix. Section 10 presents the final falsification matrix and states explicitly what observational results would kill particular branches and what results would kill the canonical core.

The outcome of this paper is decisive. The finite-capacity program is no longer only a structured theoretical construction extending from ontological time to gravity, cosmology, thermodynamics, quantum fields, galactic dynamics, and entanglement. It now stands as a unified empirical program with explicit protocol logic. The theory says where to look, what to measure, how to compare, and how it can fail. That is the final discipline of a mature physical framework. FCLET now enters that discipline in full.

2. The Experimental Logic of the Finite-Capacity Program

2.1 Falsifiability as the Final Discipline of Theory

A theory becomes experimentally serious when it states not only what it explains, but what would count against it. This principle is not external to the finite-capacity program. It is its final discipline. FCLET does not stand as a framework that survives by interpretive elasticity. It stands as a structured physical program with a canonical kernel, controlled descendant branches, regime-aware predictions, and explicit failure conditions.

The core logic is exact. The program is built from a finite-capacity substrate with bounded realized-load fraction, canonical latency response, burden-dependent proper-time generation, and a hierarchy of observational descendants. If those descendants do not appear where the core architecture requires them, the relevant branch fails. If the failures accumulate at the level of the canonical backbone itself, the theory fails.

This means that falsifiability in FCLET must be organized in layers rather than in one crude yes-or-no gesture. A theory of this scope spans many regimes:

- weak-field gravity,
- nonequilibrium timing,
- stochastic noise,
- compact-binary evolution,
- strong-field collapse,
- cosmological background history,
- primordial perturbations,
- galactic outer-disk dynamics,
- perturbative quantum-field structure,

- and nonlocal quantum correlation.

No mature framework of this scale lives or dies through one isolated datum unless that datum directly targets the kernel. The correct experimental discipline is therefore not rhetorical absolutism. It is a structured falsification hierarchy.

The hierarchy has three levels.

Branch-level falsification

A result may eliminate a specific effective descendant without destroying the canonical FCLET core. For example, a particular strong-field echo branch or a particular phenomenological parameterization of laboratory memory effects may fail while leaving the finite-capacity substrate logic intact. In this case, a branch dies but the program survives in narrowed form.

Corridor-level narrowing

A result may not eliminate a branch entirely, but may compress the admissible parameter corridor so strongly that only a narrow benchmark family remains viable. This is not cosmetic. FCLET already developed a survival-corridor logic in earlier papers, and the present blueprint elevates that logic into explicit protocol form. The theory becomes stronger when the corridor is narrow enough to be genuinely risky.

Core-kernel falsification

A result may directly violate the canonical backbone. If the burden–latency structure, the recovery hierarchy, the canonical source architecture, or the cross-sector closure logic fails under decisive multi-sector observation, then the program is not merely pressured. It is falsified at its foundation.

This layered structure is not a retreat from Popperian clarity. It is the only scientifically coherent way to handle a large unified framework. A serious theory distinguishes between:

- failure of one phenomenological descendant,
- failure of a parameter family,
- and failure of the core architecture itself.

The present paper therefore does not present falsifiability as a slogan. It presents it as the final analytic structure of the program. Every sector will be translated into the same operational language:

1. observable,
2. instrument class,
3. benchmark scaling law,
4. null expectation,

5. finite-capacity deviation,
6. exclusion threshold.

That is how FCLET enters full empirical discipline.

2.2 Sector-by-Sector Observables Already Opened by FCLET

The finite-capacity program does not begin this paper from an observational vacuum. The sectoral observables already exist in the canon. What has been missing is their assembly into one protocol architecture.

The precision-laboratory branch already opens observables tied to nonequilibrium latency memory and stochastic timing structure. In that sector, the theory predicts measurable deviations in long-baseline frequency comparison, hysteretic clock behavior under changing load conditions, and phase-noise effects in interferometric systems. These are not abstract "possible consequences." They are direct descendants of the burden-dependent proper-time law.

The compact-binary branch already opens a timing observable through the finite-capacity correction to orbital decay and through history-dependent hysteretic drag. In that domain, the theory predicts deviations from the pure tensor quadrupole decay law in systems where compact-binary dynamics load the substrate strongly enough for scalar-latency radiation and memory sectors to matter.

The strong-field branch already opens waveform and imaging observables. Saturation-shell compact objects do not behave as classical horizon structures. Their ringdown spectrum, late-time response, collapse signatures, and horizon-scale image properties are therefore not exactly those of classical black holes. The theory predicts shell-support effects, ringdown deformation, and echo-like structures tied to the finite-capacity strong-field branch.

The cosmological branch already opens multiple observables. Moderated-erasure background expansion modifies the interpretation of dark-energy-like behavior. Primordial latency fluctuations seed the scalar perturbation sector. Low-ℓ suppression in the CMB becomes a direct signature of finite-capacity freeze-out and early-universe burden moderation. Structure-growth consistency also places the theory under survey-level pressure.

The galactic branch already opens another clear arena. Disk-galaxy rotation support, baryonic Tully–Fisher scaling, and low-acceleration baryon-locked dynamics are no longer treated as evidence for mandatory invisible particle halos. They become testable consequences of latency-gradient support sourced by visible matter.

The quantum branches open still further observables. The QFT sector predicts ultraviolet suppression through latency-dressed propagators and proper-time floors, while the entanglement sector predicts bounded nonlocal correlation support, multipartite burden growth, and saturation-driven macroscopic decoherence. Although these latter sectors are more difficult to test directly in a single clean macroscopic observable, they contribute

benchmark logic and consistency conditions that constrain the interpretation of laboratory coherence phenomena.

The point is exact: FCLET already contains a rich observable vocabulary. What this paper does is to convert that vocabulary into experimental syntax. Instead of leaving the observables scattered across many papers, it places them into a unified matrix with shared benchmark discipline.

The program is therefore already observationally alive before the present paper begins. This paper is the act of operational consolidation.

2.3 Why a Unified Protocol Paper Is Required

Without a unified protocol paper, a large theory program is too easy to misread. One reader sees only cosmology. Another sees only compact objects. Another sees only quantum structure. Another sees only foundational ontology. The program then appears broader than it is operationally disciplined, because its empirical face remains distributed across many sector papers rather than integrated into one measurement agenda.

That situation is no longer acceptable for FCLET. The theory has grown too large and too structurally explicit to remain experimentally fragmented. Its sectors now share enough parameter genealogy, regime logic, and canonical architecture that their observables must be read together.

The need for a unified protocol paper follows from five exact reasons.

First, the sectors are no longer independent

The same canonical variables recur across the program. Burden, latency, realized proper time, stochastic descendants, overwrite response, and regime-dependent support all reappear in different forms across different observational domains. A clock anomaly, a pulsar residual, a ringdown deviation, a low-ℓ suppression signal, and a galactic low-acceleration scaling law are not disconnected events in FCLET. They are different observational faces of one substrate law.

Second, the parameter corridor is cross-sectoral

A viable benchmark in one sector cannot be chosen in total isolation from the others. A parameter family that fits galactic dynamics but violates compact-binary timing or cosmological moderation is not viable. A parameter family that produces strong strong-field echoes but destroys inner weak-field recovery is not viable. This means that the program's observational life must be organized as a cross-sector matrix rather than as independent local fits.

Third, branch failure and core failure must be separated clearly

A unified protocol paper is required in order to say which measurements kill only one descendant branch and which measurements kill the canonical core. Without that distinction, the theory either looks artificially invulnerable or artificially brittle. Neither is scientifically acceptable.

Fourth, experimentalists need instrument-facing language

A theory paper may speak in canonical variables, but an observational program must speak in measurement variables:

- frequency shift,
- phase drift,
- timing residual,
- echo delay,
- image deformation,
- multipole suppression,
- velocity–mass relation,
- exclusion contour.

The unified protocol paper is where that translation happens systematically.

Fifth, the final maturity of a framework is public clarity about failure

A mature theory does not hide the conditions of its own death inside dozens of separate articles. It states them plainly. This is especially necessary for a program as ambitious as FCLET. Breadth without explicit falsification looks like overreach. Breadth with explicit falsification becomes disciplined architecture.

For these reasons, the present paper is not optional synthesis. It is the final structural requirement of the program. The theory has reached the point where it must present itself not merely as a conceptual or mathematical framework, but as a full observational agenda.

2.4 Benchmark Philosophy and Exclusion Logic

The observational program of FCLET must be organized through benchmark families rather than through one numerically rigid fantasy model. A theory of this scope contains screened branches, weak-load branches, moderate-load branches, and saturation-adjacent branches. The correct experimental discipline is therefore not to pretend that one exact number should describe every sector under every condition. The correct discipline is to define admissible benchmark families and then test them ruthlessly.

The benchmark philosophy used in this paper has four layers.

Conservative benchmark family

This family stays as close as possible to standard recovery limits. Deviations are small, screening is strong, and only the cleanest low-acceleration or long-baseline sectors show visible departure from standard expectations. This benchmark asks the hardest question of null experiments: can the theory remain alive while staying minimally invasive?

Fiducial benchmark family

This family represents the program's central working corridor. Deviations are not artificially minimized and not exaggerated. Cross-sector consistency is optimized. This is the benchmark family that should be treated as the main operational target of the theory.

Aggressive benchmark family

This family explores the high-visibility edge of the admissible corridor. Stronger ringdown effects, clearer clock drifts, earlier galactic transition radii, or larger low-ℓ suppression signatures may appear here. This family is useful because it makes the theory easy to falsify quickly. If even the aggressive branch is absent where instruments are already sensitive, that side of the corridor dies.

Excluded or collapsing family

This family is not viable but must be shown explicitly to clarify boundaries. The purpose of including it is to make the observational logic sharper. A program becomes clearer when one says not only what survives, but what definitely fails.

The exclusion logic then follows in exact order.

1. **Measurement**: determine the observable in the relevant instrument class.
2. **Null baseline**: identify the standard-theory expectation.
3. **FCLET branch deviation**: compute the benchmark deviation family.
4. **Comparison**: decide whether the datum supports, narrows, or excludes the branch.
5. **Classification**: label the result as branch pressure, corridor compression, or core-kernel failure.

This is the same logic that will govern every major sector in the remainder of the paper.

The most important final rule is this: **a negative result is scientifically valuable only if the theory states in advance what that result means.** FCLET does so here. The paper will not merely list signals. It will assign each signal a branch status and an exclusion meaning.

That is the benchmark philosophy of the finite-capacity program. It is rigorous, hierarchical, and experimentally usable. The next section applies it to the first concrete arena of the theory's observational interface: precision laboratory signatures in clocks and atom interferometers.

3. Precision Laboratory Signatures

3.1 Optical Atomic-Clock Hysteresis and Memory Effects

The precision-laboratory branch of FCLET is built on one exact principle: proper time is not generated on a perfectly inert background. It is generated on a finite-capacity substrate whose local burden state modifies realized temporal flow. A precision clock is therefore not merely a passive reader of an external time parameter. It is itself a realized system embedded in a burden-sensitive timing medium. This is the root of the laboratory signature.

The canonical proper-time law is

$$d\tau = e^{-\chi} dt,$$

where $\chi$is the local latency field. In the laboratory weak-load regime, the latency field may be decomposed into a static part, a nonequilibrium memory part, and a stochastic fluctuation part:

$$\chi(t) = \bar{\chi} + \chi_{\mathrm{mem}}(t) + \delta\chi(t).$$

The static part $\bar{\chi}$is absorbed into the baseline local timing environment. The measurable laboratory effect begins with $\chi_{\mathrm{mem}}(t)$, the nonequilibrium branch inherited from the history-dependent latency sector of the program. This term records finite-response substrate burden rather than instantaneous burden alone. That is why the first decisive clock signal is not a static offset but a hysteresis effect.

Let a controlled laboratory protocol modulate local load through an external cycle $L(t)$, for example by changing field intensity, local energy density, duty cycle, or instrument-state occupation in a repeated manner. In the finite-capacity branch, the memory latency does not follow $L(t)$algebraically. It obeys a finite-response law of the form

$$\boxed{\tau_{\mathrm{mem}} \frac{d\chi_{\mathrm{mem}}}{dt} + \chi_{\mathrm{mem}} = \kappa_L L(t),}$$

where:

- $\tau_{\mathrm{mem}}$is the laboratory memory timescale,
- $\kappa_L$is the load-to-latency response coefficient of the branch.

The measured clock frequency $\nu(t)$is then shifted according to

$$\boxed{\frac{\delta\nu(t)}{\nu_0} = -\chi_{\mathrm{mem}}(t) - \delta\chi(t),}$$

to leading order in the weak-load laboratory regime. The deterministic hysteresis signal is therefore

$$\boxed{\frac{\delta\nu_{\mathrm{mem}}(t)}{\nu_0} = -\chi_{\mathrm{mem}}(t).}$$

This immediately yields the first protocol-level signature: if the same external load value $L$is reached on the rising and falling segments of a modulation cycle, the clock frequency need not return to the same instantaneous value. The clock carries branch history. That is the optical-clock hysteresis effect of FCLET.

The experimentally relevant form is obtained for sinusoidal or staircase modulation. For a sinusoidal drive,

$$L(t) = L_0\cos(\omega_{\mathrm{mod}}t),$$

the memory solution is

$$\boxed{\chi_{\mathrm{mem}}(t) = \frac{\kappa_L L_0}{\sqrt{1+\omega_{\mathrm{mod}}^2\tau_{\mathrm{mem}}^2}}\cos\left(\omega_{\mathrm{mod}}t - \phi_{\mathrm{mem}}\right),}$$

with phase lag

$$\boxed{\phi_{\mathrm{mem}} = \arctan(\omega_{\mathrm{mod}}\tau_{\mathrm{mem}}).}$$

The corresponding fractional clock shift is therefore

$$\boxed{\frac{\delta\nu_{\mathrm{mem}}(t)}{\nu_0} = -\frac{\kappa_L L_0}{\sqrt{1+\omega_{\mathrm{mod}}^2\tau_{\mathrm{mem}}^2}}\cos\left(\omega_{\mathrm{mod}}t - \phi_{\mathrm{mem}}\right).}$$

This is not ordinary instrumental lag. It is a substrate-latency lag. Its operational signature is exact:

- amplitude suppression at high modulation frequency,
- phase lag relative to the applied load cycle,
- nonzero loop area in the $\delta\nu/\nu_0$versus Lplane.

The hysteresis-loop area is the cleanest branch diagnostic. Over one cycle,

$$\boxed{\mathcal{A}_{\mathrm{hyst}} = \oint \frac{\delta\nu_{\mathrm{mem}}}{\nu_0}\,dL = \pi\,\kappa_L^2 L_0^2\,\frac{\omega_{\mathrm{mod}}\tau_{\mathrm{mem}}}{1+\omega_{\mathrm{mod}}^2\tau_{\mathrm{mem}}^2}.}$$

A strictly Markov-free and memory-free timing medium gives $\mathcal{A}_{\mathrm{hyst}} = 0$. FCLET gives $\mathcal{A}_{\mathrm{hyst}} > 0$whenever the nonequilibrium latency branch is active. This is the first decisive laboratory observable of the theory.

3.2 Frequency-Shift Windows from Nonequilibrium Latency

The hysteresis law must now be translated into benchmark measurement windows. A mature protocol paper cannot stop at functional form. It must tell experimentalists what parameter combination controls the size of the effect and how the measurement should be organized.

The leading deterministic branch prediction for a precision clock is

$$\frac{\delta\nu_{\mathrm{mem}}}{\nu_0} \sim \kappa_L L_{\mathrm{eff}},$$

where $L_{\mathrm{eff}}$is the effective load history retained by the substrate over the memory timescale τ_{mem}. The absolute frequency shift is therefore

$$\boxed{\delta\nu_{\mathrm{mem}} \sim \nu_0\, \kappa_L L_{\mathrm{eff}}.}$$

This formula organizes the benchmark logic immediately. For optical clocks operating at carrier frequencies near

$$\nu_0 \sim 10^{14} - 10^{15}\ \mathrm{Hz},$$

even extremely small fractional shifts produce measurable absolute frequency deviations. The experimental game is therefore not to create large raw frequency offsets, but to generate controlled nonequilibrium load cycles and look for residual hysteretic branch structure at the highest differential stability level of the instrument.

The benchmark families may be stated as follows.

Conservative laboratory branch

$$\kappa_L L_{\mathrm{eff}} \sim 10^{-20} - 10^{-19}.$$

This yields absolute clock deviations of order

$$\delta\nu_{\mathrm{mem}} \sim 10^{-6} - 10^{-4}\ \mathrm{Hz}$$

for optical carrier frequencies in the $10^{14} - 10^{15}$ Hzrange. This branch is deliberately close to the null baseline and is appropriate to long integration, differential comparison, and repeated-cycle stacking.

Fiducial laboratory branch

$$\kappa_L L_{\mathrm{eff}} \sim 10^{-18} - 10^{-17}.$$

This yields

$$\delta\nu_{\mathrm{mem}} \sim 10^{-3} - 10^{-1}\ \mathrm{Hz}.$$

This is the central FCLET laboratory corridor. It is large enough to generate a measurable hysteresis loop in advanced optical-clock comparisons and small enough to remain compatible with the weak-load recovery logic of the canon.

Aggressive laboratory branch

$$\kappa_L L_{\mathrm{eff}} \sim 10^{-16} - 10^{-15}.$$

This yields

$$\delta\nu_{\mathrm{mem}} \sim 10^{-1} - 10^{0}\ \mathrm{Hz}.$$

This branch is experimentally easy to rule out if absent under properly designed modulation protocols. It is therefore useful as the high-visibility edge of the allowed corridor.

The observable is not merely "a frequency shift." It is a structured frequency shift with four exact features:

1. dependence on modulation history rather than instantaneous load alone,
2. lag relative to the drive cycle,
3. loop-area scaling with modulation frequency,
4. partial relaxation after the load cycle ends.

That last point gives a second clean protocol. After a step-like load perturbation is removed, the memory branch predicts exponential recovery:

$$\boxed{\chi_{\mathrm{mem}}(t) = \chi_{\mathrm{mem}}(t_{\mathrm{off}})\, e^{-(t-t_{\mathrm{off}})/\tau_{\mathrm{mem}}},}$$

and therefore

$$\boxed{\frac{\delta\nu_{\mathrm{mem}}(t)}{\nu_0} = -\frac{\delta\nu_{\mathrm{mem}}(t_{\mathrm{off}})}{\nu_0}\, e^{-(t-t_{\mathrm{off}})/\tau_{\mathrm{mem}}}.}$$

A null theory with no finite-capacity memory branch predicts no such delayed relaxation after standard instrumental transients are removed. FCLET predicts a branch-timescale tail.

The precision-clock sector is therefore experimentally sharp. The theory predicts:

- hysteresis loop area,
- modulation-frequency phase lag,
- branch-amplitude suppression with $\omega_{\mathrm{mod}}\tau_{\mathrm{mem}}$,
- and post-cycle recovery tails.

These signatures must be sought in differential clock protocols rather than in isolated absolute-frequency readings. The signal is a structured history effect, not a static offset.

3.3 Atom-Interferometric Phase Shifts from $\delta\chi$Fluctuations

The second precision-laboratory arena is atom interferometry. If optical clocks probe deterministic memory and slow timing deformation, atom interferometers probe stochastic and path-dependent phase accumulation sourced by latency fluctuations.

The branch law is again exact. The realized proper time along each interferometric arm is

$$d\tau = e^{-(\bar{\chi}+\delta\chi)}dt.$$

In the weak-fluctuation regime,

$$e^{-(\bar{\chi}+\delta\chi)} \approx e^{-\bar{\chi}}(1-\delta\chi),$$

so the proper-time difference accumulated between two interferometric paths 1and 2is

$$\Delta\tau = e^{-\bar{\chi}}\int_0^T dt\,[\delta\chi_2(t) - \delta\chi_1(t)],$$

to leading order in the fluctuating branch.

For an interferometric phase built from an effective Compton or laser-referenced frequency scale ω_{eff}, the branch phase shift is

$$\boxed{\Delta\phi_\chi = \omega_{\mathrm{eff}}\,\Delta\tau = \omega_{\mathrm{eff}}e^{-\bar{\chi}}\int_0^T dt\,[\delta\chi_2(t) - \delta\chi_1(t)].}$$

This is the exact FCLET interferometric signal law. The theory predicts that path-dependent latency fluctuations act as a direct phase-noise and phase-bias source in atomic interferometry.

For a coherent deterministic perturbation in which one arm samples a controlled latency perturbation $\delta\chi_{\mathrm{ctrl}}(t)$and the other does not, the signal reduces to

$$\boxed{\Delta\phi_{\chi}^{\mathrm{ctrl}} = \omega_{\mathrm{eff}} e^{-\bar{\chi}} \int_0^T dt\, \delta\, \chi_{\mathrm{ctrl}}(t).}$$

If the perturbation is approximately constant during interrogation time T,

$$\delta\chi_{\mathrm{ctrl}}(t) \approx \delta\chi_0,$$

then

$$\boxed{\Delta\phi_{\chi}^{\mathrm{ctrl}} \approx \omega_{\mathrm{eff}} e^{-\bar{\chi}}\, \delta\chi_0\, T.}$$

This immediately defines the phase-shift benchmark families. Since modern atom interferometers can resolve extremely small differential phase excursions, the correct FCLET target is not an enormous branch phase but a stable branch phase with the correct geometry and modulation dependence.

The stochastic branch appears through phase variance. Define the differential latency-noise correlator

$$C_{\Delta\chi}(t, t') = \langle [\delta\chi_2(t) - \delta\chi_1(t)][\delta\chi_2(t') - \delta\chi_1(t')] \rangle.$$

Then the interferometric phase variance is

$$\boxed{\langle (\Delta\phi_{\chi})^2 \rangle = \omega_{\mathrm{eff}}^2 e^{-2\bar{\chi}} \int_0^T d\, t_1 \int_0^T d\, t_2\, C_{\Delta\chi}(t_1, t_2).}$$

In the Markovian descendant limit,

$$C_{\Delta\chi}(t - t') \approx 2D_{\Delta\chi}\delta(t - t'),$$

this becomes

$$\boxed{\langle (\Delta\phi_{\chi})^2 \rangle = 2\omega_{\mathrm{eff}}^2 e^{-2\bar{\chi}} D_{\Delta\chi}\, T.}$$

Thus FCLET predicts two exact interferometric observables:

1. a controlled path-dependent phase bias under imposed load asymmetry,
2. a stochastic phase-noise growth law under passive latency fluctuation.

This is a very clean experimental sector because atom interferometry naturally converts tiny timing differences into measurable phase. Where clocks measure substrate burden through frequency drift, interferometers measure it through phase accumulation.

3.4 Laboratory Null Tests and Exclusion Thresholds

The protocol paper must now state what would count as failure in the precision-laboratory branch. A scientific program is not strengthened by naming signals alone. It is strengthened by specifying the null tests that kill those signals.

The FCLET laboratory falsification logic has four layers.

Null Test 1: No hysteresis loop under controlled cyclic loading

If two identical optical clocks are compared while one branch is driven through a controlled cyclic load modulation and the measured differential fractional shift satisfies

$$\mathcal{A}_{\mathrm{hyst}} \approx 0$$

to a sensitivity that excludes the fiducial and aggressive benchmark families, then the nonequilibrium memory branch of the laboratory sector is strongly compressed. If repeated higher-sensitivity tests continue to show zero loop area under conditions where standard instrumental lag is independently removed, the simple laboratory memory descendant fails.

Null Test 2: No post-cycle relaxation tail

If load modulation is switched off and the clock shows no residual exponential recovery tail beyond known instrumental relaxation, then the branch timescale τ_{mem} is forced toward zero or the memory coefficient κ_L is forced toward negligibility. Repeated null results under multiple protocols can therefore eliminate broad regions of the laboratory corridor.

Null Test 3: No controlled interferometric phase bias from imposed latency asymmetry

If atom interferometers with engineered path asymmetry fail to detect any reproducible phase shift of the form

$$\Delta\phi_{\chi}^{\mathrm{ctrl}} \propto \omega_{\mathrm{eff}} \int \delta\chi_{\mathrm{ctrl}} dt$$

within the fiducial or aggressive benchmark windows, then the deterministic branch of the interferometric sector is strongly pressured.

Null Test 4: No excess stochastic phase-noise scaling

If the differential phase variance fails to exhibit any branch-consistent scaling with interrogation time,

$$\langle (\Delta\phi_\chi)^2 \rangle \propto T,$$

or its appropriate non-Markovian analogue, after standard instrumental and environmental noise sources are removed, then the stochastic laboratory branch is correspondingly compressed.

These null tests must now be classified by exclusion strength.

Branch-level exclusion

A null result that rules out the aggressive benchmark family but leaves the conservative and fiducial branches alive is a branch narrowing, not a core failure.

Corridor-level exclusion

A null result that eliminates both aggressive and fiducial families across multiple laboratory platforms compresses the corridor sharply. The laboratory branch survives only in a highly screened or ultraconservative form.

Core pressure

If precision clocks and atom interferometers together rule out all laboratory memory and fluctuation descendants while other sectors continue demanding nonzero nonequilibrium latency or stochastic burden, then cross-sector closure is endangered. At that point the pressure is no longer merely local. It begins to rise toward the canonical core.

The exact operational philosophy is therefore simple:

- clocks test deterministic memory,
- interferometers test path-sensitive phase burden,
- repeated null results narrow the branch hierarchy,
- cross-sector contradiction threatens the kernel.

This is the correct experimental discipline of the precision-laboratory sector. FCLET does not merely say “look for anomalies.” It says:

- modulate the load,
- compare the clocks,
- measure the hysteresis loop,
- search for the recovery tail,
- engineer path asymmetry,
- measure the phase shift,
- and assign the result its correct exclusion status.

The next section applies the same logic to compact-binary and pulsar timing systems, where the theory's latency-memory and scalar-radiation branches are tested on astronomical baselines far beyond anything available in the laboratory.

4. Compact-Binary and Pulsar Timing Signatures

4.1 Scalar-Latency Radiation Corrections to $\dot{P}_b$

Compact-binary timing is one of the most powerful observational sectors of the finite-capacity program because it tests the theory in a regime that is simultaneously weak-field in wave propagation, strong-burden in orbital history, and exceptionally precise in measurement. Binary pulsars do not merely provide qualitative consistency checks. They provide long-baseline phase-coherent clocks embedded inside relativistic orbital systems. That makes them a decisive interface between the nonequilibrium latency branch, the scalar-radiation branch, and the empirical survival corridor of FCLET.

The standard general-relativistic benchmark is the tensor quadrupole prediction for orbital period decay,

$$\dot{P}_b^{\mathrm{GR}},$$

which is already known to high precision in several relativistic binary systems. The finite-capacity branch modifies this baseline not by replacing the tensor channel, but by adding two further contributions:

1. scalar-latency radiation,
2. history-dependent hysteretic drag.

The total period derivative therefore takes the branch-aware form

$$\boxed{\dot{P}_b^{\mathrm{FCLET}} = \dot{P}_b^{\mathrm{GR}} + \Delta\dot{P}_b^{(\chi)} + \Delta\dot{P}_b^{(\mathrm{mem})}.}$$

The first correction,

$$\Delta\dot{P}_b^{(\chi)},$$

is the radiative descendant of the latency field. It arises because binary motion on a finite-capacity substrate does not source only tensor gravitational radiation. It also sources a scalar burden sector whose retarded response carries away energy and modifies orbital decay.

At leading branch level, the scalar-latency correction may be written as

$$\boxed{\Delta\dot{P}_b^{(\chi)} = -\mathcal{A}_\chi\, \mathcal{F}_\chi(e, m_1, m_2, P_b),}$$

where:

- $\mathcal{A}_\chi$ is the effective scalar-latency amplitude of the binary branch,
- $\mathcal{F}_\chi$ is the eccentricity-, mass-, and period-dependent timing functional derived in the dedicated binary-pulsar paper.

The exact analytic structure of $\mathcal{F}_\chi$ depends on the compact-binary branch chosen, but its operational meaning is fixed: it adds a secular correction to the standard orbital decay law and therefore shifts the measured $\dot{P}_b$ away from the pure tensor quadrupole prediction.

This immediately defines the first observational target of the pulsar sector:

$$\boxed{\Delta\dot{P}_b \equiv \dot{P}_b^{\rm obs} - \dot{P}_b^{\rm GR} = \Delta\dot{P}_b^{(\chi)} + \Delta\dot{P}_b^{(\rm mem)}.}$$

If the binary timing data remain perfectly tensor-quadrupolar after all known kinematic and environmental corrections are removed, then the scalar-latency branch is pressured. If a stable residual remains, the finite-capacity branch gains direct support.

The benchmark logic follows the same pattern used in the laboratory section.

Conservative pulsar branch

$$\left|\frac{\Delta\dot{P}_b}{\dot{P}_b^{\rm GR}}\right| \sim 10^{-5} - 10^{-4}.$$

This branch is deliberately close to current precision limits in the cleanest systems and is meant to survive only if FCLET remains heavily screened in compact-binary timing.

Fiducial pulsar branch

$$\left|\frac{\Delta\dot{P}_b}{\dot{P}_b^{\rm GR}}\right| \sim 10^{-4} - 10^{-3}.$$

This is the central timing corridor of the theory. It is large enough to produce measurable secular residuals in precision pulsar systems and small enough to remain compatible with the broader empirical survival logic of the program.

Aggressive pulsar branch

$$\left|\frac{\Delta\dot{P}_b}{\dot{P}_b^{\rm GR}}\right| \sim 10^{-3} - 10^{-2}.$$

This branch is observationally high-risk. If absent in systems where the timing baseline is already strong, it dies quickly.

The key point is exact: binary pulsars do not test one isolated correction coefficient. They test whether the finite-capacity program can insert additional scalar burden loss into orbital dynamics without violating the precision success of the tensor channel where that channel already works extremely well.

4.2 Hysteretic Timing Residuals and Secular Drift Windows

The pulsar sector does not test only scalar radiation. It also tests the nonequilibrium memory structure of the finite-capacity substrate over astronomical baselines. This is one of the most distinctive signatures of FCLET, because a binary pulsar is not merely an orbiting two-body system. It is a highly stable timing machine whose orbital history can be compared against an exceptionally rigid phase model across many years.

The finite-capacity branch predicts that the latency field of a compact binary does not respond instantaneously to orbital forcing. It carries memory. This means the effective timing sector should contain not only a secular energy-loss correction, but also a history-dependent phase residual.

Let the binary timing residual relative to the best-fit general-relativistic template be

$$R(t).$$

The finite-capacity decomposition is then

$$\boxed{R(t) = R_{\chi}(t) + R_{\mathrm{mem}}(t) + R_{\mathrm{noise}}(t),}$$

where:

- $R_{\chi}(t)$is the deterministic scalar-latency descendant,
- $R_{\mathrm{mem}}(t)$is the hysteretic memory branch,
- $R_{\mathrm{noise}}(t)$is the stochastic remainder.

The memory branch may be represented at sector level through a first-order finite-response law driven by the binary load functional $\mathcal{L}_b(t)$:

$$\boxed{\tau_b \frac{d\chi_{\mathrm{mem}}^{(b)}}{dt} + \chi_{\mathrm{mem}}^{(b)} = \kappa_b \mathcal{L}_b(t),}$$

where:

- $\tau_b$is the binary memory timescale,
- $\kappa_b$is the compact-binary latency-response coefficient.

The resulting timing residual is then

$$\boxed{R_{\mathrm{mem}}(t) = \mathcal{C}_b \int^{t} \chi_{\mathrm{mem}}^{(b)}(t')\, dt',}$$

with $\mathcal{C}_b$ a conversion coefficient from branch latency to accumulated timing phase.

This is the second exact target of the pulsar sector. FCLET predicts not only a shift in $\dot{P}_b$, but a nontrivial long-baseline timing residual whose structure is history-dependent rather than purely white-noise-like or purely tensor-template-like.

The most important operational consequence is that the residual should display one or more of the following:

1. **secular drift not absorbed by standard tensor decay alone**,
2. **phase-lagged response to slowly varying orbital burden**,
3. **persistent low-frequency timing structure correlated with orbital-state history**,
4. **branch-consistent residual evolution across long timing baselines**.

This makes pulsars particularly valuable because their timing residuals can be decomposed spectrally and compared against both deterministic and stochastic branch models. A simple extra white-noise interpretation is not enough if FCLET is correct. The residual should carry branch structure.

The benchmark families may be stated as drift windows.

Conservative drift window

$$|\, R_{\mathrm{mem}}(t)\,| \sim 10^{-8} - 10^{-7}\ \mathrm{s}$$

across the full timing baseline of a clean relativistic pulsar. This is close to the edge of detectability in many systems and corresponds to a heavily screened memory branch.

Fiducial drift window

$$|\, R_{\mathrm{mem}}(t)\,| \sim 10^{-7} - 10^{-6}\ \mathrm{s}.$$

This is the central FCLET corridor for long-baseline timing memory.

Aggressive drift window

$$|\, R_{\mathrm{mem}}(t)\,| \sim 10^{-6} - 10^{-5}\ \mathrm{s}.$$

This branch is observationally risky and should be ruled out rapidly if absent in the cleanest systems.

The exact message is therefore:
the pulsar sector tests both branch amplitude and branch structure.
A theory that predicts scalar-latency radiation but no structured memory residual is incomplete. A theory that predicts timing memory but cannot survive $\dot{P}_b$constraints is equally incomplete. FCLET is tested by both simultaneously.

4.3 Benchmark Pulsar Systems and Measurable Ranges

Not every pulsar system has equal diagnostic value. The FCLET timing branch is strongest in binaries that combine:

- long, stable timing baselines,
- relativistic orbital structure,
- clean environmental corrections,
- and high sensitivity to secular decay.

The ideal benchmark systems therefore include:

- compact double neutron-star binaries,
- relativistic neutron-star–white-dwarf systems,
- and other binaries in which standard quadrupolar timing has already been measured precisely enough that small residual sectors matter.

The observational comparison strategy is exact.

First benchmark class: relativistic double neutron-star systems

These systems probe the tensor baseline and the scalar-latency correction most cleanly because their orbital compactness and timing precision are both high. They are ideal for testing the leading secular deviation

$$\Delta\dot{P}_b = \dot{P}_b^{\mathrm{obs}} - \dot{P}_b^{\mathrm{GR}}.$$

Second benchmark class: asymmetric binaries

Systems with strong asymmetry in component structure can be especially useful for scalar descendants because asymmetry often amplifies sensitivity to non-GR channels. In FCLET language, such systems probe whether the substrate burden and response law depend only on total compactness or also on branch asymmetry in a way visible to timing.

Third benchmark class: long-baseline low-noise systems

These are the best probes of the hysteretic residual branch, because the signal of interest is not only instantaneous orbital decay but accumulated timing history over many years.

The benchmark comparison must then be organized into measurable ranges:

- fractional $\dot{P}_b$ deviation,
- cumulative timing residual amplitude,
- spectral content of low-frequency timing structure,
- cross-correlation with orbital-state evolution.

The cleanest protocol is therefore:

1. fit the standard GR timing model,
2. remove known kinematic/environmental effects,
3. compute residual $\Delta\dot{P}_b$,
4. inspect long-timescale $R(t)$ for memory-branch structure,
5. compare with FCLET benchmark families.

This is exactly the branch-aware timing protocol the theory requires. Binary pulsars are not one more generic test among many. They are the astrophysical equivalent of precision clocks with strong self-gravity built in. That is why they occupy such a central place in the master blueprint.

4.4 Binary Timing Falsification Criteria

The pulsar sector now permits a direct exclusion logic. A mature protocol paper must say exactly what kind of null result kills which branch.

Null Test 1: No residual $\dot{P}_b$ beyond the GR tensor channel

If repeated high-precision timing in clean benchmark systems yields

$$\Delta\dot{P}_b = \dot{P}_b^{\mathrm{obs}} - \dot{P}_b^{\mathrm{GR}} \approx 0$$

to a level that excludes the aggressive and fiducial FCLET timing families, then the scalar-latency radiation branch is severely narrowed. If only the conservative screened window survives, the branch remains alive but highly compressed.

Null Test 2: No low-frequency hysteretic timing residual

If, after standard timing-model subtraction and known noise treatment, no branch-consistent secular or lagged residual structure remains in

$$R(t),$$

then the binary memory branch is forced toward either:

- very small κ_b,
- very short τ_b,
- or strong screening.

Repeated null results across multiple system classes compress the timing-memory corridor strongly.

Null Test 3: Cross-sector inconsistency

If compact-binary timing requires an effectively vanishing memory and scalar branch while laboratory clocks, strong-field echoes, or stochastic sectors demand an unscreened latency-response coefficient in the same global corridor, then the problem ceases to be local. The parameter genealogy of the program is threatened. This is no longer branch pressure alone; it becomes corridor-level compression or even kernel pressure.

Null Test 4: Wrong sign or wrong scaling

A detected residual is not automatically support for FCLET. If the measured deviation has the wrong sign, wrong eccentricity dependence, wrong mass scaling, or wrong secular structure relative to the finite-capacity timing branch, then the corresponding descendant law fails even if "some anomaly" exists. The theory is not protected by anomaly-hunting. It must match the branch structure it itself predicts.

The classification logic is therefore exact.

Branch-level exclusion

A null or mismatched result eliminating only one timing descendant while leaving other timing or strong-field branches intact.

Corridor-level exclusion

A result eliminating both scalar-radiation and hysteretic-memory timing sectors across the fiducial corridor.

Core-kernel pressure

A result that destroys timing descendants in a way that cannot be reconciled with the same canonical latency architecture required elsewhere in the program.

This is the correct falsification discipline of the compact-binary sector. The theory does not merely ask observers to "look at pulsars." It tells them exactly what to test:

- the secular orbital decay residual,
- the low-frequency timing-memory branch,
- the sign and scaling structure,
- and the cross-sector consistency of the surviving corridor.

The next section moves from orbital timing to strong gravity itself and organizes the compact-object imaging and horizon-scale signatures of the finite-capacity saturation-shell branch.

5. Strong-Field and Horizon-Scale Signatures

5.1 Saturation-Shell Observables for Compact Objects

The strong-field branch of FCLET predicts that sufficiently burdened gravitational collapse does not terminate in a featureless classical horizon. It terminates in a saturation-supported finite-capacity structure: the saturation shell. This is not a metaphorical reinterpretation. It is a dynamical claim of the theory's compact-object and numerical-relativity sectors. The master blueprint must therefore translate that claim into instrument-facing observables.

The first observational task is to identify the branch quantities that distinguish a saturation-shell object from a classical black hole. The relevant strong-field observables are not limited to global mass and spin. They include shell-support structure, near-boundary latency burden, shell thickness, and finite-capacity deviations in late-time response. In the strong-field branch, the compact object is characterized not only by

$$M, J,$$

but also by shell variables such as

$$r_s, \Delta r_s, \chi_{\max}, \Xi_{\max},$$

where:

- r_s is the shell location,
- Δr_s is the effective shell thickness,
- $\chi_{\max}$ is the peak latency burden,
- $\Xi_{\max}$ is the peak overwrite or shell-support burden.

These are not directly image-plane observables by themselves, but they determine the deviations that telescopes and waveform pipelines must seek. The saturation-shell branch predicts that the near-boundary region is not a null surface with perfectly classical absorption

properties. It is a finite-thickness strong-field layer with delayed response, finite-capacity support, and partial reflectivity or branch-dependent reprocessing of infalling and perturbative structure.

This leads to the first exact protocol statement of the strong-field sector:

compact-object observables in FCLET depend on shell structure, not on a classical horizon boundary alone.

The practical consequence is that every horizon-scale observable must be read through two competing templates:

1. the classical horizon template,
2. the saturation-shell template.

The difference between them is the measurement target of the strong-field branch.

For benchmark organization, the shell-support branch may be divided into three observational families.

Conservative strong-field family

The shell lies extremely close to the classical horizon scale, and deviations are subtle. Imaging and late-time response differ only weakly from GR. This family is difficult to exclude quickly but scientifically valuable because it tests whether FCLET can remain nearly indistinguishable from classical strong gravity in the most screened corridor.

Fiducial strong-field family

The shell remains near the classical horizon scale but generates measurable ringdown deformation, mild image-shape or brightness-profile differences, and finite-latency boundary response. This is the central corridor of the strong-field program.

Aggressive strong-field family

The shell-support branch produces large reflectivity, stronger ringdown departure, more visible horizon-scale anomalies, and clearer imaging signatures. This family is experimentally easy to pressure and therefore useful for rapid exclusion of overstrong descendants.

The purpose of the present section is to organize the observables through which these families are tested.

5.2 EHT Shadow Anomalies and Shell-Support Deviations

The Event Horizon Telescope and related horizon-scale imaging programs probe the near-boundary geometry and radiative transfer structure of compact objects at an unprecedented level. In the FCLET strong-field branch, these observations are not interpreted as direct images of a classical event horizon. They are interpreted as images of a near-shell radiative environment shaped by finite-capacity boundary structure.

The observable target is therefore not simply the existence of a shadow-like feature. Classical GR already predicts that. The target is the detailed deviation of the shadow and surrounding emission profile from the classical horizon template.

Let the standard GR reference shadow radius be

$$R_{\mathrm{sh}}^{\mathrm{GR}}(M, a, \iota),$$

where $M$is mass, $a$is spin, and $\iota$is inclination. The finite-capacity branch predicts an effective observed radius

$$R_{\mathrm{sh}}^{\mathrm{FCLET}} = R_{\mathrm{sh}}^{\mathrm{GR}} + \Delta R_{\mathrm{sh}}^{(s)},$$

where $\Delta R_{\mathrm{sh}}^{(s)}$is the saturation-shell correction. Similarly, the brightness depression profile, photon-ring contrast, and near-boundary emissivity acquire branch-dependent corrections:

$$I_{\mathrm{obs}}^{\mathrm{FCLET}}(\alpha, \beta) = I_{\mathrm{GR}}(\alpha, \beta) + \Delta I_s(\alpha, \beta).$$

The strong-field imaging problem is therefore not one observable but a set of linked image-plane diagnostics:

- shadow size shift,
- shadow circularity or noncircularity departure,
- photon-ring brightness modification,
- central brightness depression depth,
- near-ring asymmetry pattern.

The finite-capacity logic of these deviations is exact. A classical horizon acts as a purely one-way boundary. A saturation shell does not. It is a finite-thickness burdened region with nontrivial boundary response. That changes how radiation is absorbed, delayed, reprocessed, or partially reflected in the immediate strong-field environment.

This means the EHT-facing benchmark observables should be organized as:

$$\boxed{\delta_{\mathrm{sh}} \equiv \frac{R_{\mathrm{sh}}^{\mathrm{FCLET}} - R_{\mathrm{sh}}^{\mathrm{GR}}}{R_{\mathrm{sh}}^{\mathrm{GR}}},}$$

$$\boxed{\delta_{\mathrm{ring}} \equiv \frac{I_{\mathrm{ring}}^{\mathrm{FCLET}} - I_{\mathrm{ring}}^{\mathrm{GR}}}{I_{\mathrm{ring}}^{\mathrm{GR}}},}$$

$$\boxed{\delta_{\mathrm{dep}} \equiv \frac{D_{\mathrm{dep}}^{\mathrm{FCLET}} - D_{\mathrm{dep}}^{\mathrm{GR}}}{D_{\mathrm{dep}}^{\mathrm{GR}}},}$$

where:

- δ_{sh}tracks shadow-size deviation,
- δ_{ring}tracks photon-ring brightness deviation,
- δ_{dep}tracks central depression deviation.

The observational protocol is then simple:

1. infer mass, spin, and viewing geometry from the best available multimessenger or imaging fit,
2. construct the GR baseline image family,
3. construct the FCLET shell-supported image family,
4. compare residuals in size, morphology, and ring/depression structure.

The exact benchmark philosophy remains the same as in earlier sectors.

Conservative imaging branch

$$|\delta_{\mathrm{sh}}|, |\delta_{\mathrm{ring}}|, |\delta_{\mathrm{dep}}| \lesssim 10^{-2}.$$

Fiducial imaging branch

$$|\delta_{\mathrm{sh}}|, |\delta_{\mathrm{ring}}|, |\delta_{\mathrm{dep}}| \sim 10^{-2} - 10^{-1}.$$

Aggressive imaging branch

$$|\delta_{\mathrm{sh}}|, |\delta_{\mathrm{ring}}|, |\delta_{\mathrm{dep}}| \gtrsim 10^{-1}.$$

A theory branch predicting aggressive horizon-scale anomalies that fail to appear under increasingly precise imaging constraints dies quickly. A conservative branch may survive much longer. The important point is that the theory states this openly rather than retreating into qualitative language.

5.3 Collapse and Merger Signatures in the Strong-Field Branch

Strong-field observables are not limited to static or quasi-static images. The FCLET compact-object program is dynamical. Its 3+1 numerical-relativity branch predicts that collapse and merger do not evolve toward a featureless horizon endpoint, but toward shell formation, shell interaction, and shell-supported late-time response. The master blueprint must therefore identify the corresponding strong-field observables.

The first such observable is the shell-formation threshold itself. In the numerical branch, shell formation occurs when the local strong-field burden enters the simultaneous regime

$$\chi \geq \chi_{\mathrm{sat}}, \Xi \geq \Xi_{\mathrm{sat}},$$

together with a steep shell-localized gradient profile. This implies that collapse outcomes can be classified into:

- sub-saturation compact objects,
- saturation-adjacent shell objects,
- merger remnants with oscillatory or settling shell structure.

The dynamical observables are then:

- shell formation time,
- shell stabilization or oscillation timescale,
- post-merger shell settling profile,
- branch-dependent late-time response amplitude.

These may be represented schematically as

$$t_{\mathrm{shell}}, \tau_{\mathrm{osc}}, \mathcal{A}_{\mathrm{late}}, \omega_{\mathrm{shell}}.$$

They matter observationally because they feed directly into gravitational-wave and imaging sectors. A classical horizon swallows perturbation with no shell support signature. A saturation shell does not. It carries a real dynamical memory of the collapse or merger history.

This means that the observational program must distinguish between:

1. static branch diagnostics, such as shadow or ring structure;
2. dynamical branch diagnostics, such as post-merger oscillatory and delayed-response behavior.

This distinction is crucial. A compact object might look nearly classical in a static snapshot while still revealing a finite-capacity shell in its dynamical response. That is why strong-field FCLET cannot be tested by imaging alone.

The branch-aware protocol for collapse and merger is therefore:

- use numerical-relativity FCLET templates to extract shell-formation observables,
- compare those observables against GR remnant-settlement expectations,
- identify whether the remnant behaves as a pure horizon absorber or as a shell-supported strong-field object.

This is the exact measurement logic that connects the numerical branch to the observational blueprint.

5.4 Imaging-Based Exclusion Windows

The strong-field imaging sector now permits a direct exclusion logic. The theory must state exactly what image-plane outcomes narrow or exclude which branch.

Null Test 1: No horizon-scale deviation beyond GR template uncertainties

If shadow size, circularity, and near-ring structure remain consistent with GR across improving image resolution and modelling pipelines, then the aggressive imaging branch of FCLET is excluded first. If the fiducial corridor also predicts deviations larger than the observational error budget and those deviations remain absent, the corridor is sharply compressed.

Null Test 2: No shell-supported radiative reprocessing signature

If image-domain reconstructions and radiative-transfer modelling show no stable indication of shell-induced brightness redistribution, delayed boundary response, or nonclassical near-boundary emissivity, then strongly reflective or strongly reprocessing shell branches are ruled out.

Null Test 3: Incompatible multimessenger cross-fit

If a branch of FCLET requires a shadow deformation or ring enhancement that is incompatible with the same mass–spin–inclination parameters required by gravitational-wave or timing sectors, then the branch fails by cross-sector inconsistency even if one imaging feature alone appears suggestive.

Null Test 4: Wrong sign or morphology of deviation

A deviation from GR is not enough. If the observed image anomaly has the wrong sign, wrong radial structure, or wrong azimuthal morphology relative to the FCLET shell template, then the corresponding imaging descendant fails. The theory is not protected by generic "non-GR-looking" behavior. It must match its own branch structure.

The exclusion levels follow the now-familiar hierarchy.

Branch-level exclusion

An imaging null result that kills only an aggressive shell-reprocessing or large-deformation descendant.

Corridor-level exclusion

A multi-observable imaging result that eliminates both aggressive and fiducial shell-imaging families.

Core pressure

A result showing that compact objects behave as pure classical absorbers in a way irreconcilable with the same strong-field finite-capacity architecture required by waveform, collapse, and compact-object sectors elsewhere in the canon.

This is the exact imaging discipline of the strong-field branch. FCLET does not merely suggest that "compact objects may differ." It specifies the observable families, the benchmark sizes of deviation, and the exclusion logic.

The next section takes the strongest dynamical extension of this same branch and organizes the gravitational-wave tests of ringdown deformation and saturation-shell echoes across present and future detector classes.

6. Gravitational-Wave Signatures in LIGO, Virgo, KAGRA, and LISA

6.1 Ringdown Modification from Saturation-Shell Structure

The gravitational-wave sector is one of the most decisive observational arenas of the finite-capacity program because it probes the post-merger strong-field boundary directly. In classical general relativity, the remnant ringdown is governed by quasinormal modes of a horizon-bearing geometry. In the FCLET strong-field branch, that endpoint is replaced by a saturation-shell object. The post-merger spectrum is therefore not the spectrum of a featureless absorber. It is the spectrum of a shell-supported compact remnant with finite-capacity boundary response.

The observational target is immediate. The dominant ringdown mode of the remnant is no longer exactly

$$\omega_{220}^{\mathrm{GR}},$$

but becomes

$$\boxed{\omega_{220}^{\mathrm{FCLET}} = \omega_{220}^{\mathrm{GR}} + \Delta\omega_{220}^{(s)},}$$

with corresponding damping time

$$\boxed{\tau_{220}^{\mathrm{FCLET}} = \tau_{220}^{\mathrm{GR}} + \Delta\tau_{220}^{(s)}.}$$

The shell correction terms

$$\Delta\omega_{220}^{(s)}, \Delta\tau_{220}^{(s)}$$

are controlled by the saturation-shell variables:

- shell radius r_s,
- shell thickness Δr_s,
- shell support burden $\Xi_{\max}$,
- near-shell latency $\chi_{\max}$.

At the waveform level, the dominant post-merger strain may therefore be written as

$$\boxed{h_{\mathrm{RD}}(t) = A_{220}\, e^{-t/\tau_{220}^{\mathrm{FCLET}}} \cos\left(\omega_{220}^{\mathrm{FCLET}} t + \phi_{220}\right) + \cdots ,}$$

where the ellipsis includes subdominant modes and, when present, later shell-reflection structure.

The physical meaning is exact. A classical horizon acts as a one-way dissipative boundary. A saturation shell does not. It can delay, store, partially reflect, and reprocess perturbative flux. The first and cleanest gravitational-wave signature of that fact is ringdown deformation:

- shifted mode frequencies,
- shifted damping times,
- altered overtone content,
- and branch-dependent late-time residual structure.

The most practical waveform diagnostics are therefore the fractional mode deviations

$$\boxed{\delta\omega_{220} \equiv \frac{\omega_{220}^{\mathrm{FCLET}} - \omega_{220}^{\mathrm{GR}}}{\omega_{220}^{\mathrm{GR}}},} \qquad \boxed{\delta\tau_{220} \equiv \frac{\tau_{220}^{\mathrm{FCLET}} - \tau_{220}^{\mathrm{GR}}}{\tau_{220}^{\mathrm{GR}}}.}$$

These define the first ringdown benchmark windows.

Conservative ringdown branch

$$|\,\delta\omega_{220}\,|\,,\ |\,\delta\tau_{220}\,| \lesssim 10^{-3} - 10^{-2}.$$

Fiducial ringdown branch

$$|\,\delta\omega_{220}\,|\,,\ |\,\delta\tau_{220}\,| \sim 10^{-2} - 10^{-1}.$$

Aggressive ringdown branch

$$|\,\delta\omega_{220}\,|\,,\ |\,\delta\tau_{220}\,| \gtrsim 10^{-1}.$$

The interpretation is straightforward. If high-SNR post-merger spectroscopy continues to return purely GR-like mode frequencies and damping times, aggressive shell branches die first, then fiducial branches are compressed, and only highly screened strong-field descendants remain viable. If stable ringdown shifts appear with the right sign and mass–spin scaling, the finite-capacity shell branch gains direct support.

6.2 Echo Delay Times and Frequency Spacing

The second and more distinctive gravitational-wave signature of the strong-field branch is the appearance of delayed post-ringdown echoes. These do not arise because the theory inserts arbitrary reflectivity by hand. They arise because a saturation shell is not a perfect null absorber. Perturbative flux can be partially reprocessed between the shell and the exterior curvature barrier, generating late-time delayed pulses.

Let the shell lie at radius

$$r_s = r_H(1+\epsilon_s), 0 < \epsilon_s \ll 1,$$

where r_H is the classical horizon-scale radius associated with the remnant mass and spin, and ϵ_s measures the shell offset from the classical horizon scale. Then the leading echo delay time is controlled by the effective cavity travel time between the shell and the exterior barrier.

At branch level, the delay may be written as

$$\boxed{\Delta t_{\text{echo}} = 2\int_{r_s}^{r_{\text{peak}}} \frac{dr}{v_{\text{eff}}(r)},}$$

where r_{peak} is the effective peak of the exterior barrier and $v_{\text{eff}}(r)$ is the branch-dependent propagation speed of the perturbation in the strong-field background. In the near-horizon logarithmic approximation, this reduces to the universal strong-field form

$$\boxed{\Delta t_{\text{echo}} \approx \alpha_M\, M \ln\left(\frac{1}{\epsilon_s}\right) + \beta_s\, M,}$$

where:

- M is the remnant mass,
- α_M is an order-unity geometry coefficient,
- β_s encodes shell-thickness and branch-structure corrections.

This formula is decisive. Echoes are not random late-time wiggles. Their delay is a calculable logarithmic function of shell compactness. The more closely the shell approaches the classical horizon scale, the longer the delay.

The corresponding approximate echo frequency spacing is

$$\boxed{\Delta f_{\mathrm{echo}} \sim \frac{1}{\Delta t_{\mathrm{echo}}}.}$$

This gives the direct observable pair of the shell-reflection branch:

- a characteristic delay time,
- and a characteristic late-time spacing scale.

The strain contribution of the echo train may then be written schematically as

$$\boxed{h_{\mathrm{echo}}(t) = \sum_{n=1}^{\infty} A_n \; e^{-(t-n\Delta t_{\mathrm{echo}})/\tau_n} \cos\left[\omega_n (t - n\Delta t_{\mathrm{echo}}) + \phi_n\right] \Theta(t - n\Delta t_{\mathrm{echo}}),}$$

where:

- A_n is the n-th echo amplitude,
- τ_n is the branch-dependent damping time of that echo component,
- ω_n is its dominant frequency content.

The amplitude hierarchy A_n is controlled by shell reflectivity and barrier transmission. The exact branch is therefore constrained by three measurable families:

1. delay,
2. spacing,
3. amplitude decay.

This yields the benchmark windows.

Conservative echo branch

- long delays,
- weak amplitudes,
- rapid amplitude suppression with echo number.

Fiducial echo branch

- measurable delays,
- detectable but subdominant first echoes,
- branch-consistent spacing tied to remnant mass.

Aggressive echo branch

- strong first echo,
- multiple visible late-time pulses,
- large reflectivity or low damping.

The aggressive branch is especially easy to pressure observationally. Repeated absence of such strong post-ringdown structures in high-SNR events kills it quickly. The conservative branch survives longer because the shell can remain extremely close to the classical horizon scale and weakly reflective while still differing physically from a pure absorber.

The exact gravitational-wave message is therefore:
if the FCLET strong-field branch is correct, the post-merger sector is not exhausted by deformed quasinormal modes alone; it also contains a branch-dependent late-time echo structure tied to shell compactness and finite-capacity boundary response.

6.3 Branch-Aware Waveform Windows for Present Detectors

The present detector network—LIGO, Virgo, and KAGRA—already defines a strong selection pressure on the most visible strong-field descendants of the theory. The correct FCLET protocol is therefore not to ask generically whether "waveforms differ." It is to define branch-aware waveform windows that map directly onto current detector sensitivity.

The finite-capacity post-merger signal may be decomposed into three layers:

$$\boxed{h(t) = h_{\mathrm{insp}}(t) + h_{\mathrm{RD}}^{\mathrm{FCLET}}(t) + h_{\mathrm{echo}}(t).}$$

The inspiral branch remains close to GR in the strongly screened corridor except where compact-binary timing descendants are already allowed. The decisive strong-field tests in the current detector era therefore live mainly in:

- post-merger mode shifts,
- late-time ringdown residuals,
- and possible echo trains.

This suggests a detector-facing parameterization in terms of:

$$\delta\omega_{220}, \delta\tau_{220}, \Delta t_{\mathrm{echo}}, \mathcal{R}_{\mathrm{echo}} \equiv \frac{A_1}{A_{220}},$$

where $\mathcal{R}_{\mathrm{echo}}$ is the first-echo amplitude relative to the dominant ringdown mode.

These four quantities define the practical waveform window of the strong-field branch.

Present-detector conservative window

$$|\delta\omega_{220}|, |\delta\tau_{220}| \lesssim 10^{-3} - 10^{-2}, \mathcal{R}_{\rm echo} \ll 10^{-1}.$$

In this branch, only the loudest events or stacked analyses can place serious pressure on the theory.

Present-detector fiducial window

$$|\delta\omega_{220}|, |\delta\tau_{220}| \sim 10^{-2} - 10^{-1}, \mathcal{R}_{\rm echo} \sim 10^{-2} - 10^{-1}.$$

This is the central observational target of current post-merger analyses. It is large enough to matter and small enough to survive current uncertainty ceilings in many events.

Present-detector aggressive window

$$|\delta\omega_{220}|, |\delta\tau_{220}| \gtrsim 10^{-1}, \mathcal{R}_{\rm echo} \gtrsim 10^{-1}.$$

This branch is high-risk. If absent in well-measured ringdown events, it is excluded rapidly.

The exclusion logic for current detectors is therefore exact.

Null Test 1: No branch-consistent ringdown deformation

If high-SNR events show no deviation in dominant post-merger frequencies and damping times beyond GR error budgets, the aggressive ringdown branch dies first. Repeated null results begin to compress the fiducial branch as well.

Null Test 2: No stable echo pattern

If no mass-scaled, delay-consistent, branch-structured late-time pulse family appears across candidate high-SNR post-merger events, then strongly reflective shell descendants are eliminated.

Null Test 3: Wrong sign or wrong scaling

A post-ringdown anomaly is not enough. If a deviation has the wrong mass dependence, wrong echo spacing law, or wrong mode-shift sign relative to the FCLET shell branch, then the corresponding descendant fails even if "some anomaly" is present.

The waveform program must therefore be branch-aware from the start. FCLET does not merely say "look for echoes." It gives:

- mode-shift observables,
- delay observables,
- amplitude-ratio observables,
- and exclusion families.

That is what makes the strong-field waveform sector scientifically usable.

6.4 Space-Based Strong-Field Spectroscopy and Future Reach

The full observational power of the FCLET strong-field branch will not be exhausted by the present ground-based network. Space-based detectors, especially LISA-class observatories, are uniquely positioned to probe heavier systems, longer coherent ringdown phases, and cleaner strong-field spectroscopy windows. The master blueprint must therefore include future reach explicitly.

The importance of LISA-like detectors follows from three exact reasons.

First, larger black-hole or shell-supported remnant masses shift characteristic timescales upward, stretching late-time structures such as echo delays into a cleaner instrumental window.

Second, longer coherent ringdown observation makes mode spectroscopy more precise, especially for subdominant branches that are difficult to resolve in short post-merger ground-based signals.

Third, massive-black-hole mergers probe strong-field compactness in a regime where horizon-scale deviations and shell-support structure may be both more stable and more cleanly separated from detector noise.

The FCLET future-facing waveform observables remain the same in kind:

$$\delta\omega_{lmn}, \delta\tau_{lmn}, \Delta t_{\mathrm{echo}}, \mathcal{R}_{\mathrm{echo}},$$

but the accessible branch window widens because longer delays and weaker echoes become observable in principle.

This means that space-based spectroscopy is not merely “more of the same.” It is the regime where the conservative strong-field branch itself becomes experimentally vulnerable. A shell offset so small that present detectors cannot resolve its effect may still produce a measurable delay or mode shift in a long-lived, high-mass post-merger event observed by a space-based mission.

The future-reach logic can therefore be stated sharply.

Ground-based network

Best suited to:

- stellar-mass remnant mode shifts,
- aggressive or fiducial echo branches,
- near-term exclusion of overstrong shell descendants.

Space-based network

Best suited to:

- massive-remnant spectroscopy,
- conservative shell offsets,
- long-delay echo searches,
- precise multiplet deformation tests.

This directly enlarges the falsification corridor of the theory. A branch that survives current detectors by remaining too compact and too weakly reflective to resolve may still be killed by future space-based spectroscopy if it predicts persistent mass-scaled shell structure.

The strongest future-facing protocol is therefore:

1. infer remnant mass and spin from inspiral/merger modelling,
2. fit the classical GR ringdown multiplet,
3. fit the FCLET shell-deformed multiplet,
4. search for branch-consistent delayed residual structure,
5. assign the result to branch exclusion, corridor compression, or strong-field support.

This is the exact future measurement agenda of the gravitational-wave sector. The finite-capacity program does not postpone its strongest tests indefinitely into abstraction. It states openly which future detector class should probe which remaining branch of the strong-field corridor.

The next section moves from strong-field mergers to cosmology and organizes the observational windows associated with primordial latency fluctuations, low-ℓ suppression, and moderated-erasure background structure.

7. Cosmological Signatures

7.1 Low-ℓ Suppression in the CMB Sector

The cosmological branch of FCLET does not treat the early universe as a perfectly scale-free continuum governed by unconstrained primordial support. It treats it as a high-burden finite-capacity regime in which primordial realization load, latency fluctuations, and moderated-erasure freeze-out shape the large-angle structure of the cosmic microwave background. The cleanest observational consequence of that branch is low-ℓ power suppression.

The observational target is not the entire angular power spectrum at once. The most decisive branch signal lies in the largest angular scales, where the finite-capacity freeze-out sector predicts a reduction of scalar power relative to the simplest unsuppressed baseline. Let the standard reference spectrum be

$$C_\ell^{\mathrm{std}},$$

and the FCLET descendant be

$$C_\ell^{\mathrm{FCLET}} = C_\ell^{\mathrm{std}}\, \mathcal{S}_\ell,$$

where $\mathcal{S}_\ell$is the finite-capacity suppression factor. The defining branch property is

$$\boxed{\mathcal{S}_\ell < 1 \text{for low } \ell, \mathcal{S}_\ell \to 1 \text{for higher } \ell.}$$

This is the exact observational structure demanded by the primordial latency-fluctuation branch. The substrate does not erase the entire primordial spectrum indiscriminately. It suppresses power preferentially in the horizon-scale sector where finite-capacity moderation and freeze-out are strongest.

The detector-facing observable is therefore the low-multipole power ratio

$$\boxed{\mathcal{R}_{\text{low-}\ell} \equiv \frac{\sum_{\ell=\ell_{\min}}^{\ell_{\max}} (2\ell+1)\; C_\ell^{\mathrm{obs}}}{\sum_{\ell=\ell_{\min}}^{\ell_{\max}} (2\ell+1)\; C_\ell^{\mathrm{std}}},}$$

with a typical low-ℓ window chosen to isolate the large-angle sector. FCLET predicts

$$\mathcal{R}_{\text{low-}\ell} < 1$$

in the fiducial primordial branch.

The benchmark families are then straightforward.

Conservative CMB branch

$$1 - \mathcal{R}_{\text{low-}\ell} \sim 1\% - 5\%.$$

Fiducial CMB branch

$$1 - \mathcal{R}_{\text{low-}\ell} \sim 5\% - 15\%.$$

Aggressive CMB branch

$$1 - \mathcal{R}_{\text{low-}\ell} \gtrsim 15\%.$$

The aggressive branch is easy to pressure because large-scale suppression beyond cosmic-variance-compatible windows is difficult to hide. The conservative branch survives longer because low-ℓ measurements are intrinsically cosmic-variance limited. The fiducial branch is therefore the real cosmological battleground of the theory.

The exact protocol is:

1. adopt the standard best-fit baseline spectrum,
2. construct the FCLET low-ℓ suppression template,
3. fit the suppression amplitude and turnover scale,
4. classify the result as support, corridor narrowing, or branch exclusion.

The strong point of the branch is that it predicts a **specific direction of departure**: suppressed low-ℓ power, not arbitrary large-angle distortion.

7.2 Primordial-Latency Fluctuation Benchmarks

The low-ℓ sector is only one face of the cosmological branch. The deeper observable structure lies in the primordial latency fluctuations themselves. In FCLET, primordial scalar structure is not sourced by an ad hoc inflaton field in a fully unconstrained continuum background. It is sourced by stochastic burden irregularities of a finite-capacity early-universe substrate. The relevant primordial variable is the latency fluctuation field

$$\delta\chi(\mathbf{x}),$$

with primordial spectrum

$$P_\chi(k).$$

The CMB-facing transfer law then maps this substrate fluctuation spectrum into observable anisotropy multipoles. The benchmark quantities are:

- overall scalar amplitude,
- spectral tilt or effective running,
- large-scale suppression turnover,
- and coherence scale of the primordial burden field.

The most useful observational protocol is not to ask whether FCLET predicts a wholly exotic CMB sky. It does not need to. It asks whether the observed primordial sector can be fit by a latency-fluctuation spectrum with a finite-capacity turnover scale k_χ. A generic benchmark form is

$$\boxed{P_\chi(k) = A_\chi \left(\frac{k}{k_*}\right)^{n_\chi - 1} \mathcal{T}_\chi(k; k_\chi),}$$

where:

- A_χ is the primordial latency amplitude,
- n_χ is the effective tilt,
- $\mathcal{T}_\chi$ is the finite-capacity transfer factor,
- k_χ is the turnover scale below which suppression becomes significant.

The key branch prediction is

$$\boxed{\mathcal{T}_\chi(k;k_\chi) \to 1 \text{for } k \gg k_\chi, \mathcal{T}_\chi(k;k_\chi) < 1 \text{for } k \lesssim k_\chi.}$$

This means the theory is not trying to replace the entire measured primordial spectrum with a radically different object. It predicts a controlled large-scale deformation of an otherwise viable scalar sector. That is the correct regime-aware cosmological behavior.

The benchmark cosmological observables are therefore:

1. low-k primordial suppression scale,
2. amplitude of the primordial latency branch,
3. compatibility with observed near-scale-invariant intermediate-k structure,
4. absence of uncontrolled excess running or oscillation unless a more specific branch demands it.

The exclusion logic is equally clear. If future CMB and large-scale-structure analyses show no evidence whatsoever for an admissible turnover window while also constraining the allowed branch amplitude below the fiducial corridor, then the primordial finite-capacity branch is forced into a heavily screened corner. If, on the contrary, a stable large-scale suppression with the correct transfer structure survives improving inference, the cosmological FCLET branch gains direct support.

The exact strength of this sector lies in the fact that it does not ask observers to search blindly for "anything unusual." It gives them a benchmark structure:

- a suppressed large-scale branch,
- a recovery to ordinary structure at smaller scales,
- and a finite-capacity turnover parameter that can be fitted or excluded.

7.3 Background-Expansion and Moderated-Erasure Windows

The cosmological branch of FCLET also predicts that the large-scale background expansion history is not governed by a perfectly passive vacuum component. It is governed by

moderated-erasure dynamics on a finite-capacity substrate. The observational target is therefore not only the perturbation sector but also the background history itself.

Let the standard expansion law be written in terms of the Hubble parameter

$$H_{\mathrm{std}}(z),$$

and the finite-capacity descendant by

$$H_{\mathrm{FCLET}}(z) = H_{\mathrm{std}}(z) + \Delta H_{\chi}(z).$$

The quantity $\Delta H_{\chi}(z)$is not arbitrary. In the moderated-erasure branch, it must satisfy three exact requirements:

1. negligible distortion of early-time recovery where standard thermal history is tightly constrained,
2. controlled late-time deviation in the redshift window where dark-energy-like behavior becomes relevant,
3. cross-consistency with the same finite-capacity parameters that appear in other cosmological descendants.

This means the detector-facing background observables are:

- the Hubble history $H(z)$,
- distance measures $D_L(z)$and $D_A(z)$,
- and any effective-equation-of-state reconstruction of the late-time branch.

The benchmark parameterization is best expressed in differential form:

$$\boxed{\delta_H(z) \equiv \frac{H_{\mathrm{FCLET}}(z) - H_{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)}.}$$

The theory does not require large deviations across all redshifts. It requires a late-time moderated branch that is small enough to preserve broad background success and large enough to replace a purely passive dark-energy interpretation with a substrate-driven one.

The benchmark families are therefore:

Conservative background branch

$$|\,\delta_H(z)\,| \lesssim 0.5\% - 1\%$$

across the critical late-time window.

Fiducial background branch

$$|\,\delta_H(z)\,| \sim 1\% - 5\%.$$

Aggressive background branch

$$|\,\delta_H(z)\,| \gtrsim 5\%.$$

The observational protocol then combines:

- supernova distance ladders,
- baryon-acoustic-oscillation distances,
- cosmic chronometer measurements,
- and any external background probes used in the broader cosmological inference pipeline.

The critical point is that the theory's background branch must be read together with the perturbation branch. A background history that works while its perturbation sector fails is not sufficient. Likewise, a low-ℓ suppression branch that works while the late-time background becomes grossly inconsistent is not sufficient. That is why this section belongs inside the master blueprint rather than in an isolated cosmology paper.

The moderated-erasure window is therefore a cross-sector cosmological test:

- it must reproduce viable late-time expansion,
- it must coexist with primordial suppression,
- and it must remain inside the broader empirical corridor of the program.

7.4 Structure-Growth and Survey-Based Exclusion Criteria

A cosmological theory is not disciplined by background history and the CMB alone. It must also survive structure growth. The finite-capacity program already recognized this in its perturbation-consistency and survival-corridor branches. The master blueprint now turns that recognition into an explicit exclusion matrix.

Let the standard linear growth factor be

$$D_{\mathrm{std}}(z),$$

and the finite-capacity descendant be

$$D_{\mathrm{FCLET}}(z) = D_{\mathrm{std}}(z) + \Delta D_{\chi}(z).$$

Similarly, for growth-rate observables one may write

$$f\sigma_8^{\mathrm{FCLET}}(z) = f\sigma_8^{\mathrm{std}}(z) + \Delta(f\sigma_8)_{\chi}(z).$$

The observational question is exact: does the same finite-capacity branch that modifies low-ℓ power and late-time expansion also leave a structure-growth imprint compatible with survey data?

This sector is powerful because it can exclude models that look acceptable in one cosmological subwindow while quietly failing in another. The growth observables therefore serve as the bridge between primordial suppression, background moderation, and present-epoch large-scale structure.

The benchmark exclusion logic is:

Branch-compatible growth sector

The finite-capacity corrections remain within a corridor that preserves overall structure-growth consistency while still permitting the low-ℓ and background signatures required elsewhere.

Corridor-compressed growth sector

Survey data force the allowed growth deviation so low that only the most weakly active cosmological branches remain viable.

Branch-killing growth sector

The data exclude the same primordial or background benchmark family that appeared attractive elsewhere, thereby killing that descendant branch by cross-sector inconsistency.

The precise survey-facing observables include:

- $f\sigma_8(z)$measurements,
- lensing amplitude consistency,
- large-scale power-spectrum shape,
- and joint CMB–BAO–growth inference windows.

The strongest cosmological exclusion criterion may therefore be stated in one line:

$$("Any\ FCLET\ cosmological\ branch\ must\ fit\ the\ CMB\ large-angle\ sector, late-time\ background\ history, and\ structure - growth\ sector\ simultaneously.")$$

That is the exact cosmological falsification rule. A branch that succeeds only in one of these three domains is not viable.

This completes the cosmological section of the blueprint. FCLET does not merely predict "some cosmological anomaly." It specifies:

- low-ℓ suppression,
- primordial turnover structure,
- moderated late-time expansion,
- and cross-consistent structure-growth windows.

The next section turns to galactic and dark-sector phenomenology and organizes the rotation-curve, baryonic-scaling, and dark-matter-mimicry tests of the finite-capacity galactic branch.

8. Galactic and Dark-Sector Phenomenology

8.1 Rotation-Curve Tests of Latency-Gradient Gravity

The galactic branch of FCLET is one of the clearest observational interfaces of the entire program because it translates the finite-capacity substrate law into a directly measurable orbital-support relation. The relevant prediction is not generic "modified gravity." It is a specific baryon-sourced acceleration law:

$$\boxed{a_{\mathrm{eff}}(r) = a_N(r) + \sqrt{a_\chi\, a_N(r)},}$$

with

$$a_N(r) = \frac{GM_b(<r)}{r^2}.$$

This law yields the circular-speed profile

$$\boxed{v_c^2(r) = \frac{GM_b(<r)}{r} + \sqrt{Ga_\chi M_b(<r).}}$$

The observational target is therefore exact. Disk-galaxy rotation curves must be tested not against free halo families first, but against the latency-gradient prediction constructed directly from the observed baryonic profile $M_b(<r)$.

The measurement protocol is straightforward:

1. infer the stellar and gas surface-density profile;
2. construct the enclosed baryonic mass function $M_b(< r)$;
3. compute the Newtonian branch $a_N(r)$;
4. apply the FCLET correction $\sqrt{a_\chi a_N(r)}$;
5. compare the resulting $v_c(r)$with the observed rotation curve.

This is the most important practical difference between the finite-capacity galactic branch and ordinary halo modelling. FCLET does not begin with an invisible halo profile and then fit the baryons around it. It begins with the baryons and derives the missing support from the substrate response of those baryons themselves.

The key benchmark windows are profile-based rather than single-number based.

Conservative galactic branch

The onset scale $a_\chi$is low enough that the correction activates only deep in the outer disk. Inner and intermediate radii remain almost entirely baryon-Newtonian. This branch is the hardest to exclude quickly and corresponds to a highly screened dark-matter-mimicry sector.

Fiducial galactic branch

The onset scale activates near the observed low-acceleration transition window of disk galaxies. Rotation curves begin to deviate from Newtonian expectations where baryonic support weakens, and the outer disk approaches a clear latency-supported branch. This is the central observational corridor of the galactic sector.

Aggressive galactic branch

The correction turns on too early or too strongly, distorting inner and mid-disk structure and oversupporting the outer profile. This branch is observationally vulnerable and should be excluded rapidly if absent.

The test is therefore not “does the theory flatten curves somehow?” The test is:

- does it preserve baryon-dominated inner structure,
- does it turn on in the observed low-acceleration regime,
- and does it produce the right outer asymptotics from the baryons alone?

That is the exact experimental logic of the rotation-curve branch.

8.2 Baryonic Tully–Fisher and Radial-Acceleration Benchmarks

The most decisive global scaling test of the galactic branch is the baryonic Tully–Fisher relation. FCLET predicts the exact asymptotic law

$$\boxed{v_f^4 = G a_\chi M_b,}$$

where:

- v_f is the asymptotic flat circular speed,
- M_b is the total visible baryonic mass,
- a_χ is the finite-capacity galactic onset scale.

This relation is not phenomenological decoration. It is the direct asymptotic consequence of baryon-sourced latency-gradient gravity. The benchmark question is therefore exact: does one universal onset scale a_χ organize the asymptotic velocity–mass scaling of viable disk galaxies?

The corresponding protocol is:

1. measure the outer flat velocity v_f,
2. infer the total baryonic mass M_b,
3. test whether the population obeys

$$M_b = \frac{v_f^4}{G a_\chi}$$

with one admissible onset scale or narrow corridor of scales.

This gives the global scaling benchmark families:

Conservative BTFR branch

A very narrow allowed a_χ corridor with minimal tolerated scatter beyond observational and baryonic-inference uncertainty.

Fiducial BTFR branch

A universal or near-universal a_χ that reproduces the observed quartic scaling across the central viable galaxy population.

Aggressive BTFR branch

A branch in which a_χ drifts too strongly from system to system or produces a slope or normalization inconsistent with the observed baryonic scaling. This branch dies quickly.

The same law yields the radial-acceleration benchmark. FCLET predicts

$$\boxed{a_{\text{eff}} = a_N + \sqrt{a_\chi a_N}.}$$

The high-acceleration limit is

$$a_{\text{eff}} \approx a_N (a_N \gg a_\chi),$$

and the low-acceleration limit is

$$a_{\text{eff}} \approx \sqrt{a_\chi a_N} (a_N \ll a_\chi).$$

This makes the radial-acceleration relation one of the cleanest local tests of the theory. The branch prediction is not arbitrary scatter around the baryonic Newtonian law. It is a specific functional departure from that law.

The exact benchmark observables are therefore:

- inner-regime Newtonian recovery,
- transition-region bend,
- low-acceleration square-root branch,
- asymptotic baryonic quartic scaling.

A theory that fits rotation curves but fails BTFR or fails the radial-acceleration relation is not viable. FCLET states this openly. The galactic branch survives only if all three fit together:

1. profile shape,
2. local acceleration relation,
3. global velocity–mass scaling.

That is the galactic equivalent of the cross-sector discipline already enforced in cosmology and strong-field gravity.

8.3 Cluster-Scale Tension Windows

A mature galactic and dark-sector program must also state where its simplest branch may come under pressure. The finite-capacity galactic branch is designed first and foremost for rotationally supported galaxies, especially disk systems in the low-acceleration regime. It is not scientifically strengthened by pretending that every dark-sector arena is already solved at identical level by the same minimal descendant law. The correct protocol paper states the tension windows explicitly.

Galaxy clusters are the most important such window. They probe larger gravitational potentials, more complex baryon distributions, hotter intracluster media, and strong lensing environments that need not be captured in full by the simplest disk-galaxy latency-gradient law. The correct FCLET position is therefore exact: the minimal galactic branch must be tested against cluster phenomenology, and cluster mismatch would not automatically falsify the canonical core in the same way that galaxy failure would.

This means the cluster sector is treated as a **tension window**, not as an automatic victory claim.

The observational targets are:

- dynamical mass discrepancy in cluster potentials,
- lensing-based effective mass excess,
- hot-gas distribution consistency,
- any required extension from pure disk-galaxy latency gradients to cluster-scale collective burden structure.

The benchmark classification is therefore:

Branch-compatible cluster window

The simple galactic branch or its nearest collective descendant can reproduce at least the main dynamical mass-support trends without contradiction.

Tension window

The disk-galaxy branch underpredicts part of the cluster-scale support requirement, indicating that either:

- additional collective-burden descendants are needed,
- or the minimal galactic law is not sufficient outside its primary regime.

Branch-killing window

The cluster data directly contradict the same baryon-locked finite-capacity support logic that succeeds in galaxies, in a way that cannot be repaired without violating the canonical weak-field structure.

This distinction matters enormously. It prevents the protocol paper from overclaiming while still being experimentally sharp. The exact statement is:

$$\square(\text{"}Disk-galaxy\ success\ is\ mandatory\ for\ the\ galactic\ branch.\ Cluster-scale\ consistency\ is\ a\ critical\ extension\ test.\text{"})$$

That is the correct falsification discipline. The theory does not hide the cluster sector. It names it as one of the strongest windows where the minimal dark-matter-mimicry branch must either generalize coherently or accept pressure.

8.4 Dark-Matter-Mimicry Falsification Logic

The galactic branch now permits a full dark-sector falsification structure. This is the most important practical outcome of the section, because FCLET must say exactly what kind of galactic or dark-sector observation kills which branch.

Null Test 1: No baryon-locked outer support

If rotation curves systematically require support that cannot be generated from the observed baryonic profile through

$$a_{\mathrm{eff}} = a_N + \sqrt{a_\chi a_N},$$

even after allowing the conservative and fiducial corridors, then the minimal latency-gradient dark-matter-mimicry branch fails.

Null Test 2: Wrong Tully–Fisher scaling

If the observed asymptotic velocity–mass relation cannot be organized by

$$v_f^4 = G a_\chi M_b$$

with a universal or narrowly corridor-constrained onset scale, then the asymptotic branch of the galactic finite-capacity sector fails.

Null Test 3: Wrong radial-acceleration structure

If the observed local acceleration field does not approach Newtonian recovery at high acceleration and the finite-capacity square-root branch at low acceleration, then the local branch structure fails even if some global scaling looks suggestive.

Null Test 4: Cross-sector inconsistency

If a galactic onset scale $a_\chi$required by rotation curves and BTFR is incompatible with the weak-field, cosmological, or strong-field survival corridor of the rest of the program, then the branch is not viable as part of the unified FCLET canon. It is not enough for a galactic fit to work in isolation.

Null Test 5: Cluster contradiction without admissible extension

If the galactic branch succeeds in disk systems but cannot be extended coherently to cluster-scale dark-sector phenomenology without breaking the canonical backbone, then the minimal dark-matter-mimicry descendant is narrowed or killed as a universal dark-sector replacement.

This exclusion logic is then classified exactly as in the earlier sectors.

Branch-level exclusion

A result that kills only the simplest disk-galaxy latency-gradient descendant while leaving the broader finite-capacity kernel alive.

Corridor-level exclusion

A combined rotation-curve, BTFR, and radial-acceleration dataset that compresses the galactic support branch into a vanishingly narrow or implausible corner.

Core pressure

A result showing that the canonical burden–latency weak-field architecture cannot simultaneously preserve inner Newtonian recovery, outer baryonic support, and cross-sector closure.

That is the exact dark-sector falsification charter of the galactic branch. FCLET does not simply say that dark matter may be mimicked. It says:

- which relation should appear,
- where the onset should occur,
- how the branch scales,
- where the extension to clusters becomes risky,
- and what would count as failure.

This completes the sectoral observational map of the theory. The next section assembles all branches together into one FCLET benchmark matrix and states the cross-sector parameter families that survive or fail as a unified empirical program.

9. The FCLET Benchmark Matrix

9.1 Conservative, Fiducial, and Aggressive Benchmark Families

The finite-capacity program cannot be tested through one rigid numerical guess pretending to cover every sector simultaneously. It must be tested through benchmark families disciplined enough to be falsifiable and flexible enough to represent the actual regime hierarchy of the theory. The benchmark matrix assembled here is therefore not a collection of arbitrary fit windows. It is the empirical image of the program's canonical branch structure.

The three operational families are:

$$\mathcal{B}_{\mathrm{cons}}, \mathcal{B}_{\mathrm{fid}}, \mathcal{B}_{\mathrm{aggr}}.$$

These correspond respectively to the conservative, fiducial, and aggressive branches already introduced sector by sector. Their meaning is exact.

The conservative family is the screened branch of the program. It preserves the standard recovery limits as strongly as possible and allows only the smallest admissible finite-capacity deviations compatible with the canonical architecture. It is the branch hardest to exclude quickly and the easiest to mistake for standard physics in any one isolated sector. But it remains scientifically valuable because it tests whether FCLET can survive as a disciplined, minimally invasive completion rather than as a spectacular but fragile anomaly engine.

The fiducial family is the central empirical corridor of the theory. It is not artificially weakened and not exaggerated. It represents the branch in which the canonical finite-capacity structure becomes visible exactly where the program says it should become visible:

- low-acceleration outer galaxies,
- nonequilibrium timing platforms,
- post-merger strong-field response,
- large-angle cosmological suppression,
- and related sectors already opened elsewhere in the canon.

The aggressive family is the high-visibility edge of the allowed space. It predicts the strongest ringdown distortions, the clearest clock hysteresis, the earliest galactic transition radii, the most obvious echo structures, and the most visible cosmological or timing departures still marginally compatible with the program's kernel. This branch is the fastest to falsify and therefore the most useful for rapid empirical pressure.

The benchmark matrix is not meant to imply that every sector should carry exactly the same strength of deviation. That would violate the regime-aware nature of the program. Rather, each benchmark family defines a coherent cross-sector load–latency corridor. If a family predicts strong galactic effects, negligible laboratory effects, and impossible timing sectors all at once, it is not a coherent benchmark family. It is an inconsistent patchwork. The benchmark matrix exists precisely to prevent that inconsistency.

The correct FCLET benchmark philosophy is therefore:

> a benchmark family is admissible only if its sectoral descendants are mutually consistent.

This is the principle that turns a set of separate papers into one empirical program.

9.2 Cross-Sector Parameter Consistency

The benchmark matrix requires a cross-sector parameter genealogy. The program cannot be tested coherently unless its descendants are tied to common branch scales and common corridor logic. The purpose of this subsection is not to rederive every parameter from first principles again. It is to state how the benchmark matrix organizes them.

At master-blueprint level, the relevant sectoral scales are:

a_χ(galactic onset scale),
τ_{mem}, κ_L, κ_b(laboratory and binary memory scales),
Λ_χ(QFT and finite-proper-time descendant scale),
χ_{sat}, Ξ_{sat}, ϵ_s(strong-field shell and compactness scales),
A_χ, n_χ, k_χ(primordial latency-fluctuation branch),
D_χ, D_{χ_N}(stochastic fluctuation and decoherence strengths).

These quantities are not all equal, but they are not independent in an unrestricted sense either. They descend from one canonical substrate law. That means three exact consistency requirements must hold.

First, **recovery consistency** must hold. A benchmark family that produces visible deviations in one sector cannot destroy the weak-load or low-burden recovery structure in another unless the theory itself predicts that regime coupling. For example, a galactic branch that fixes outer-disk support by forcing strong inner weak-field deviations is not viable. Likewise, a strong-field branch that generates massive echoes while simultaneously demanding negligible shell structure is not viable.

Second, **order-of-magnitude coherence** must hold. A family that predicts laboratory hysteresis at the fiducial level while forcing compact-binary timing entirely into the null branch, with no canonical mechanism for this disparity, is not coherent. Screening and regime hierarchy are allowed. Arbitrary disconnected scales are not.

Third, **branch-sign consistency** must hold. The program often predicts not only a magnitude but a direction:

- low-ℓ suppression rather than enhancement,
- additional outer-disk support rather than extra orbital depletion,
- shell-induced late-time gravitational-wave structure rather than pure absorber behavior,
- nonzero correlation burden without signalling capacity in the entanglement sector.
  A benchmark family that gets the sign wrong is excluded even if it preserves rough magnitudes.

This gives the master consistency law of the benchmark matrix:

$$\Box(\mathcal{B}\_i \text{ " is admissible "} \Rightarrow \text{"all sectoral descendants of " } \mathcal{B}\_i \text{ " obey recovery, magnitude, and sign consistency together."})$$

This law is what prevents the theory from dissolving into independent phenomenological fits. It is also what makes the master blueprint a genuine capstone rather than a catalogue.

9.3 Decisive-Island Logic and Surviving Parameter Corridors

The FCLET program does not need every sector to be equally constraining at every stage. Some sectors are cosmic-variance limited. Some are instrument-limited. Some are already precision-dominant. This is why the empirical life of the theory is best organized through what earlier FCLET work identified as decisive-island logic.

A decisive island is a sectoral domain in which:

1. the theory predicts a clear branch deviation,
2. the relevant instruments are already precise enough or soon will be,
3. the standard baseline is tight enough that a null result has exclusion force.

In the master matrix, the main decisive islands are:

- precision clocks and interferometers for nonequilibrium timing and stochastic phase burden,
- binary pulsars for scalar-latency radiation and timing memory,
- ringdown spectroscopy and echo searches for strong-field shell structure,
- low-ℓ CMB and large-scale cosmology for primordial suppression,
- disk-galaxy rotation and BTFR tests for the galactic latency-gradient branch.

These islands are decisive because they do not merely "inform" the theory. They cut its parameter corridor.

Let the total admissible corridor be denoted

$$\mathcal{C}_{\mathrm{FCLET}}.$$

Each decisive island contributes an exclusion map

$$\mathcal{E}_j,$$

and the surviving corridor after all currently active tests is

$$\boxed{\mathcal{C}_{\mathrm{surv}} = \mathcal{C}_{\mathrm{FCLET}} \setminus \bigcup_j \mathcal{E}_j .}$$

This is the exact master-blueprint meaning of empirical survival. The theory is not protected by breadth. Its breadth generates more decisive islands, not fewer. A program that speaks to clocks, pulsars, galaxies, strong-field waveforms, and cosmology simultaneously is easier to corner if its parameter genealogy is real. FCLET accepts that pressure openly.

This also clarifies why the benchmark matrix uses three named families instead of an undifferentiated continuum alone. At the current stage of the program, the question is not whether every last continuous parameter point has been surveyed. The question is whether the conservative, fiducial, and aggressive islands survive under joint pressure. If the aggressive island dies, the theory narrows. If the fiducial island dies, the program becomes heavily screened. If even the conservative island dies in decisive sectors, the canonical kernel itself is endangered.

The empirical life of the theory is therefore not vague. It is geometric. It is a survival corridor shaped by intersecting exclusion islands.

9.4 Protocol Tables for Experimental Teams

The master blueprint now reaches its most practical form. Every sector can be written into one protocol table format with the same columns:

Observable	Instrument Class	Null Baseline	FCLET Branch Signal	Benchmark Window	Exclusion Meaning

This is the correct operational language for experimental teams. The theory no longer arrives as a diffuse conceptual architecture. It arrives as a measurement instruction set.

At minimum, the protocol matrix contains the following rows.

For clocks:

hysteresis loop area,phase lag,post-cycle relaxation tail.

For interferometers:

controlled phase bias,phase-variance growth law.

For pulsars:

$\Delta\dot{P}_b, R_{\mathrm{mem}}(t)$,sign/scaling of timing residuals.

For strong-field waveforms:

$$\delta\omega_{220}, \delta\tau_{220}, \Delta t_{\mathrm{echo}}, \mathcal{R}_{\mathrm{echo}}.$$

For horizon-scale imaging:

$$\delta_{\mathrm{sh}}, \delta_{\mathrm{ring}}, \delta_{\mathrm{dep}}.$$

For cosmology:

$$\mathcal{R}_{\text{low-}\ell}, k_\chi, \delta_H(z), \Delta(f\sigma_8)_\chi.$$

For galactic dynamics:

$$a_{\text{eff}}(r) - a_N(r), v_f^4/(GM_b),$$rotation-curve profile residuals.

These are not just a list of observables. They are the protocol coordinates of the theory. Every future FCLET data paper should be readable in this table language. That is the final operational standard imposed by the master blueprint.

The next section turns that protocol matrix into the final falsification charter of the program and states exactly what kinds of observational outcomes would kill a branch, collapse a corridor, or falsify the canonical core.

10. The Falsification Matrix

10.1 What Result Rules Out Which Branch

A mature physical framework must distinguish clearly between a failed descendant and a failed theory. The falsification matrix of FCLET is therefore organized around branch attribution. A result is scientifically decisive only if the theory states in advance what structure that result targets.

The first level of the matrix is sector-specific branch exclusion. The rules are exact.

A precision-clock result that repeatedly yields

$$\mathcal{A}_{\text{hyst}} \approx 0$$

and no branch-consistent recovery tail under controlled load modulation rules out the aggressive laboratory memory branch first, then compresses the fiducial branch, and finally pressures the conservative screened branch if the null persists at sufficient sensitivity.

A binary-pulsar result that yields

$$\Delta\dot{P}_b \approx 0$$

and no structured long-baseline timing residual eliminates strong scalar-radiation descendants and large hysteretic timing-memory descendants. It does not immediately kill the canonical core unless the surviving screened corridor becomes incompatible with other sectors.

A gravitational-wave result that shows purely GR-like ringdown across improving spectroscopy and no branch-consistent echo structure eliminates aggressive shell and echo descendants first, then narrows fiducial shell branches.

A cosmological result that excludes low-ℓ suppression beyond the cosmic-variance-compatible conservative branch compresses the primordial finite-capacity sector sharply. A result that simultaneously excludes both low-ℓ suppression and late-time moderated-erasure deviations in the same corridor strikes much deeper.

A galactic result that shows no viable baryon-locked outer support law of the form

$$a_{\mathrm{eff}} = a_N + \sqrt{a_\chi a_N}$$

rules out the minimal latency-gradient dark-matter-mimicry branch.

The first row of the falsification matrix is therefore:

Observation ⟶ Targeted descendant branch

Without this first mapping, falsification talk is empty. With it, the theory becomes testable in the correct structured way.

10.2 Sectoral Failure versus Total-Program Failure

The second level of the matrix distinguishes local sectoral failure from total-program failure. This distinction is not weakness. It is scientific clarity.

A sectoral failure means that one effective descendant has failed in the observational regime where it claimed visibility, while the canonical kernel and other descendants remain mutually consistent. For example:

- a particular echo family may fail while the shell branch survives in a more weakly reflective corridor,
- a laboratory hysteresis branch may fail while stochastic timing and strong-field branches remain viable,
- a simple disk-galaxy latency-gradient law may need extension before cluster-scale interpretation can be claimed.

These are real failures, but they are not total-program deaths. They are branch deaths.

A total-program failure is different. It occurs when the failures are not local, but cross-sectoral and kernel-facing. This happens when the same canonical substrate law is forced into contradiction by multiple decisive islands at once. If clocks require vanishing latency memory, pulsars require vanishing latency memory, cosmology requires visible burden structure, strong-field sectors require shell structure, and the canonical kernel can no longer

assign one coherent substrate law to all of them, then the program is not merely narrowed. It is breaking.

The correct formal distinction is therefore:

$$\boxed{\text{sectoral failure} \neq \text{kernel failure.}}$$

But also:

$$\boxed{\text{repeated cross-sector contradiction} \Longrightarrow \text{kernel failure.}}$$

This is the exact logical backbone of the falsification matrix. It allows the theory to be large without becoming slippery. It says openly:

- which losses are acceptable branch pruning,
- and which losses amount to death of the canonical architecture itself.

A theory of this scale must make that distinction or it is not experimentally honest. FCLET makes it here.

10.3 Hard Exclusion Conditions for the Core Kernel

The master blueprint now reaches the sharpest level of falsification: core-kernel exclusion. These are not soft pressures or aesthetic tensions. These are outcomes that, if stably established, would directly violate the central finite-capacity architecture of the program.

The first hard exclusion condition is **failure of burden-dependent timing structure** across decisive islands. If precision clocks, atom interferometers, and compact-binary timing all converge toward a world in which no measurable or admissible burden-dependent timing, memory, or stochastic latency descendants survive at any meaningful corridor level, then the core proper-time law of FCLET is gravely threatened. A theory built on realized proper time cannot lose every accessible timing descendant and remain unchanged.

The second hard exclusion condition is **failure of cross-regime recovery logic**. If the theory cannot simultaneously preserve:

- weak-field recovery,
- low-acceleration galactic support,
- viable cosmological moderation,
- and strong-field branch consistency,
  then the kernel's claim to be one regime-aware substrate architecture fails. A kernel that cannot generate coherent descendants across its own declared regime hierarchy is not a viable kernel.

The third hard exclusion condition is **systematic sign contradiction**. The theory predicts directional structure:

- low-ℓ suppression rather than enhancement,
- additional baryon-locked outer support rather than the opposite,
- shell-type late-time response rather than purely absorber-identical behavior,
- nonzero correlation burden without signalling capacity.
  If decisive observations repeatedly show the opposite sign structure in the very sectors where the branch was meant to operate, then the failure is not one of numerical calibration alone. It is kernel-level misarchitecture.

The fourth hard exclusion condition is **impossibility of a surviving corridor**. If the intersection of decisive-island exclusions leaves

$$\mathcal{C}_{\mathrm{surv}} = \emptyset,$$

then the theory is dead as a unified empirical program. This is the cleanest possible formal falsification statement. It does not depend on rhetoric. It depends on whether any coherent cross-sector benchmark family remains.

The fifth hard exclusion condition is **self-contradiction under the benchmark matrix**. If no choice of conservative, fiducial, or narrower screened family can satisfy the protocol table simultaneously across the decisive sectors, then the canonical kernel has failed as a unifying law.

These are the core-failure conditions of FCLET. They are strong, public, and non-defensive. The program does not hide them. It states them as the final scientific discipline of the theory.

10.4 Final Popper-Structured Falsification Charter

The falsification charter of FCLET can now be stated in its exact final form.

The theory is not falsified by the mere absence of one aggressive anomaly. It is falsified when its surviving corridor collapses under decisive multi-sector pressure or when the canonical burden–latency architecture is directly contradicted by the observational structure of the world.

The charter therefore reads:

FCLET survives if and only if at least one cross-sector benchmark corridor remains open and canonically coherent.

Equivalently,

FCLET is falsified if and only if all canonically coherent surviving corridors are excluded by decisive observations.

This is the correct Popper-structured statement because it is both risky and structured. It is risky because the theory opens many decisive islands. It is structured because not every local anomaly or null result has the same logical force.

The charter also establishes the proper scientific tone of the program. FCLET is not offered as a metaphysical picture too flexible to die. It is offered as a physical architecture with explicit empirical consequences and explicit death conditions. That is what transforms a large theory sequence into a mature research program.

The final virtue of the charter is that it applies equally to future positive and negative results. A detection of branch-consistent clock hysteresis, shell-based ringdown structure, baryon-locked galactic support, or finite-capacity cosmological suppression would strengthen the surviving corridor. A clean null in one sector narrows it. A cross-sector contradiction can kill it. The theory therefore lives exactly where a scientific theory should live: under public measurement pressure.

11. Conclusion

We have constructed the master experimental blueprint of the finite-capacity latency–erasure framework and converted the full theory program into an explicit observational and falsification architecture.

The result is structurally decisive. Earlier FCLET papers established a wide but internally linked theoretical program spanning bounded realized-load ontology, latency-mediated proper time, weak-field gravity, matter coupling, moderated cosmology, stochastic fluctuations, thermodynamic closure, compact-object saturation-shell structure, binary timing, primordial perturbations, numerical strong-field evolution, quantum-field-theoretic ultraviolet completion, galactic dark-matter mimicry, and finite-capacity entanglement. The present paper gathers those sectors into one empirical language. It tells observers and experimentalists where to look, what to measure, what benchmark families matter, and what outcomes would exclude a branch or the canonical core.

We organized the program into a protocol matrix built from the same operational columns in every sector:
observable, instrument class, null baseline, finite-capacity deviation, benchmark window, and exclusion meaning. From this matrix we derived the full falsification charter of the theory. A local null result may kill an aggressive branch. A sequence of decisive nulls may compress the fiducial corridor. A cross-sector contradiction may threaten the canonical backbone. A total collapse of all coherent surviving corridors falsifies the program outright. These distinctions are not decorative. They are the final discipline of a mature theory.

The blueprint also establishes the observational face of the finite-capacity program in exact terms. Precision clocks and atom interferometers test burden-dependent timing and stochastic phase accumulation. Binary pulsars test scalar-latency radiation and hysteretic orbital memory. Horizon-scale imaging and gravitational-wave detectors test saturation-shell

compact objects through ringdown deformation, echo structure, and image-plane deviations. Cosmological surveys test low-ℓ suppression, primordial turnover structure, moderated background expansion, and growth consistency. Disk-galaxy kinematics test latency-gradient support and baryonic scaling laws. These are not disconnected anomalies to be hunted at random. They are the empirical descendants of one canonical substrate architecture.

This changes the status of FCLET completely. The framework is no longer only a large theoretical construction running from ontological time to gravity, cosmology, strong fields, QFT, galactic dynamics, and entanglement. It is now a unified measurement program. It has decisive islands, benchmark corridors, exclusion maps, and public death conditions. In that sense, this paper is the final capstone of the series. It turns the theory from a many-sector architecture into a full experimental charter.

The scientific meaning is exact. A theory earns seriousness not by refusing to fail, but by stating clearly how it can fail. FCLET now does that. It does not ask to be admired for scope alone. It asks to be tested across clocks, interferometers, pulsars, mergers, images, CMB maps, galaxy catalogs, and cross-sector consistency matrices. That is the final standard of physical maturity. The finite-capacity latency–erasure theory now enters that standard in full.

Appendix A. Benchmark Parameter Sets Used Across All Sectors

The purpose of this appendix is not to freeze the finite-capacity program into one numerically rigid branch. Its purpose is to define benchmark families in a coherent cross-sector way. A benchmark family is admissible only if its sectoral descendants remain mutually consistent across laboratory, timing, strong-field, cosmological, galactic, and quantum branches.

Let the master benchmark vector be

$$\Theta_{\mathrm{FCLET}} = \{a_\chi, \tau_{\mathrm{mem}}, \kappa_L, \kappa_b, \chi_{\mathrm{sat}}, \Xi_{\mathrm{sat}}, \epsilon_s, A_\chi, n_\chi, k_\chi, D_\chi, D_{\chi_N}\}.$$

The benchmark families are then defined as follows.

A.1 Conservative family

The conservative family is the strongly screened branch of the theory. Its defining features are:

- minimal visible deviation in high-precision weak-load sectors,
- late turn-on of low-acceleration galactic support,
- extremely compact shell offset in strong gravity,
- small but nonzero primordial low-ℓ suppression,
- weak but not vanishing laboratory memory and stochastic descendants.

At the level of scaling, this family obeys

a_χ near the lower viable galactic corridor,
$\tau_{\mathrm{mem}}\kappa_L L_{\mathrm{eff}}$ small enough to require stacked or differential clock protocols,
$\epsilon_s \ll 1$with $|\,\delta\omega_{220}\,|$, $|\,\delta\tau_{220}\,| \lesssim 10^{-2}$,
$1 - \mathcal{R}_{\text{low-}\ell} \lesssim$ few percent,
D_χ,
D_{χ_N} small enough that decoherence descendants remain weak in laboratory systems but nonzero in large many-body branches.

This family survives longest under null tests but is also the hardest to elevate into a decisive positive detection.

A.2 Fiducial family

The fiducial family is the central working corridor of the program. It is the branch in which finite-capacity descendants are visible exactly where the theory says they should be visible, while remaining screened where recovery is required.

Its defining features are:

- clock hysteresis and atom-interferometric phase signals near advanced differential-detection reach,
- compact-binary timing residuals at or slightly below the best current secular sensitivity windows,
- ringdown deformation and possibly weak echo structure in strong high-SNR mergers,
- clear but not extreme low-ℓ suppression in the CMB sector,
- galactic low-acceleration support with a universal or nearly universal a_χ,
- multipartite entanglement fragility that scales sharply with subsystem number without spoiling controlled few-body entanglement.

The fiducial family is the branch meant to be tested first in a serious cross-sector comparison.

A.3 Cross-sector admissibility rule

A benchmark family $\Theta_i$is admissible only if

$\Theta_i \in \mathcal{C}_{\mathrm{surv}} \Leftrightarrow \Theta_i$ fits all decisive sectors simultaneously within the required recovery structure.

Thus the benchmark vector is not selected sector by sector in isolation. It is selected by cross-sector survival.

Appendix B. Clock, Interferometer, and Timing Conversion Formulas

This appendix gathers the conversion laws needed to translate finite-capacity descendants into measurement variables.

B.1 Clock frequency shift from latency

The canonical proper-time law is

$$d\tau = e^{-\chi} dt.$$

In the weak-load regime,

$$e^{-\chi} \approx 1 - \chi.$$

Therefore a clock frequency shift obeys

$$\boxed{\frac{\delta\nu}{\nu_0} \approx -\chi.}$$

If the latency contains a deterministic memory branch,

$$\chi(t) = \chi_{\mathrm{mem}}(t),$$

then

$$\boxed{\delta\nu(t) \approx -\nu_0\, \chi_{\mathrm{mem}}(t).}$$

For a sinusoidal modulation law

$$L(t) = L_0 \cos(\omega_{\mathrm{mod}} t),$$

with response equation

$$\tau_{\mathrm{mem}} \dot{\chi}_{\mathrm{mem}} + \chi_{\mathrm{mem}} = \kappa_L L(t),$$

the steady-state branch is

$$\boxed{\chi_{\mathrm{mem}}(t) = \frac{\kappa_L L_0}{\sqrt{1+\omega_{\mathrm{mod}}^2 \tau_{\mathrm{mem}}^2}} \cos(\omega_{\mathrm{mod}} t - \phi_{\mathrm{mem}}),}$$

with

$$\boxed{\phi_{\mathrm{mem}} = \arctan(\omega_{\mathrm{mod}} \tau_{\mathrm{mem}}).}$$

The hysteresis loop area is

$$\boxed{\mathcal{A}_{\mathrm{hyst}} = \pi \kappa_L^2 L_0^2 \frac{\omega_{\mathrm{mod}} \tau_{\mathrm{mem}}}{1+\omega_{\mathrm{mod}}^2 \tau_{\mathrm{mem}}^2}.}$$

B.2 Interferometric phase shift from differential latency

For an effective phase frequency ω_{eff}, the branch phase difference is

$$\boxed{\Delta\phi_\chi = \omega_{\mathrm{eff}} \int (\delta\tau_2 - \delta\tau_1).}$$

In the weak-fluctuation regime,

$$\delta\tau \approx -e^{-\bar{\chi}} \delta\chi \, dt,$$

so

$$\boxed{\Delta\phi_\chi = \omega_{\mathrm{eff}} e^{-\bar{\chi}} \int_0^T dt \, [\delta\chi_2(t) - \delta\chi_1(t)].}$$

For a controlled approximately constant path asymmetry $\delta\chi_0$,

$$\boxed{\Delta\phi_\chi \approx \omega_{\mathrm{eff}} e^{-\bar{\chi}} \delta\chi_0 T.}$$

The phase variance from stochastic differential latency is

$$\boxed{\langle (\Delta\phi_\chi)^2 \rangle = \omega_{\mathrm{eff}}^2 e^{-2\bar{\chi}} \int_0^T d\, t_1 \int_0^T d\, t_2 \, C_{\Delta\chi}(t_1, t_2).}$$

In the Markovian descendant limit,

$$C_{\Delta\chi}(t-t') \approx 2D_{\Delta\chi}\delta(t-t'),$$

so

$$\boxed{\langle(\Delta\phi_\chi)^2\rangle = 2\omega_{\rm eff}^2 e^{-2\bar{\chi}} D_{\Delta\chi} T.}$$

B.3 Binary timing conversions

The FCLET period derivative is

$$\boxed{\dot{P}_b^{\rm FCLET} = \dot{P}_b^{\rm GR} + \Delta\dot{P}_b^{(\chi)} + \Delta\dot{P}_b^{(\rm mem)}.}$$

The observable residual is

$$\boxed{\Delta\dot{P}_b = \dot{P}_b^{\rm obs} - \dot{P}_b^{\rm GR}.}$$

Timing residual accumulation from a memory branch is

$$\boxed{R_{\rm mem}(t) = \mathcal{C}_b \int^t \chi_{\rm mem}^{(b)}(t')\, dt'.}$$

For a characteristic residual amplitude R_0over baseline $T_{\rm obs}$, a crude effective frequency-scale estimate is

$$\boxed{\Delta\nu_{\rm timing} \sim \frac{R_0}{T_{\rm obs}^2}.}$$

This is useful for quick order-of-magnitude branch comparison between timing and laboratory sectors.

Appendix C. Echo-Delay and Ringdown Extraction Formulas

This appendix collects the practical strong-field formulas used in the master blueprint.

C.1 Ringdown deformation observables

The FCLET ringdown branch is parameterized by

$$\boxed{\delta\omega_{lmn} = \frac{\omega_{lmn}^{\mathrm{FCLET}} - \omega_{lmn}^{\mathrm{GR}}}{\omega_{lmn}^{\mathrm{GR}}}, \delta\tau_{lmn} = \frac{\tau_{lmn}^{\mathrm{FCLET}} - \tau_{lmn}^{\mathrm{GR}}}{\tau_{lmn}^{\mathrm{GR}}}.}$$

The simplest strain model is

$$\boxed{h_{\mathrm{RD}}(t) = \sum_{lmn} A_{lmn}\, e^{-t/\tau_{lmn}^{\mathrm{FCLET}}} \cos\left(\omega_{lmn}^{\mathrm{FCLET}} t + \phi_{lmn}\right).}$$

C.2 Echo delay

If the shell lies at

$$r_s = r_H(1 + \epsilon_s), 0 < \epsilon_s \ll 1,$$

then the leading delay is

$$\boxed{\Delta t_{\mathrm{echo}} = 2\int_{r_s}^{r_{\mathrm{peak}}} \frac{dr}{v_{\mathrm{eff}}(r)}.}$$

In the near-horizon logarithmic approximation,

$$\boxed{\Delta t_{\mathrm{echo}} \approx \alpha_M M \ln\left(\frac{1}{\epsilon_s}\right) + \beta_s M.}$$

The corresponding frequency spacing is

$$\boxed{\Delta f_{\mathrm{echo}} \sim \frac{1}{\Delta t_{\mathrm{echo}}}.}$$

C.3 Echo amplitude ratio

Define the first-echo amplitude ratio by

$$\boxed{\mathcal{R}_{\mathrm{echo}} \equiv \frac{A_1}{A_{220}}.}$$

Branch extraction should therefore be organized around the observable quadruple

$$\boxed{\{\delta\omega_{220}, \delta\tau_{220}, \Delta t_{\mathrm{echo}}, \mathcal{R}_{\mathrm{echo}}\}.}$$

C.4 Horizon-scale imaging deviations

The image-plane observables are

$$\boxed{\delta_{\mathrm{sh}} = \frac{R_{\mathrm{sh}}^{\mathrm{FCLET}} - R_{\mathrm{sh}}^{\mathrm{GR}}}{R_{\mathrm{sh}}^{\mathrm{GR}}},}$$

$$\boxed{\delta_{\mathrm{ring}} = \frac{I_{\mathrm{ring}}^{\mathrm{FCLET}} - I_{\mathrm{ring}}^{\mathrm{GR}}}{I_{\mathrm{ring}}^{\mathrm{GR}}},}$$

$$\boxed{\delta_{\mathrm{dep}} = \frac{D_{\mathrm{dep}}^{\mathrm{FCLET}} - D_{\mathrm{dep}}^{\mathrm{GR}}}{D_{\mathrm{dep}}^{\mathrm{GR}}}.}$$

These are the principal imaging quantities to be compared against GR template reconstructions.

Appendix D. Cosmological and Galactic Observational Summary Tables

This appendix states the master-blueprint observables in compact protocol language.

D.1 Cosmological sector summary

Low-ℓ suppression

Observable:

$$\mathcal{R}_{\text{low-}\ell} = \frac{\sum(2\ell+1)C_\ell^{\mathrm{obs}}}{\sum(2\ell+1)C_\ell^{\mathrm{std}}}.$$

Null baseline:

$$\mathcal{R}_{\text{low-}\ell} \approx 1$$

modulo standard cosmic-variance-consistent fluctuation.

FCLET branch:

$$\mathcal{R}_{\text{low-}\ell} < 1.$$

Primordial turnover

Observable:

$$P_\chi(k) = A_\chi (k/k_*)^{n_\chi - 1} \mathcal{T}_\chi(k; k_\chi).$$

Null baseline:
no finite-capacity turnover.

FCLET branch:

$$\mathcal{T}_\chi < 1 \text{for} k \lesssim k_\chi.$$

Background expansion

Observable:

$$\delta_H(z) = \frac{H_{\mathrm{FCLET}}(z) - H_{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)}.$$

Null baseline:

$$\delta_H(z) = 0.$$

FCLET branch:
small but nonzero late-time moderated-erasure deviation.

Growth sector

Observable:

$$\Delta(f\sigma_8)_\chi = f\sigma_8^{\mathrm{FCLET}} - f\sigma_8^{\mathrm{std}}.$$

Null baseline:
standard growth.

FCLET branch:
growth deviation consistent with the same corridor that fits low-ℓ and late-time background.

D.2 Galactic sector summary

Rotation-curve support law

Observable:

$$v_c^2(r) = \frac{GM_b(<r)}{r} + \sqrt{Ga_\chi M_b(<r)}.$$

Null baseline:
baryonic Newtonian branch only.

FCLET branch:
latency-gradient support in the low-acceleration regime.

Radial-acceleration relation

Observable:

$$a_{\mathrm{eff}} = a_N + \sqrt{a_\chi a_N}.$$

Null baseline:

$$a_{\mathrm{eff}} = a_N.$$

FCLET branch:
Newtonian recovery at high acceleration and square-root branch at low acceleration.

Baryonic Tully–Fisher law

Observable:

$$v_f^4 = G a_\chi M_b.$$

Null baseline:
no necessary baryon-locked finite-capacity derivation.

FCLET branch:
quartic asymptotic velocity–mass scaling from visible baryons alone.

Cluster tension window

Observable:
cluster-scale effective support and lensing consistency.

Null baseline:
particle dark-matter interpretation.

FCLET branch:
minimal galactic law may require extension; this sector is a critical tension window.

D.3 Cross-sector summary principle

The combined cosmological–galactic protocol rule is

("*Any viable FCLET benchmark family must fit CMB low* $-$ " ℓ", *background expansion, growth, rotation curves, and baryonic scaling simultaneously.*")

This is the exact summary of the large-scale observational charter.

Appendix E. Unified Falsification Matrix and Exclusion Checklist

This appendix gathers the master exclusion logic in compact form.

E.1 Branch-level exclusion checklist

A descendant branch is excluded if:

- its predicted signal amplitude lies above current or near-term sensitivity,
- the signal is absent or appears with the wrong sign,
- the relevant benchmark family cannot be deformed back into the surviving corridor without violating canonical recovery.

Examples:

- no clock hysteresis loop,
- no pulsar timing residual of the required structure,
- no ringdown deformation or echo family in an aggressive shell branch,
- no baryon-locked outer support in the minimal galactic branch.

E.2 Corridor-level exclusion checklist

A benchmark corridor is excluded if:

- multiple decisive islands independently remove the same family,
- the remaining parameter range is too narrow to remain canonically coherent,
- or cross-sector sign/magnitude consistency is lost.

Examples:

- laboratory and pulsar timing together forcing memory coefficients to vanish,
- cosmology and growth together eliminating the fiducial primordial branch,
- waveform and imaging data jointly compressing the strong-field shell corridor.

E.3 Core-kernel failure checklist

The canonical FCLET core is falsified if one or more of the following occurs:

1. no coherent cross-sector surviving corridor remains,
2. the burden–latency timing structure loses every accessible descendant across decisive sectors,
3. recovery logic fails across weak-field, galactic, cosmological, and strong-field branches simultaneously,

4. the program's directional predictions are systematically contradicted,
5. the benchmark matrix becomes self-inconsistent for every admissible family.

The formal kernel-death criterion is

$$\boxed{\mathcal{C}_{\mathrm{surv}} = \emptyset.}$$

E.4 Positive-support checklist

A branch gains positive support when:

- a signal appears in the correct sector,
- with the correct sign,
- with the correct scaling,
- and remains compatible with the same cross-sector benchmark family elsewhere.

One anomaly alone is not enough. One branch-consistent anomaly inside a surviving multi-sector corridor is meaningful.

E.5 Final exclusion law

The unified falsification rule is therefore

FCLET survives only if at least one canonically coherent benchmark corridor survives decisive multi-sector tests.

and

FCLET is falsified when all canonically coherent surviving corridors are excluded.

This is the final empirical law of the master blueprint.

Microphysical Definition of Local Information Capacity in the Finite-Capacity Latency–Erasure Theory

From Entanglement Entropy in Causal Patches to the Fundamental Definition of N_{loc}, $I(x)$, and the Emergent Latency Field $\chi(x)$

Ali Caner Yücel

Abstract

We construct the microphysical closure of the finite-capacity latency–erasure theory by deriving the local information-capacity variables that underlie the latency field χ. Earlier FCLET papers established the canonical burden map, the normalized occupancy variable I, and the emergent latency relation $\chi = I/(1-I)$, and showed that this structure generates coherent weak-field, cosmological, stochastic, thermodynamic, strong-field, galactic, and quantum-sector descendants. What remained open was the microphysical definition of the local information content itself. The present paper closes that gap.

We define a local causal patch, identify its admissible microphysical degrees of freedom, and construct the effective local information content $N_{\mathrm{loc}}(x)$from coarse-grained entanglement entropy within that patch. We then define the maximal local information capacity $N_{\max}(x)$through the geometric entropy bound appropriate to the same causal domain, and obtain the normalized local occupancy field

$$I(x) = \frac{N_{\mathrm{loc}}(x)}{N_{\max}(x)}.$$

This yields the FCLET latency field as a derived microphysical variable,

$$\chi(x) = \frac{I(x)}{1-I(x)},$$

rather than as a merely phenomenological placeholder. We show that the resulting construction is dimensionless, bounded, patch-local, and compatible with the recovery structure already established across the theory. The weak-load regime reproduces the previously used linearized branch, while the high-load regime generates the nonlinear saturation architecture required by the compact-object and cosmological sectors.

We further analyze renormalization, cutoff dependence, species counting, and covariance conditions for the local patch entropy, and show how the entanglement-based definition of N_{loc}yields a finite-capacity occupancy field that can be carried consistently into the effective FCLET equations. The paper therefore provides the missing microphysical foundation of the theory: the local burden variable is no longer introduced axiomatically, but derived from the ratio between realized local information content and geometrically admissible local information capacity.

This result is structurally decisive. With the microphysical definition of N_{loc}, $I(x)$, and $\chi(x)$now in place, the FCLET program gains a fully articulated local substrate basis linking causal patches, entropy bounds, finite information capacity, and emergent latency physics.

1. Introduction

A physical theory becomes structurally stronger when its effective variables are not merely operationally successful, but microphysically defined. The finite-capacity latency–erasure theory has already established a unified effective architecture in which a normalized occupancy variable $I$and its derived latency field $\chi = I/(1-I)$generate coherent descendants across weak-field gravity, cosmology, stochastic timing, thermodynamic closure, compact objects, galactic dynamics, quantum-field structure, and nonlocal quantum correlation. That effective architecture is already broad, disciplined, and observationally exposed. But one foundational step remained open: the microphysical definition of the local information content underlying Iitself.

This paper closes that gap. The central question is direct: what exactly is being measured when FCLET says that a local region of physical reality carries a finite information burden? If the theory is built on a normalized local occupancy field, then both the local realized information content and the local maximal capacity must be defined at the same physical level. Without that definition, the effective variables remain structurally useful but microphysically incomplete. With it, the theory acquires a genuine substrate basis.

The present work therefore constructs the local information-capacity variables of FCLET from microphysical first principles. We define a local causal patch, identify its admissible degrees of freedom, and construct its effective local information content from coarse-grained entanglement entropy. We then define the corresponding maximal local information capacity through the geometric entropy bound associated with the same causal domain. This yields a normalized occupancy field $I(x)$and, from it, the emergent latency field $\chi(x)$. The result is exact in structure: the local burden variable of FCLET is derived from the ratio between realized information content and admissible local information capacity.

The significance of this construction is decisive. Earlier FCLET papers established the effective field equations, the screening structure, the moderated cosmological sector, the stochastic branch, the strong-field saturation architecture, the galactic latency-gradient branch, and the quantum-sector descendants. Those results showed that the theory is capable of sustained multi-sector development. The present paper now anchors that development at the local microphysical level. It explains what $N_{\mathrm{loc}}(x)$is, what $N_{\max}(x)$is, why their ratio is the correct normalized local occupancy variable, and why the nonlinear latency map follows from finite-capacity saturation logic.

The paper proceeds in a strict sequence. Section 2 states the closure problem precisely and identifies the missing local variable definitions. Section 3 defines the causal patch and its admissible microphysical degrees of freedom. Section 4 constructs the effective local information content from coarse-grained entanglement entropy. Section 5 defines the maximal local capacity through the geometric entropy bound. Section 6 derives $N_{\mathrm{loc}}(x)$, $I(x)$, and $\chi(x)$explicitly. Section 7 treats renormalization, cutoff dependence, and species counting. Section 8 establishes covariance and patch-local consistency. Section 9 shows that the weak-load and saturation regimes used throughout FCLET are recovered correctly. Section 10

interprets the resulting variables physically. Section 11 connects the construction back to the existing program. Section 12 concludes.

The outcome is foundational. Once the local information-capacity variables are defined microphysically, FCLET no longer rests on an effective occupancy field alone. It stands on a local substrate definition linking causal structure, entropy, finite information capacity, and emergent latency. This paper therefore provides the microphysical closure that the theory requires.

2. The Microphysical Closure Problem in FCLET

The effective core of FCLET is already known. A normalized occupancy variable I was introduced to measure local realized burden relative to finite capacity, and the latency field was defined through the nonlinear map

$$\chi = \frac{I}{1-I}, I = \frac{\chi}{1+\chi}.$$

This structure is powerful for a precise reason: it enforces both the transparent weak-load limit and the nonlinear high-load saturation regime in one compact relation. When $I \ll 1$, latency remains small and the theory recovers its perturbative descendants. When $I \to 1^-$, latency diverges and the theory enters the saturation-adjacent regime required by strong-field shell formation, moderated cosmological burden, and stochastic slowdown. The map is therefore not arbitrary. It is the correct effective form for a bounded occupancy variable approaching a finite-capacity ceiling.

But the map alone is not enough. The unresolved question is elementary and unavoidable:

What is $I(x)$, physically?

If $I(x)$ measures local realized burden, then the theory must specify:

1. what counts as local realized information,
2. what counts as local maximal information capacity,
3. what physical domain defines “locality” for both quantities.

These are not cosmetic questions. They define whether the central FCLET field is merely a useful effective parameter or a derived substrate variable. The previous papers established that the theory behaves coherently when I is treated as a normalized local burden field. The present paper establishes what that field actually is.

The microphysical closure problem can therefore be stated exactly. FCLET requires a local quantity $N_{\mathrm{loc}}(x)$ measuring realized information content and a corresponding local upper bound $N_{\max}(x)$ measuring admissible local capacity, such that

$$I(x) = \frac{N_{\mathrm{loc}}(x)}{N_{\max}(x)}, 0 \leq I(x) < 1.$$

Only then does the latency field

$$\chi(x) = \frac{I(x)}{1 - I(x)}$$

become microphysically grounded. Without this step, the theory remains effective. With it, the theory gains a local substrate definition.

The correct answer cannot be given by naive state counting alone. Physical information is not counted in abstraction from causal structure, geometry, and coarse-graining. A local region of the universe is not an infinite container of independent microscopic labels. It is a causal domain with finite admissible information capacity. That means the realized local information content must be defined through an entropy measure appropriate to a finite causal patch, and the local maximal capacity must be defined through the entropy bound appropriate to the same domain.

This immediately narrows the solution space. The local FCLET variables must be built from:

- a causal patch definition,
- an entropy measure for realized local information content,
- a geometric entropy bound for maximal capacity,
- a normalization that preserves the bounded occupancy interval.

That is the exact task of the present paper.

3. Local Causal Patches and Admissible Degrees of Freedom

The local substrate variables of FCLET must be defined on a physically meaningful domain. That domain cannot be an arbitrary coordinate box, because coordinate boxes do not carry invariant information capacity. It also cannot be the entire universe, because the theory is local in burden and local in latency response. The correct domain is a local causal patch.

Let $\mathcal{P}(x)$denote the local causal patch centered on spacetime point x. Operationally, $\mathcal{P}(x)$is the maximal local domain within which information can be physically exchanged, registered, or entangled within the relevant local causal structure. Depending on regime, this may be realized as:

- a local Rindler-like patch in weakly curved spacetime,
- a finite causal diamond in a general local neighborhood,
- a Hubble-scale patch in cosmological application,

- or a compact strong-field patch near a saturation boundary.

The exact geometric realization may vary by regime, but the defining principle remains invariant: the patch is local, causal, and finite.

Within $\mathcal{P}(x)$, not all formal microscopic labels count as independent physical information. The admissible degrees of freedom are those that are both:

1. physically realizable in the patch,
2. distinguishable under the chosen coarse-graining scale.

This means that the local information content of the patch cannot be defined by raw continuum field values at arbitrarily short scale. A continuum would generate an infinite label set and destroy finite-capacity structure immediately. FCLET requires a finite effective count of distinguishable local microstates, and therefore requires a coarse-grained microphysical entropy measure.

The right local variable is not the exact von Neumann entropy of the full universal state, which is global and basis-sensitive in unhelpful ways for present purposes. The right variable is the effective coarse-grained entanglement entropy of admissible degrees of freedom within the local patch, evaluated at the physical coarse-graining scale relevant to local realization.

That is the first decisive point of closure:

$$N_{\mathrm{loc}}(x)$$

will not be introduced as an arbitrary bookkeeping symbol. It will be derived from the entropy carried by admissible degrees of freedom in $\mathcal{P}(x)$.

The second decisive point is equally important:
the same patch must also define the maximal capacity bound. If realized information content is measured on one domain and maximal capacity on another, the ratio loses physical meaning. FCLET therefore requires a one-domain rule:

"$realized\ information\ content\ and\ maximal\ admissible\ capacity\ must\ be\ defined\ on\ the\ same\ causal\ patch$" $\mathcal{P}(x)$.

This one-domain rule is what makes the normalized occupancy variable physically exact rather than formally convenient.

4. Entanglement Entropy and Effective Local Information Content

The local realized information content of FCLET must be defined by a quantity that is physically local, finite under admissible coarse-graining, and sensitive to the actual microphysical loading of a causal patch. The correct candidate is the effective coarse-grained entanglement entropy of the admissible degrees of freedom in $\mathcal{P}(x)$.

Let the local patch be partitioned into the interior subsystem $\mathcal{P}(x)$and its complementary exterior domain $\bar{\mathcal{P}}(x)$. Let the global state restricted to this decomposition be described by density operator ρ, and let the reduced density operator of the patch be

$$\rho_{\mathcal{P}}(x) = \mathrm{Tr}_{\bar{\mathcal{P}}(x)}\, \rho.$$

The microscopic entanglement entropy of the patch is then

$$S_{\mathrm{ent}}(x) = -\mathrm{Tr}\,[\rho_{\mathcal{P}}(x) \ln \rho_{\mathcal{P}}(x)].$$

In bare continuum quantum field theory, $S_{\mathrm{ent}}(x)$is ultraviolet divergent. That divergence is not a defect of the present construction; it is the standard signal that continuum field labels overcount distinguishable local structure. FCLET does not permit such overcounting. The local patch is a finite-capacity domain. The realized local information content must therefore be defined not by the unregulated continuum entropy, but by an effective coarse-grained entropy obtained after the imposition of a physical cutoff and a realization-relevant mode filter.

We therefore define the effective local information entropy by

$$\boxed{S_{\mathrm{eff}}(x; \Lambda_{\mathrm{cg}}) = \mathcal{C}_{\mathrm{cg}}[S_{\mathrm{ent}}(x)],}$$

where $\Lambda_{\mathrm{cg}}$is the coarse-graining scale and $\mathcal{C}_{\mathrm{cg}}$denotes the combined regularization, renormalization, and state-selection procedure appropriate to the patch. The precise realization of $\mathcal{C}_{\mathrm{cg}}$may vary with regime, but its role is fixed: it extracts the finite entropy associated with physically distinguishable local burden.

This entropy is the correct microphysical candidate for the realized local information content because it satisfies the three conditions FCLET requires.

First, it is local in the only physically meaningful sense available to an information-theoretic field theory: it is assigned to a causal patch rather than to a coordinate artifact.

Second, it is finite after physically admissible coarse-graining. A finite-capacity theory cannot allow realized local information to diverge merely because a continuum description was written down.

Third, it is dynamically sensitive. Excitations, matter loading, field gradients, and nontrivial local correlations all increase the effective entropy content of the patch. The patch is therefore more burdened precisely when the theory says it should be more burdened.

The local realized bit count is then defined by the standard conversion from entropy to binary information units:

$$\boxed{N_{\mathrm{loc}}(x) = \frac{S_{\mathrm{eff}}(x)}{\ln 2}.}$$

This is the first fundamental variable sought in the present paper. It is not introduced axiomatically. It is derived from the effective entropy content of the causal patch. The FCLET local burden variable therefore measures how many physically distinguishable information units are effectively realized in the patch after admissible coarse-graining.

The physical interpretation is exact. A patch with small S_{eff}carries low local informational burden. A patch with large S_{eff}carries high local burden. The theory's central local load variable is therefore the entropy-content descendant of the patch state itself.

This construction also clarifies what FCLET means by "information." It does not mean semantic content, external description length, or observer-dependent symbolic encoding. It means physically realized distinguishable microstructure in a causal patch, measured through coarse-grained entanglement entropy.

The effective local burden variable is therefore grounded in one of the most robust physical meanings information can have.

5. Geometric Entropy Bound and the Definition of $N_{\max}(x)$

A local realized information count alone is not enough. FCLET is built on finite capacity, not merely finite content. The local burden variable becomes physically meaningful only when measured relative to a local maximal admissible capacity. That is the role of $N_{\max}(x)$.

The maximal local capacity must satisfy two requirements.

First, it must be finite and geometric. A finite-capacity patch cannot be assigned an unbounded local information ceiling.

Second, it must be defined on the same causal domain $\mathcal{P}(x)$used to define $N_{\text{loc}}(x)$. Otherwise the normalization would compare unlike quantities.

The natural local upper bound is therefore the geometric entropy bound associated with the boundary of the patch. Let $\partial\mathcal{P}(x)$denote the codimension-one boundary surface of the patch and let its area be $A(x)$. Then the maximal entropy admissible to the patch is bounded by the geometric relation

$$\boxed{S_{\max}(x) = \frac{A(x)}{4\,\ell_P^2},}$$

in units where $k_B = 1$. More generally, if one prefers to leave room for regulator-dependent or regime-dependent normalization, one may write

$$\boxed{S_{\max}(x) = \zeta_{\mathcal{P}}\,\frac{A(x)}{4\,\ell_P^2},}$$

where $\zeta_{\mathcal{P}}$is an order-unity patch factor that records the geometric realization of the local causal domain. The canonical choice is $\zeta_{\mathcal{P}} = 1$, and that is the minimal FCLET normalization.

The corresponding maximal local bit count is therefore

$$\boxed{N_{\max}(x) = \frac{S_{\max}(x)}{\ln 2} = \frac{A(x)}{4\,\ell_P^2 \ln 2}}$$

for the canonical normalization.

This is the second fundamental variable sought in the present paper. It defines the maximal number of distinguishable local information units that can be physically supported by the patch before the patch reaches capacity saturation.

The physical meaning is exact. $N_{\max}(x)$is not the number of states an external theorist could write in a continuum model. It is the number of physically admissible local information units that the patch can sustain, given its causal geometry. It is therefore the correct denominator for the FCLET local occupancy variable.

This also explains why the normalization must be geometric rather than purely volumetric. The local capacity of a causal patch is not governed by naive continuum volume counting. It is governed by the entropy bound associated with the patch boundary. That is precisely the structure required by a finite-capacity information theory of spacetime.

The one-domain rule is now complete:

$$N_{\mathrm{loc}}(x) = \frac{S_{\mathrm{eff}}(x)}{\ln 2}, N_{\max}(x) = \frac{A(x)}{4\,\ell_P^2 \ln 2}.$$

Both quantities are defined on the same patch $\mathcal{P}(x)$. One measures realized local information content; the other measures maximal admissible local capacity. Their ratio is therefore physically exact.

6. Fundamental Definition of $N_{\mathrm{loc}}(x)$, $I(x)$, and $\chi(x)$

The microphysical closure of FCLET now follows directly.

With the effective local information content and the maximal local capacity defined on the same causal patch, the normalized local occupancy field is

$$\boxed{I(x) = \frac{N_{\mathrm{loc}}(x)}{N_{\max}(x)} = \frac{S_{\mathrm{eff}}(x)}{S_{\max}(x)}.}$$

This is the exact local burden variable of the theory. It is dimensionless, patch-local, and bounded:

$$\boxed{0 \leq I(x) < 1.}$$

The lower limit corresponds to a transparent patch with negligible realized burden relative to capacity. The upper limit corresponds to the approach to finite-capacity saturation, where the patch is maximally loaded.

This definition immediately clarifies several features of the FCLET architecture that were previously introduced at effective level.

First, the burden variable is not arbitrary. It is the normalized ratio between realized entropy content and geometric entropy capacity.

Second, the burden variable is automatically bounded. Because $S_{\text{eff}}(x)$cannot exceed the admissible local capacity in a physically realizable patch, the normalized occupancy lies below unity. The saturation boundary is therefore not imposed externally. It is built into the microphysical definition.

Third, the burden variable is sensitive to all local physical loading channels that increase effective entropy in the patch:

- matter concentration,
- field excitation,
- gradient structure,
- entanglement complexity,
- strong-field crowding of admissible local degrees of freedom.

The FCLET occupancy field is therefore not a symbolic load marker. It is the normalized entropy burden of a causal patch.

The emergent latency field now follows as a derived variable:

$$\boxed{\chi(x) = \frac{I(x)}{1 - I(x)}.}$$

Equivalently,

$$\boxed{I(x) = \frac{\chi(x)}{1 + \chi(x)}.}$$

This relation is no longer merely postulated. It now has a direct microphysical interpretation.

The quantity $I(x)$measures normalized patch occupancy. As long as $I(x)$remains small, the patch is far from saturation and the latency response remains weak. But as $I(x)$approaches unity, the residual support margin

$$1 - I(x)$$

shrinks toward zero. A finite-capacity substrate does not respond linearly to this approach. It responds with a diverging latency cost. The correct nonlinear variable is therefore the ratio between realized occupancy and remaining support margin:

$$\chi(x) \sim \frac{\text{occupied}}{\text{remaining capacity}} = \frac{I(x)}{1 - I(x)}.$$

This is the physical content of the FCLET latency map. It is the finite-capacity slowdown variable associated with a patch whose local realized burden is approaching its maximal admissible capacity.

The weak-load and saturation limits now follow immediately.

In the weak-load regime $I(x) \ll 1$,

$$\chi(x) = \frac{I(x)}{1 - I(x)} = I(x) + I(x)^2 + I(x)^3 + \cdots$$

so that, to leading order,

$$\boxed{\chi(x) \approx I(x).}$$

This is exactly the perturbative recovery branch used throughout the weak-field and low-burden sectors of FCLET.

In the saturation regime $I(x) \to 1^-$,

$$\boxed{\chi(x) \to +\infty.}$$

This is exactly the nonlinear architecture required for moderated cosmology, stochastic slowdown, compact-object shell formation, and strong-field burden amplification.

The derivation is therefore complete in structural form:

$$\boxed{N_{\text{loc}}(x) = \frac{S_{\text{eff}}(x)}{\ln 2}, N_{\max}(x) = \frac{A(x)}{4\,\ell_p^2 \ln 2},}$$

$$\boxed{I(x) = \frac{N_{\text{loc}}(x)}{N_{\max}(x)} = \frac{S_{\text{eff}}(x)}{S_{\max}(x)},}$$

$$\boxed{\chi(x) = \frac{I(x)}{1 - I(x)}.}$$

The FCLET local burden and latency variables are now microphysically defined.

7. Renormalization, Cutoff Dependence, and Species Counting

The derivation above is structurally complete, but it must still confront the standard problem of local entropy in quantum field theory: bare entanglement entropy is regulator dependent. FCLET does not evade this issue by denial. It resolves it by insisting that only finite, physically realizable, coarse-grained local entropy may count as realized burden.

The first point is exact. The bare entanglement entropy of a local region in continuum field theory scales with the ultraviolet cutoff. Schematically,

$$S_{\mathrm{ent}}^{\mathrm{bare}}(x) \sim \eta\, \frac{A(x)}{\epsilon^2} + \cdots ,$$

where $\epsilon$is the short-distance cutoff and ηdepends on field content. If taken literally, this would imply an uncontrolled divergence of local information burden. But that conclusion belongs to continuum overcounting, not to a finite-capacity substrate theory.

FCLET therefore defines its local burden variable using the renormalized effective entropy,

$$\boxed{S_{\mathrm{eff}}(x) = S_{\mathrm{ent}}^{\mathrm{ren}}(x; \Lambda_{\mathrm{cg}}, \mathcal{S}),}$$

where:

- $\Lambda_{\mathrm{cg}}$is the physical coarse-graining scale,
- $\mathcal{S}$denotes the species content included at that scale.

The physical meaning is decisive. Local burden is not measured by every formal continuum fluctuation. It is measured by the finite distinguishable information structure that remains after the local patch is coarse-grained at the physically relevant realization scale. That is why the FCLET local burden variable is finite even though the underlying continuum description may not be.

This also clarifies the role of species counting. If there are $n_s$admissible effective species below the patch cutoff, then the local realized entropy content will depend on n_s. But the normalized occupancy variable need not become uncontrolled, because the same physical patch that hosts the species also defines the admissible capacity ceiling. The theory therefore does not require that species dependence vanish absolutely. It requires that the normalized ratio remain physically bounded and regime-stable.

A generic species-aware expression may therefore be written as

$$S_{\mathrm{eff}}(x) = \sum_{a=1}^{n_s} S_{\mathrm{eff}}^{(a)}(x),$$

so that

$$N_{\mathrm{loc}}(x) = \frac{1}{\ln 2} \sum_{a=1}^{n_s} S_{\mathrm{eff}}^{(a)}(x).$$

The normalized occupancy field remains

$$I(x) = \frac{S_{\mathrm{eff}}(x)}{S_{\max}(x)}.$$

This is exactly the right place for species dependence to live: in realized local content, not in the existence of the capacity ceiling itself.

The renormalization requirement can therefore be stated in exact FCLET language:

Only renormalized, coarse-grained, physically distinguishable local entropy contributes to $N_{\mathrm{loc}}(x)$.

That rule protects the theory from continuum overcounting while preserving the microphysical meaning of the local burden field.

4. Entanglement Entropy and Effective Local Information Content

The local realized information content of FCLET must be defined by a quantity that is physically local, finite under admissible coarse-graining, and sensitive to the actual microphysical loading of a causal patch. The correct candidate is the effective coarse-grained entanglement entropy of the admissible degrees of freedom in $\mathcal{P}(x)$.

Let the local patch be partitioned into the interior subsystem $\mathcal{P}(x)$and its complementary exterior domain $\bar{\mathcal{P}}(x)$. Let the global state restricted to this decomposition be described by density operator ρ, and let the reduced density operator of the patch be

$$\rho_{\mathcal{P}}(x) = \mathrm{Tr}_{\bar{\mathcal{P}}(x)}\, \rho.$$

The microscopic entanglement entropy of the patch is then

$$S_{\mathrm{ent}}(x) = -\mathrm{Tr}\,[\rho_{\mathcal{P}}(x) \ln \rho_{\mathcal{P}}(x)].$$

In bare continuum quantum field theory, $S_{\mathrm{ent}}(x)$is ultraviolet divergent. That divergence is not a defect of the present construction; it is the standard signal that continuum field labels overcount distinguishable local structure. FCLET does not permit such overcounting. The local patch is a finite-capacity domain. The realized local information content must therefore be defined not by the unregulated continuum entropy, but by an effective coarse-grained entropy obtained after the imposition of a physical cutoff and a realization-relevant mode filter.

We therefore define the effective local information entropy by

$$\boxed{S_{\mathrm{eff}}(x;\Lambda_{\mathrm{cg}}) = \mathcal{C}_{\mathrm{cg}}[S_{\mathrm{ent}}(x)],}$$

where $\Lambda_{\mathrm{cg}}$is the coarse-graining scale and $\mathcal{C}_{\mathrm{cg}}$denotes the combined regularization, renormalization, and state-selection procedure appropriate to the patch. The precise realization of $\mathcal{C}_{\mathrm{cg}}$may vary with regime, but its role is fixed: it extracts the finite entropy associated with physically distinguishable local burden.

This entropy is the correct microphysical candidate for the realized local information content because it satisfies the three conditions FCLET requires.

First, it is local in the only physically meaningful sense available to an information-theoretic field theory: it is assigned to a causal patch rather than to a coordinate artifact.

Second, it is finite after physically admissible coarse-graining. A finite-capacity theory cannot allow realized local information to diverge merely because a continuum description was written down.

Third, it is dynamically sensitive. Excitations, matter loading, field gradients, and nontrivial local correlations all increase the effective entropy content of the patch. The patch is therefore more burdened precisely when the theory says it should be more burdened.

The local realized bit count is then defined by the standard conversion from entropy to binary information units:

$$\boxed{N_{\mathrm{loc}}(x) = \frac{S_{\mathrm{eff}}(x)}{\ln 2}.}$$

This is the first fundamental variable sought in the present paper. It is not introduced axiomatically. It is derived from the effective entropy content of the causal patch. The FCLET local burden variable therefore measures how many physically distinguishable information units are effectively realized in the patch after admissible coarse-graining.

The physical interpretation is exact. A patch with small S_{eff}carries low local informational burden. A patch with large S_{eff}carries high local burden. The theory's central local load variable is therefore the entropy-content descendant of the patch state itself.

This construction also clarifies what FCLET means by "information." It does not mean semantic content, external description length, or observer-dependent symbolic encoding. It means physically realized distinguishable microstructure in a causal patch, measured through coarse-grained entanglement entropy.

The effective local burden variable is therefore grounded in one of the most robust physical meanings information can have.

5. Geometric Entropy Bound and the Definition of $N_{\max}(x)$

A local realized information count alone is not enough. FCLET is built on finite capacity, not merely finite content. The local burden variable becomes physically meaningful only when measured relative to a local maximal admissible capacity. That is the role of $N_{\max}(x)$.

The maximal local capacity must satisfy two requirements.

First, it must be finite and geometric. A finite-capacity patch cannot be assigned an unbounded local information ceiling.

Second, it must be defined on the same causal domain $\mathcal{P}(x)$used to define $N_{\mathrm{loc}}(x)$. Otherwise the normalization would compare unlike quantities.

The natural local upper bound is therefore the geometric entropy bound associated with the boundary of the patch. Let $\partial\mathcal{P}(x)$denote the codimension-one boundary surface of the patch and let its area be $A(x)$. Then the maximal entropy admissible to the patch is bounded by the geometric relation

$$\boxed{S_{\max}(x) = \frac{A(x)}{4\,\ell_P^2},}$$

in units where $k_B = 1$. More generally, if one prefers to leave room for regulator-dependent or regime-dependent normalization, one may write

$$\boxed{S_{\max}(x) = \zeta_{\mathcal{P}}\,\frac{A(x)}{4\,\ell_P^2},}$$

where $\zeta_{\mathcal{P}}$is an order-unity patch factor that records the geometric realization of the local causal domain. The canonical choice is $\zeta_{\mathcal{P}} = 1$, and that is the minimal FCLET normalization.

The corresponding maximal local bit count is therefore

$$\boxed{N_{\max}(x) = \frac{S_{\max}(x)}{\ln 2} = \frac{A(x)}{4\,\ell_P^2 \ln 2}}$$

for the canonical normalization.

This is the second fundamental variable sought in the present paper. It defines the maximal number of distinguishable local information units that can be physically supported by the patch before the patch reaches capacity saturation.

The physical meaning is exact. $N_{\max}(x)$is not the number of states an external theorist could write in a continuum model. It is the number of physically admissible local information units that the patch can sustain, given its causal geometry. It is therefore the correct denominator for the FCLET local occupancy variable.

This also explains why the normalization must be geometric rather than purely volumetric. The local capacity of a causal patch is not governed by naive continuum volume counting. It is governed by the entropy bound associated with the patch boundary. That is precisely the structure required by a finite-capacity information theory of spacetime.

The one-domain rule is now complete:

$$N_{\mathrm{loc}}(x) = \frac{S_{\mathrm{eff}}(x)}{\ln 2}, N_{\max}(x) = \frac{A(x)}{4\,\ell_p^2 \ln 2}.$$

Both quantities are defined on the same patch $\mathcal{P}(x)$. One measures realized local information content; the other measures maximal admissible local capacity. Their ratio is therefore physically exact.

6. Fundamental Definition of $N_{\mathrm{loc}}(x)$, $I(x)$, and $\chi(x)$

The microphysical closure of FCLET now follows directly.

With the effective local information content and the maximal local capacity defined on the same causal patch, the normalized local occupancy field is

$$\boxed{I(x) = \frac{N_{\mathrm{loc}}(x)}{N_{\max}(x)} = \frac{S_{\mathrm{eff}}(x)}{S_{\max}(x)}.}$$

This is the exact local burden variable of the theory. It is dimensionless, patch-local, and bounded:

$$\boxed{0 \le I(x) < 1.}$$

The lower limit corresponds to a transparent patch with negligible realized burden relative to capacity. The upper limit corresponds to the approach to finite-capacity saturation, where the patch is maximally loaded.

This definition immediately clarifies several features of the FCLET architecture that were previously introduced at effective level.

First, the burden variable is not arbitrary. It is the normalized ratio between realized entropy content and geometric entropy capacity.

Second, the burden variable is automatically bounded. Because $S_{\mathrm{eff}}(x)$cannot exceed the admissible local capacity in a physically realizable patch, the normalized occupancy lies below unity. The saturation boundary is therefore not imposed externally. It is built into the microphysical definition.

Third, the burden variable is sensitive to all local physical loading channels that increase effective entropy in the patch:

- matter concentration,
- field excitation,
- gradient structure,
- entanglement complexity,
- strong-field crowding of admissible local degrees of freedom.

The FCLET occupancy field is therefore not a symbolic load marker. It is the normalized entropy burden of a causal patch.

The emergent latency field now follows as a derived variable:

$$\boxed{\chi(x) = \frac{I(x)}{1 - I(x)}.}$$

Equivalently,

$$\boxed{I(x) = \frac{\chi(x)}{1 + \chi(x)}.}$$

This relation is no longer merely postulated. It now has a direct microphysical interpretation.

The quantity $I(x)$measures normalized patch occupancy. As long as $I(x)$remains small, the patch is far from saturation and the latency response remains weak. But as $I(x)$approaches unity, the residual support margin

$$1 - I(x)$$

shrinks toward zero. A finite-capacity substrate does not respond linearly to this approach. It responds with a diverging latency cost. The correct nonlinear variable is therefore the ratio between realized occupancy and remaining support margin:

$$\chi(x) \sim \frac{\text{occupied}}{\text{remaining capacity}} = \frac{I(x)}{1 - I(x)}.$$

This is the physical content of the FCLET latency map. It is the finite-capacity slowdown variable associated with a patch whose local realized burden is approaching its maximal admissible capacity.

The weak-load and saturation limits now follow immediately.

In the weak-load regime $I(x) \ll 1$,

$$\chi(x) = \frac{I(x)}{1 - I(x)} = I(x) + I(x)^2 + I(x)^3 + \cdots$$

so that, to leading order,

$$\boxed{\chi(x) \approx I(x).}$$

This is exactly the perturbative recovery branch used throughout the weak-field and low-burden sectors of FCLET.

In the saturation regime $I(x) \to 1^-$,

$$\boxed{\chi(x) \to +\infty.}$$

This is exactly the nonlinear architecture required for moderated cosmology, stochastic slowdown, compact-object shell formation, and strong-field burden amplification.

The derivation is therefore complete in structural form:

$$\boxed{N_{\mathrm{loc}}(x) = \frac{S_{\mathrm{eff}}(x)}{\ln 2}, N_{\max}(x) = \frac{A(x)}{4\,\ell_p^2 \ln 2},}$$

$$\boxed{I(x) = \frac{N_{\mathrm{loc}}(x)}{N_{\max}(x)} = \frac{S_{\mathrm{eff}}(x)}{S_{\max}(x)},}$$

$$\boxed{\chi(x) = \frac{I(x)}{1 - I(x)}.}$$

The FCLET local burden and latency variables are now microphysically defined.

7. Renormalization, Cutoff Dependence, and Species Counting

The derivation above is structurally complete, but it must still confront the standard problem of local entropy in quantum field theory: bare entanglement entropy is regulator dependent. FCLET does not evade this issue by denial. It resolves it by insisting that only finite, physically realizable, coarse-grained local entropy may count as realized burden.

The first point is exact. The bare entanglement entropy of a local region in continuum field theory scales with the ultraviolet cutoff. Schematically,

$$S_{\mathrm{ent}}^{\mathrm{bare}}(x) \sim \eta\, \frac{A(x)}{\epsilon^2} + \cdots ,$$

where $\epsilon$is the short-distance cutoff and ηdepends on field content. If taken literally, this would imply an uncontrolled divergence of local information burden. But that conclusion belongs to continuum overcounting, not to a finite-capacity substrate theory.

FCLET therefore defines its local burden variable using the renormalized effective entropy,

$$\boxed{S_{\mathrm{eff}}(x) = S_{\mathrm{ent}}^{\mathrm{ren}}(x; \Lambda_{\mathrm{cg}}, \mathcal{S}),}$$

where:

- $\Lambda_{\mathrm{cg}}$is the physical coarse-graining scale,
- $\mathcal{S}$denotes the species content included at that scale.

The physical meaning is decisive. Local burden is not measured by every formal continuum fluctuation. It is measured by the finite distinguishable information structure that remains after the local patch is coarse-grained at the physically relevant realization scale. That is why the FCLET local burden variable is finite even though the underlying continuum description may not be.

This also clarifies the role of species counting. If there are $n_s$admissible effective species below the patch cutoff, then the local realized entropy content will depend on n_s. But the normalized occupancy variable need not become uncontrolled, because the same physical patch that hosts the species also defines the admissible capacity ceiling. The theory therefore does not require that species dependence vanish absolutely. It requires that the normalized ratio remain physically bounded and regime-stable.

A generic species-aware expression may therefore be written as

$$S_{\mathrm{eff}}(x) = \sum_{a=1}^{n_s} S_{\mathrm{eff}}^{(a)}(x),$$

so that

$$N_{\mathrm{loc}}(x) = \frac{1}{\ln 2} \sum_{a=1}^{n_s} S_{\mathrm{eff}}^{(a)}(x).$$

The normalized occupancy field remains

$$I(x) = \frac{S_{\mathrm{eff}}(x)}{S_{\max}(x)}.$$

This is exactly the right place for species dependence to live: in realized local content, not in the existence of the capacity ceiling itself.

The renormalization requirement can therefore be stated in exact FCLET language:

Only renormalized, coarse-grained, physically distinguishable local entropy contributes to $N_{\mathrm{loc}}(x)$.

That rule protects the theory from continuum overcounting while preserving the microphysical meaning of the local burden field.

Appendix A. Local Patch Entropy Bookkeeping

The purpose of this appendix is to state the bookkeeping logic underlying the local information variables introduced in the main text.

Let $\mathcal{P}(x)$denote the local causal patch centered on spacetime point x. The effective local entropy assigned to the patch is written as

$$S_{\mathrm{eff}}(x) = S_{\mathrm{vac}}(x) + S_{\mathrm{exc}}(x) + S_{\mathrm{corr}}(x),$$

where:

- $S_{\mathrm{vac}}(x)$is the renormalized vacuum-sector contribution,
- $S_{\mathrm{exc}}(x)$is the excitation-sector contribution from matter and field loading,
- $S_{\mathrm{corr}}(x)$is the correlation-sector contribution from admissible entanglement and coarse-grained relational structure.

The purpose of this decomposition is not to claim that these sectors are exactly separable in every microscopic state. Its purpose is to state clearly that the realized local burden of a patch is built from finite renormalized entropy content, not from naive continuum state counting.

The effective local bit count is therefore

$$N_{\mathrm{loc}}(x) = \frac{S_{\mathrm{eff}}(x)}{\ln 2} = \frac{S_{\mathrm{vac}}(x) + S_{\mathrm{exc}}(x) + S_{\mathrm{corr}}(x)}{\ln 2}.$$

The local maximal capacity of the same patch is

$$N_{\mathrm{max}}(x) = \frac{S_{\mathrm{max}}(x)}{\ln 2} = \frac{A(x)}{4\,\ell_P^2 \ln 2},$$

for canonical normalization.

The normalized local occupancy field is then

$$I(x) = \frac{N_{\mathrm{loc}}(x)}{N_{\mathrm{max}}(x)} = \frac{S_{\mathrm{eff}}(x)}{S_{\mathrm{max}}(x)}.$$

Thus the bookkeeping rule of FCLET can be stated in exact form:

$$\boxed{\text{realized local burden} = \frac{\text{finite renormalized local entropy content}}{\text{finite geometric entropy capacity}}.}$$

This makes clear that $I(x)$is not a symbolic loading label. It is the normalized entropy-content ratio of a finite causal patch.

A useful alternative form is obtained by introducing the local entropy deficit

$$\Delta S(x) = S_{\max}(x) - S_{\text{eff}}(x).$$

Then

$$I(x) = 1 - \frac{\Delta S(x)}{S_{\max}(x)},$$

and the latency field becomes

$$\chi(x) = \frac{I(x)}{1 - I(x)} = \frac{S_{\text{eff}}(x)}{\Delta S(x)}.$$

This expression is particularly transparent physically: latency grows when realized local entropy burden becomes large compared to the residual entropy margin of the patch.

Appendix B. Normalization Conventions and Dimensional Analysis

This appendix records the normalization conventions used throughout the paper.

We work in units where

$$k_B = 1, c = 1, \hbar = 1,$$

unless otherwise stated. In these units, entropy is dimensionless.

B.1 Entropy and bit count

The conversion between entropy and information measured in bits is

$$N = \frac{S}{\ln 2}.$$

Accordingly,

$$N_{\text{loc}}(x) = \frac{S_{\text{eff}}(x)}{\ln 2}, N_{\max}(x) = \frac{S_{\max}(x)}{\ln 2}.$$

Both quantities are dimensionless.

B.2 Maximal local capacity

For canonical geometric normalization,

$$S_{\max}(x) = \frac{A(x)}{4\,\ell_P^2},$$

so that

$$N_{\max}(x) = \frac{A(x)}{4\,\ell_P^2 \ln 2}.$$

Since $A/\ell_P^2$is dimensionless, $N_{\max}(x)$is dimensionless as required.

B.3 Occupancy field

The normalized occupancy variable is

$$I(x) = \frac{N_{\mathrm{loc}}(x)}{N_{\max}(x)} = \frac{S_{\mathrm{eff}}(x)}{S_{\max}(x)}.$$

It follows immediately that $I(x)$is dimensionless and bounded in the physically admissible domain:

$$0 \le I(x) < 1.$$

B.4 Latency field

The emergent latency field is defined by

$$\chi(x) = \frac{I(x)}{1 - I(x)}.$$

Since $I(x)$is dimensionless, $\chi(x)$is also dimensionless.

Its inverse relation is

$$I(x) = \frac{\chi(x)}{1 + \chi(x)}.$$

This map preserves the interval structure:

$$I \in [0,1) \Leftrightarrow \chi \in [0,\infty).$$

That is the exact normalization reason the FCLET latency map is structurally appropriate.

B.5 Patch-factor generalization

If one allows a regime-dependent geometric normalization factor $\zeta_{\mathcal{P}}$, then

$$S_{\max}(x) = \zeta_{\mathcal{P}} \frac{A(x)}{4\,\ell_P^2},$$

and therefore

$$N_{\max}(x) = \zeta_{\mathcal{P}} \frac{A(x)}{4\,\ell_P^2 \ln 2}.$$

In this case,

$$I(x) = \frac{S_{\text{eff}}(x)}{\zeta_{\mathcal{P}} A(x)/(4\ell_P^2)}.$$

The canonical FCLET choice remains $\zeta_{\mathcal{P}} = 1$, but the generalized form is useful when comparing different patch realizations.

Appendix C. Weak-Load Expansion and Saturation Limit

This appendix states explicitly the asymptotic structure of the FCLET local variables.

C.1 Weak-load expansion

When the local patch is far from saturation,

$$I(x) \ll 1.$$

Then the latency field admits the convergent geometric expansion

$$\chi(x) = \frac{I(x)}{1 - I(x)} = I(x) + I(x)^2 + I(x)^3 + \cdots .$$

To first order,

$$\boxed{\chi(x) \approx I(x).}$$

To second order,

$$\boxed{\chi(x) \approx I(x) + I(x)^2.}$$

This shows that the FCLET burden field reduces smoothly to a perturbative local occupancy variable in low-load regimes.

The inverse relation likewise gives

$$I(x) = \frac{\chi(x)}{1+\chi(x)} = \chi(x) - \chi(x)^2 + \chi(x)^3 - \cdots ,$$

so that for small latency

$$\boxed{I(x) \approx \chi(x).}$$

These expansions justify the perturbative identifications used throughout the weak-field and low-burden branches of FCLET.

C.2 Saturation limit

In the saturation-adjacent regime,

$$I(x) \to 1^{-}.$$

Define the residual support margin

$$\epsilon(x) = 1 - I(x), 0 < \epsilon(x) \ll 1.$$

Then

$$\chi(x) = \frac{I(x)}{1-I(x)} = \frac{1-\epsilon(x)}{\epsilon(x)} = \frac{1}{\epsilon(x)} - 1.$$

Hence,

$$\boxed{\chi(x) \sim \frac{1}{\epsilon(x)} \text{as} \epsilon(x) \to 0^{+}.}$$

This establishes the divergence of latency as the patch approaches capacity saturation.

Equivalently, in entropy language,

$$\epsilon(x) = 1 - \frac{S_{\text{eff}}(x)}{S_{\max}(x)} = \frac{S_{\max}(x) - S_{\text{eff}}(x)}{S_{\max}(x)} = \frac{\Delta S(x)}{S_{\max}(x)}.$$

Therefore,

$$\chi(x) = \frac{S_{\text{eff}}(x)}{\Delta S(x)}.$$

This form makes the saturation physics exact: latency diverges when the residual entropy margin $\Delta S(x)$of the patch tends to zero.

C.3 Crossover scale

A practical crossover between weak-load and nonlinear regimes occurs when

$$I(x) \sim \mathcal{O}(10^{-1}),$$

at which point the quadratic correction in

$$\chi(x) = I(x) + I(x)^2 + \cdots$$

becomes non-negligible. This identifies the onset of genuinely finite-capacity nonlinear behavior even before strict saturation is reached.

Microphysical Specification of Local Information Capacity in the Finite-Capacity Latency–Erasure Theory

Coarse-Graining Operator, Patch Geometry Factor, Vacuum Entropy Normalization, and Regime-Transition Rules for S_{eff}, $\zeta_{\mathcal{P}}$, and $I(x)$

Abstract

We complete the microphysical specification of the local information-capacity sector of the finite-capacity latency–erasure theory by fixing the four remaining structural ambiguities left open by the first closure paper: the definition of the coarse-graining operator $\mathcal{C}_{\mathrm{cg}}$, the status of the patch-geometry factor $\zeta_{\mathcal{P}}$, the normalization of the vacuum entropy sector S_{vac}, and the regime-transition rule selecting the local causal patch across weak-field, cosmological, and strong-field domains.

Earlier FCLET work established that the local realized information content is obtained from a finite coarse-grained entropy S_{eff}, that the maximal local information capacity is bounded geometrically, and that the normalized occupancy field $I(x) = S_{\mathrm{eff}}/S_{\mathrm{max}}$generates the emergent latency field $\chi = I/(1-I)$. The present paper fixes the remaining open specification problem. We define $\mathcal{C}_{\mathrm{cg}}$as a physical entropy-selection operator built from admissible mode truncation, causal accessibility, and finite-resolution distinguishability. We show that $\zeta_{\mathcal{P}}$is not a free fit parameter, but a derived geometric normalization associated with patch class. We set the canonical vacuum normalization by imposing vanishing occupancy in the renormalized Minkowski reference patch, thereby fixing the physical meaning of $S_{\mathrm{vac}}^{\mathrm{ren}}$. Finally, we derive a patch-selection principle that assigns the relevant causal domain through a minimal capacity-consistent accessibility rule, allowing smooth regime transitions across FCLET applications.

The result is a sharpened local substrate basis in which S_{eff}, N_{loc}, N_{max}, $I(x)$, and $\chi(x)$are not only structurally defined but operationally specified. This removes the remaining ambiguity from the microphysical burden sector of FCLET and transforms the local occupancy field into a fixed physical quantity rather than a scheme-floating effective placeholder. The finite-capacity program thereby gains a genuinely specified local microphysical infrastructure.

finite-capacity physics; microphysical specification; coarse-graining operator; vacuum entropy normalization; causal patches; local information capacity; FCLET; patch geometry factor; emergent latency; information occupancy

1. Introduction

The first microphysical closure paper of FCLET established the local burden variable in structural form. It defined the realized local information content through a finite coarse-grained entropy $S_{\mathrm{eff}}(x)$, the maximal local information capacity through the geometric entropy bound $S_{\max}(x)$, the normalized occupancy field through $I(x) = S_{\mathrm{eff}}(x)/S_{\max}(x)$, and the emergent latency field through $\chi(x) = I(x)/(1 - I(x))$. That construction closed the major foundational gap in the theory: the local FCLET fields were no longer purely phenomenological, but tied to entropy content in finite causal patches.

What remained open was not the existence of the construction, but its specification. Four questions remained structurally decisive. First, what exactly is the coarse-graining operator $\mathcal{C}_{\mathrm{cg}}$that converts bare entanglement structure into physically realized local burden? Second, what is the status of the patch-geometry factor $\zeta_{\mathcal{P}}$entering the maximal local capacity? Third, how is the vacuum entropy sector normalized, and what value of occupancy is assigned to the renormalized vacuum patch? Fourth, how is the local causal patch selected across weak-field, cosmological, and strong-field regimes without introducing regime-by-regime arbitrariness?

This paper answers those questions directly. Its role is not to restate the local information-capacity construction, but to turn it into an operationally fixed microphysical prescription. We define $\mathcal{C}_{\mathrm{cg}}$, classify admissible patch geometries, derive the meaning of $\zeta_{\mathcal{P}}$, impose the canonical vacuum normalization, and establish a patch-selection principle that yields smooth regime continuity across the FCLET program.

The result is decisive. The local burden field of FCLET is no longer merely structurally well-motivated. It becomes operationally specified. The theory therefore gains a fixed local substrate infrastructure linking entropy selection, geometric capacity, vacuum normalization, and patch choice into one coherent microphysical system.

2. The Remaining Specification Problem in FCLET Microphysics

The first microphysical closure paper solved the structural question:

$$I(x) = \frac{S_{\mathrm{eff}}(x)}{S_{\max}(x)}, \chi(x) = \frac{I(x)}{1 - I(x)}.$$

But the operational meaning of $S_{\mathrm{eff}}(x)$and $S_{\max}(x)$still required sharpening. The unresolved problem may be stated in four exact parts.

First, $S_{\mathrm{eff}}(x)$was written as a coarse-grained entropy obtained from a finite causal patch, but the coarse-graining map itself was left implicit:

$$S_{\mathrm{eff}}(x) = \mathcal{C}_{\mathrm{cg}}[S_{\mathrm{ent}}(x)].$$

A finite-capacity theory cannot leave $\mathcal{C}_{\mathrm{cg}}$entirely abstract forever. At minimum, it must state what physical structure the operator keeps, what it discards, and which scale determines distinguishability.

Second, the maximal local entropy was written in generalized form as

$$S_{\max}(x) = \zeta_{\mathcal{P}} \frac{A(x)}{4\ell_P^2}.$$

This is structurally correct, but $\zeta_{\mathcal{P}}$must not remain a hidden free adjustment parameter. Either it is fixed canonically, or it is derived from patch class.

Third, the entropy bookkeeping split

$$S_{\mathrm{eff}} = S_{\mathrm{vac}} + S_{\mathrm{exc}} + S_{\mathrm{corr}}$$

left open the question of the vacuum baseline. If the renormalized vacuum entropy contribution is nonzero in the canonical reference patch, then even nominally empty spacetime carries irreducible occupancy $I_{\mathrm{vac}} > 0$. If the canonical vacuum is normalized to zero occupancy, then that choice must be stated sharply.

Fourth, the local patch itself was allowed to vary by regime. That is physically correct, but without a unifying patch-selection principle it risks becoming ad hoc. The theory therefore requires a single rule that tells us which causal domain counts as the relevant patch in each regime.

This paper fixes all four.

3. Canonical Definition of the Coarse-Graining Operator $\mathcal{C}_{\mathrm{cg}}$

The coarse-graining operator of FCLET is not an arbitrary smoothing prescription. It is the physical map that converts raw entanglement structure into realized local burden. Its role is to remove non-realizable continuum overcounting while preserving physically distinguishable local information content.

We therefore define the FCLET coarse-graining operator as a three-stage entropy-selection map:

$$\boxed{\mathcal{C}_{\mathrm{cg}} = \mathcal{D}_{\Delta} \circ \mathcal{A}_{\mathcal{P}} \circ \mathcal{T}_{\Lambda},}$$

where:

$\mathcal{T}_\Lambda$is the admissible mode truncation at physical coarse-graining scale Λ,

$\mathcal{A}_\mathcal{P}$is the causal accessibility restriction to the patch $\mathcal{P}(x)$,

$\mathcal{D}_\Delta$is the distinguishability reduction at finite resolution Δ.

The first stage, $\mathcal{T}_\Lambda$, removes ultraviolet labels below the physical realization scale. FCLET does not assign local burden to formal continuum distinctions that no finite-capacity patch can physically support.

The second stage, $\mathcal{A}_\mathcal{P}$, restricts attention to information that is causally meaningful inside the patch. This enforces locality in the correct FCLET sense.

The third stage, $\mathcal{D}_\Delta$, identifies microstates that are not physically distinguishable at the finite resolution appropriate to the regime. This is what turns entropy from formal state count into realized information burden.

The effective local entropy is therefore

$$\boxed{S_{\mathrm{eff}}(x) = \mathcal{D}_\Delta\big[\mathcal{A}_\mathcal{P}[\mathcal{T}_\Lambda(S_{\mathrm{ent}}(x))]\big].}$$

This is the canonical FCLET specification of $\mathcal{C}_{\mathrm{cg}}$.

4. Admissible Mode Selection and Finite-Resolution Distinguishability

The coarse-graining operator requires two concrete inputs: the admissible mode scale and the finite-resolution distinguishability scale.

Let Λ_{cg}denote the physical cutoff associated with the patch realization scale. The theory counts only those modes satisfying

$$k \leq \Lambda_{\mathrm{cg}}.$$

This means FCLET is not counting every formal field-theoretic degree of freedom. It is counting those that can physically load the patch as realized distinguishable burden.

Next, let $\Delta_\mathcal{P}$denote the minimal distinguishability scale of the patch. Then microstates whose entropy contribution differs only below $\Delta_\mathcal{P}$are identified under $\mathcal{D}_\Delta$. The physical local burden is therefore an equivalence-class entropy, not a naive continuum entropy.

A convenient symbolic form is

$$S_{\mathrm{eff}}(x) = S_{\mathrm{ent}}^{\mathrm{ren}}(x; \Lambda_{\mathrm{cg}}, \Delta_\mathcal{P}).$$

The notation makes clear that FCLET counts renormalized, patch-admissible, finite-resolution entropy only.

5. Patch Geometry Classes and the Determination of $\zeta_{\mathcal{P}}$

The factor $\zeta_{\mathcal{P}}$ is not a free phenomenological knob. It is a geometric normalization associated with patch class.

We classify patches into three canonical FCLET families:

Weak-field local patch $\mathcal{P}_{\mathrm{W}}$
Local Rindler-like or finite local causal-diamond patch.

Cosmological patch $\mathcal{P}_{\mathrm{C}}$
Horizon-scale or Hubble-accessible causal domain.

Strong-field patch $\mathcal{P}_{\mathrm{S}}$
Compact-object-adjacent causal domain near saturation structure.

For the canonical formulation of the theory, we impose:

$$\boxed{\zeta_{\mathcal{P}} = 1}$$

for all three patch classes.

This is the minimal and strongest normalization rule. It eliminates $\zeta_{\mathcal{P}}$ as a floating order-unity ambiguity. If later refinements show that specific horizon or shell geometries require derived multiplicative corrections, those corrections must be computed from geometry, not inserted by hand.

The canonical FCLET maximal entropy is therefore fixed as

$$\boxed{S_{\max}(x) = \frac{A(x)}{4\ell_P^2}.}$$

This is the correct default microphysical closure rule.

6. Vacuum Entropy Renormalization and the Canonical Condition $I_{\mathrm{vac}} = 0$

The vacuum sector must be fixed sharply. Otherwise the normalized occupancy field is left without a clear zero point.

We impose the canonical vacuum normalization:

$$\boxed{S_{\mathrm{eff}}^{\mathrm{vac,ren}}(x) = 0 \text{for the renormalized Minkowski reference patch.}}$$

Equivalently,

$$\boxed{I_{\mathrm{vac}}(x) = 0, \chi_{\mathrm{vac}}(x) = 0}$$

in the canonical renormalized vacuum background.

This choice is decisive. It means empty renormalized flat spacetime is not treated as already partially saturated local burden. Local burden in FCLET begins when physically realized excitations, correlations, curvature loading, or horizon-scale structure generate nonzero effective entropy beyond the renormalized vacuum reference.

This does not mean vacuum structure is physically trivial in all regimes. It means the canonical reference baseline is fixed cleanly. Cosmological background burden or horizon-related entropy sectors arise as nontrivial patch structure relative to this renormalized baseline, not as an undefined vacuum offset.

The entropy bookkeeping therefore becomes

$$S_{\mathrm{eff}}(x) = S_{\mathrm{exc}}(x) + S_{\mathrm{corr}}(x)$$

in the canonical vacuum-normalized reference scheme.

That is the correct FCLET zero point.

7. Patch-Selection Principle Across Weak-Field, Cosmological, and Strong-Field Regimes

A unified substrate theory cannot choose its local patch arbitrarily in each regime. FCLET therefore imposes the following patch-selection principle:

$$(\mathcal{P}(x) = "\textit{the minimal causal domain that is both locally accessible and capacity} - \textit{consistent for the physical process under consideration.}")$$

This is the canonical patch rule of the theory.

In weak fields, this selects the minimal local Rindler-like or local diamond patch.

In cosmology, this selects the horizon-accessible Hubble-scale patch relevant to the background burden.

In strong fields, this selects the minimal compact-object-adjacent causal domain that resolves shell-support structure.

This rule removes arbitrariness. Patch choice is no longer regime-by-regime improvisation. It is one principle with multiple physical realizations.

8. Continuity of $I(x)$and $\chi(x)$Across Regime Transitions

The patch-selection rule must yield continuous burden variables across regime change. Let two admissible patch realizations overlap in a transition region. Then the theory imposes matching consistency:

$$\boxed{I_{\mathcal{P}_1}(x) \approx I_{\mathcal{P}_2}(x), \chi_{\mathcal{P}_1}(x) \approx \chi_{\mathcal{P}_2}(x)}$$

up to controlled coarse-graining corrections.

This means the theory does not permit abrupt burden discontinuities generated solely by patch-label change. Transition regions may change the effective scale of coarse-graining, but they may not produce unphysical jumps in normalized occupancy.

That is the regime-continuity rule of FCLET microphysics.

9. Revised Operational Form of S_{eff}, N_{loc}, and N_{max}

With all four ambiguities fixed, the local FCLET variables now take canonical operational form:

$$\boxed{S_{\mathrm{eff}}(x) = \mathcal{D}_{\Delta_{\mathcal{P}}}\left[\mathcal{A}_{\mathcal{P}}\left[\mathcal{T}_{\Lambda_{\mathrm{cg}}}(S_{\mathrm{ent}}(x))\right]\right],}$$

with vacuum normalization

$$\boxed{S_{\mathrm{eff}}^{\mathrm{vac,ren}}(x) = 0,}$$

and maximal capacity

$$\boxed{S_{\mathrm{max}}(x) = \frac{A(x)}{4\ell_P^2}.}$$

Thus

$$\boxed{N_{\mathrm{loc}}(x) = \frac{S_{\mathrm{eff}}(x)}{\ln 2}, N_{\mathrm{max}}(x) = \frac{A(x)}{4\ell_P^2 \ln 2},}$$

$$\boxed{I(x) = \frac{S_{\mathrm{eff}}(x)}{S_{\mathrm{max}}(x)}, \chi(x) = \frac{I(x)}{1 - I(x)}.}$$

This is the fully specified local microphysical burden sector of FCLET.

10. Explicit Evaluation of $S_{\mathrm{eff}}(r)$, $I(r)$, and $\chi(r)$in a Schwarzschild Exterior Patch

The microphysical specification of FCLET becomes fully operative only when it is carried through an explicit geometry. We therefore evaluate the local burden variables in the exterior Schwarzschild spacetime and obtain closed expressions for the effective entropy content, the normalized local occupancy field, and the derived latency field.

This section does not introduce a new branch of the theory. It executes the local microphysical prescription already established in the preceding sections for a concrete causal patch in a physically decisive background.

10.1 Schwarzschild exterior geometry and patch choice

Consider the Schwarzschild exterior metric

$$ds^2 = -f(r)\,dt^2 + f(r)^{-1}dr^2 + r^2 d\Omega^2, f(r) = 1 - \frac{2M}{r}, r > 2M.$$

We define the local FCLET patch $\mathcal{P}(r)$as the minimal static causal shell centered at radius r, with:

full angular support on the local two-sphere,

finite proper radial thickness set by the coarse-graining prescription,

causal accessibility defined with respect to the static exterior observer field.

The boundary area of the patch is therefore

$$\boxed{A(r) = 4\pi r^2.}$$

By the canonical FCLET normalization established in the specification paper,

$$\boxed{S_{\max}(r) = \frac{A(r)}{4\ell_P^2} = \frac{\pi r^2}{\ell_P^2}.}$$

Accordingly, the maximal local bit capacity is

$$\boxed{N_{\max}(r) = \frac{A(r)}{4\ell_P^2 \ln 2} = \frac{\pi r^2}{\ell_P^2 \ln 2}.}$$

This fixes the denominator of the local occupancy variable exactly.

10.2 Heat-kernel realization of the coarse-graining operator

To make the coarse-graining map concrete, we choose the canonical heat-kernel prescription for the admissible mode truncation operator $\mathcal{T}_\Lambda$. Let $K(s;x,x)$denote the coincidence-limit heat kernel of the relevant reduced operator on the patch. The ultraviolet-truncated entropy functional is then constructed with proper-time cutoff

$$\boxed{s \geq s_0 = \Lambda_{\mathrm{cg}}^{-2}.}$$

The FCLET coarse-graining map acts in three stages:

$$\mathcal{C}_{\mathrm{cg}} = \mathcal{D}_\Delta \circ \mathcal{A}_{\mathcal{P}(r)} \circ \mathcal{T}_{\Lambda_{\mathrm{cg}}},$$

where:

- $\mathcal{T}_{\Lambda_{\mathrm{cg}}}$suppresses sub-resolution ultraviolet modes,
- $\mathcal{A}_{\mathcal{P}(r)}$restricts entropy bookkeeping to the shell patch,
- $\mathcal{D}_\Delta$identifies locally indistinguishable microstates.

After canonical vacuum subtraction, the leading finite local entropy content of the shell takes the universal FCLET form

$$\boxed{S_{\mathrm{eff}}(r) = \eta_s\, A(r)\, T_a(r)^2,}$$

where:

- $\eta_s$is the dimensionless species-and-regulator coefficient emerging from the heat-kernel regularized local entropy density,
- $T_a(r)$is the local acceleration temperature of the static patch observer.

This is the simplest finite renormalized realization of the microphysical prescription. It is local, dimensionless, patch-based, and explicitly computable.

10.3 Local acceleration temperature and effective entropy content

A static observer at Schwarzschild radius $r$has proper acceleration

$$\boxed{a(r) = \frac{M}{r^2\sqrt{f(r)}}.}$$

The corresponding local acceleration temperature is

$$\boxed{T_a(r) = \frac{a(r)}{2\pi} = \frac{M}{2\pi r^2\sqrt{f(r)}}.}$$

Substituting into the coarse-grained entropy formula gives

$$S_{\text{eff}}(r) = \eta_s\, A(r)\, T_a(r)^2 = \eta_s(4\pi r^2)\left(\frac{M^2}{4\pi^2 r^4 f(r)}\right).$$

Therefore

$$\boxed{S_{\text{eff}}(r) = \eta_s\, \frac{M^2}{\pi r^2 f(r)}.}$$

This is the explicit finite local realized entropy content of the Schwarzschild exterior patch in the canonical heat-kernel FCLET prescription.

The corresponding realized local bit count is

$$\boxed{N_{\text{loc}}(r) = \frac{S_{\text{eff}}(r)}{\ln 2} = \eta_s\, \frac{M^2}{\pi r^2 f(r)\ln 2}.}$$

The physical content is immediate:

far from the compact object, local burden decays,

as the horizon is approached, the redshift factor drives local burden upward,

the patch therefore enters the nonlinear finite-capacity regime near the strong-field boundary.

10.4 Explicit local occupancy field $I(r)$

The normalized local occupancy field is

$$I(r) = \frac{S_{\text{eff}}(r)}{S_{\max}(r)}.$$

Using the expressions above,

$$I(r) = \frac{\eta_s\, M^2/(\pi r^2 f(r))}{\pi r^2/\ell_P^2} = \eta_s\, \frac{\ell_P^2 M^2}{\pi^2 r^4 f(r)}.$$

Thus the Schwarzschild exterior FCLET burden field is

$$\boxed{I(r) = \eta_s \frac{\ell_P^2 M^2}{\pi^2 r^4 \left(1 - \frac{2M}{r}\right)}.}$$

This is the first explicit worked expression for the FCLET local occupancy field in a concrete background.

It has exactly the behavior the theory requires.

Far-field behavior

For $r \gg 2M$,

$$f(r) \approx 1,$$

and therefore

$$\boxed{I(r) \approx \eta_s \frac{\ell_P^2 M^2}{\pi^2 r^4}.}$$

The burden decays quartically with radius. The local patch is therefore weakly loaded in the far exterior region.

Near-horizon behavior

For $r \to 2M^+$,

$$f(r) \to 0^+,$$

so the burden grows as

$$\boxed{I(r) \sim \frac{1}{f(r)}.}$$

More explicitly, near the horizon one may set $r = 2M(1 + \varepsilon)$with $0 < \varepsilon \ll 1$, so that $f(r) \approx \varepsilon$. Then

$$r^4 \approx 16M^4,$$

and the occupancy field becomes

$$\boxed{I(r) \approx \eta_s \frac{\ell_P^2}{16\pi^2 M^2 f(r)}.}$$

This is the precise strong-field amplification law of the local burden variable in the Schwarzschild exterior.

10.5 Explicit latency field $\chi(r)$

The FCLET latency field is

$$\chi(r) = \frac{I(r)}{1 - I(r)}.$$

Substituting the explicit Schwarzschild occupancy field gives

$$\boxed{\chi(r) = \frac{\eta_s \ell_P^2 M^2}{\pi^2 r^4 f(r) - \eta_s \ell_P^2 M^2}.}$$

Equivalently,

$$\boxed{\chi(r) = \frac{\eta_s \ell_P^2 M^2}{\pi^2 r^4 \left(1 - \frac{2M}{r}\right) - \eta_s \ell_P^2 M^2}.}$$

This is the first explicit FCLET latency profile in a concrete compact-object exterior.

Its physical behavior is exact:

for large r, $I(r) \ll 1$and therefore $\chi(r) \approx I(r)$,

for sufficiently small residual support margin, $I(r) \to 1^-$and $\chi(r)$grows sharply,

the strong-field branch is therefore not postulated but recovered by direct calculation.

10.6 Saturation-shell radius

The strong-field shell forms when the local patch reaches saturation-adjacent burden. Let I_{sat}denote the shell-onset threshold, with

$$0 < I_{\mathrm{sat}} < 1.$$

Then the shell radius $r_s$is defined by

$$\boxed{I(r_s) = I_{\mathrm{sat}}.}$$

Using the near-horizon form,

$$I(r_s) \approx \eta_s \frac{\ell_P^2}{16\pi^2 M^2 f(r_s)} = I_{\text{sat}},$$

so that

$$\boxed{f(r_s) = \eta_s \frac{\ell_P^2}{16\pi^2 M^2 I_{\text{sat}}}.}$$

Near the horizon, $f(r) \approx (r - 2M)/(2M)$, hence

$$\boxed{r_s - 2M \approx \eta_s \frac{\ell_P^2}{8\pi^2 M I_{\text{sat}}}.}$$

This gives the shell radius directly in Schwarzschild coordinate form.

A more physically transparent result is obtained in proper radial distance from the horizon. The near-horizon Schwarzschild line element gives

$$f(r) \approx \frac{\rho^2}{16M^2},$$

where $\rho$is the proper distance from the horizon. Substituting into the near-horizon occupancy field yields

$$I(\rho) \approx \eta_s \frac{\ell_P^2}{\pi^2 \rho^2}.$$

Therefore the shell-onset proper distance is

$$\boxed{\rho_s = \frac{\sqrt{\eta_s}}{\pi\sqrt{I_{\text{sat}}}}\, \ell_P.}$$

This result is structurally decisive. The shell forms at a proper distance of order the Planck length, up to the FCLET species coefficient and the chosen saturation threshold. The theory therefore generates a finite-capacity strong-field shell at a microphysically natural distance from the classical horizon scale.

10.7 Physical consequences of the explicit example

The worked Schwarzschild example establishes five decisive points.

First, the FCLET local burden field is computable in a concrete geometry. It is no longer a purely formal normalized variable.

Second, the local occupancy field decays in the far exterior region and grows sharply near the horizon. This reproduces exactly the qualitative burden profile previously assigned to the strong-field branch.

Third, the latency field is recovered as a genuine derived local slowdown profile. Its strong-field enhancement is not inserted by hand.

Fourth, the shell radius emerges from the occupancy threshold directly. The saturation shell is therefore a calculable finite-capacity structure.

Fifth, the proper shell distance is of order ℓ_P in the canonical heat-kernel realization. This gives the FCLET strong-field sector a concrete microscopic scale and prepares the ground for direct quasi-normal mode and echo calculations.

The worked example therefore does what the first two microphysical papers alone did not yet do: it turns the specification of the local capacity sector into an explicit calculation.

10.8 Consequences for Strong-Field Spectroscopy and Echo Delays

The explicit Schwarzschild-shell calculation immediately generates the first FCLET spectroscopy consequences. Once the saturation shell radius r_s is known, the strong-field compact object no longer obeys the classical black-hole boundary condition of pure horizon absorption. The shell acts instead as a finite-capacity boundary layer with nontrivial response. That single change is enough to modify both the quasi-normal mode spectrum and the late-time echo structure.

10.8.1 Tortoise-coordinate location of the shell

The Schwarzschild tortoise coordinate is

$$r_* = r + 2M\ln\left(\frac{r}{2M} - 1\right).$$

For a shell at

$$r_s = 2M + \delta r_s, 0 < \delta r_s \ll 2M,$$

its tortoise location is

$$r_{*,s} = r_s + 2M\ln\left(\frac{\delta r_s}{2M}\right).$$

Since $\delta r_s$is extremely small, the logarithmic term dominates and pushes the shell to a large negative tortoise coordinate. This is the exact strong-field cavity structure required for FCLET echo formation.

Using the result already derived,

$$\delta r_s \approx \eta_s \frac{\ell_P^2}{8\pi^2 M\, I_{\rm sat}},$$

we obtain

$$\boxed{r_{*,s} \approx 2M + 2M\ln\left(\frac{\eta_s\, \ell_P^2}{16\pi^2 M^2 I_{\rm sat}}\right).}$$

Thus the shell position is fixed by the same microphysical quantities that defined the local occupancy threshold.

10.8.2 Echo delay time

Let $r_{*,\rm peak}$denote the tortoise-coordinate location of the exterior curvature barrier. For the dominant gravitational barrier in Schwarzschild geometry this lies in the neighborhood of the photon-sphere region, $r \sim 3M$, and therefore contributes an order-M constant at leading logarithmic level. The round-trip echo delay is

$$\boxed{\Delta t_{\rm echo} = 2\left(r_{*,\rm peak} - r_{*,s}\right).}$$

Substituting the shell location gives

$$\Delta t_{\rm echo} \approx 4M\ln\left(\frac{2M}{\delta r_s}\right) + \mathcal{O}(M).$$

Using the explicit shell offset,

$$\delta r_s = \eta_s \frac{\ell_P^2}{8\pi^2 M\, I_{\rm sat}},$$

we obtain the FCLET echo law

$$\boxed{\Delta t_{\mathrm{echo}} \approx 4M \ln\left(\frac{16\pi^2 M^2 I_{\mathrm{sat}}}{\eta_s\, \ell_P^2}\right) + \mathcal{O}(M).}$$

This result is decisive. The delay is not arbitrary and not phenomenological. It is fixed by:

the compact-object mass M,

the species coefficient η_s,

the saturation threshold I_{sat},

and the Planck scale.

Equivalently, using the proper shell distance

$$\rho_s = \frac{\sqrt{\eta_s}}{\pi\sqrt{I_{\mathrm{sat}}}}\ell_P,$$

the delay may be written as

$$\boxed{\Delta t_{\mathrm{echo}} \approx 4M \ln\left(\frac{8M}{\rho_s}\right) + \mathcal{O}(M).}$$

This is the cleanest strong-field FCLET echo formula.

10.8.3 Echo frequency spacing

The shell and the exterior barrier form an effective cavity. The characteristic echo frequency spacing is therefore set by the inverse delay scale:

$$\boxed{\Delta f_{\mathrm{echo}} \sim \frac{1}{\Delta t_{\mathrm{echo}}}.}$$

A more precise cavity estimate gives the angular-frequency spacing

$$\boxed{\Delta \omega_{\mathrm{echo}} \sim \frac{\pi}{r_{*,\mathrm{peak}} - r_{*,s}} = \frac{2\pi}{\Delta t_{\mathrm{echo}}}.}$$

Thus the same shell location that determines the latency-saturation boundary also fixes the late-time spectral comb of the remnant.

10.8.4 Modified boundary condition and quasi-normal mode shift

The classical Schwarzschild black hole imposes a purely ingoing boundary condition at the horizon:

$$\Psi(r_*) \sim e^{-i\omega r_*}, r_* \to -\infty.$$

The FCLET shell changes this. At the shell location, the correct linear perturbation boundary condition is no longer purely absorbing. It takes the finite-capacity form

$$\boxed{\Psi(r_{*,s}) \sim e^{-i\omega r_*} + \mathcal{R}_s(\omega)\, e^{+i\omega r_*},}$$

where $\mathcal{R}_s(\omega)$is the shell reflectivity. The shell need not be perfectly reflecting; partial absorption and delayed reprocessing are both admissible. What matters is that $\mathcal{R}_s \neq 0$generically.

This shifts the quasi-normal mode spectrum away from the classical GR values. At leading order, the mode correction has the generic form

$$\boxed{\delta\omega_n \propto \mathcal{R}_s(\omega_n^{\mathrm{GR}})\exp\left(2i\omega_n^{\mathrm{GR}} r_{*,s}\right),}$$

so that the corrected frequencies become

$$\boxed{\omega_n^{\mathrm{FCLET}} = \omega_n^{\mathrm{GR}} + \delta\omega_n.}$$

The correction is exponentially sensitive to the shell position through the large negative tortoise coordinate $r_{*,s}$. This is exactly what one expects from a compact cavity correction: even a shell microscopically close to the classical horizon can produce logarithmically delayed and spectroscopically structured deviations.

10.8.5 Ringdown hierarchy

The explicit Schwarzschild FCLET example therefore implies a three-layer ringdown structure:

Primary ringdown:
: an early-time response close to the classical Schwarzschild quasi-normal spectrum, because the exterior barrier still dominates the first burst of emitted radiation.

Mode-deformed intermediate ringdown:
: small but definite shifts in damping times and oscillation frequencies due to the finite-capacity shell boundary condition.

Late-time echo train:

delayed secondary pulses with spacing set by Δt_{echo}, amplitude controlled by $\mathcal{R}_s$, and spectral spacing controlled by the same cavity scale.

This hierarchy follows directly from the explicit shell radius already derived. It is not an added phenomenological branch. It is the observational continuation of the microphysical local-capacity calculation.

10.8.6 FCLET strong-field prediction

The strong-field prediction of the explicit Schwarzschild patch example can therefore be stated in exact form:

A compact object whose local occupancy field reaches I_{sat} develops a shell at $\rho_s = \dfrac{\sqrt{\eta_s}}{\pi\sqrt{I_{\mathrm{sat}}}}\ell_P$,

and this shell induces both quasi-normal mode shifts and an echo delay $\Delta t_{\mathrm{echo}} \approx 4M\ln\left(\dfrac{8M}{\rho_s}\right) + \mathcal{O}(M)$.

This is the first direct bridge from FCLET microphysical burden variables to observable ringdown phenomenology.

10.9 Interpretation of the Worked Example

The importance of the Schwarzschild calculation is not limited to strong-field phenomenology. It demonstrates something more basic and more important: the FCLET local-capacity prescription can be executed.

The theory now possesses:

a concrete patch choice,

a concrete entropy regularization prescription,

a concrete maximal capacity,

a concrete occupancy profile,

a concrete latency profile,

and a concrete shell radius.

That is the difference between an abstract burden field and a calculable one.

The worked example also clarifies the logic of the FCLET hierarchy.

Far from the compact object,

$$I(r) \ll 1, \chi(r) \approx I(r),$$

so the patch is perturbative and weakly burdened. This reproduces the low-load recovery structure of the program.

Near the strong-field boundary,

$$I(r) \to I_{\mathrm{sat}}, \chi(r) \text{ grows sharply,}$$

and a shell emerges at a finite proper distance from the classical horizon scale. This reproduces the saturation logic of the compact-object branch.

The local microphysical calculation therefore recovers both extremes of the theory inside one explicit geometry.

10.10 Consequences for the Existing FCLET Program

The Schwarzschild worked example materially strengthens the entire program.

First, it shows that the local microphysical variables are not merely formal definitions. They can be evaluated in a real background.

Second, it ties the microphysical capacity sector directly to the strong-field branch, thereby joining two parts of the FCLET architecture that were previously connected only conceptually.

Third, it provides a direct route to the next decisive calculation: the full quasi-normal mode spectrum of saturation-shell compact objects. The quantities needed for that problem are now explicit:

shell radius,

shell proper distance,

cavity delay scale,

and modified boundary condition.

Fourth, it establishes the methodological standard for future FCLET microphysical applications. The theory no longer needs to speak only in structural language. It can now take a geometry, define a patch, compute S_{eff}, derive $I(x)$, and obtain $\chi(x)$.

That is a major strengthening of the program.

11. Benchmark Numerical Estimates for ρ_s, Δt_{echo}, and Δf_{echo} in FCLET Schwarzschild Shells

The worked Schwarzschild example of Section 10 establishes the exact structural relations of the FCLET shell sector. To convert that structure into an observationally legible benchmark, we now fix a canonical numerical choice for the two remaining shell parameters and evaluate

the resulting proper shell distance, echo delay, and characteristic echo-frequency spacing for representative stellar-mass compact objects.

11.1 Canonical benchmark choice

For the purposes of a concrete benchmark estimate, we adopt

$$\boxed{\eta_s = 1, I_{\mathrm{sat}} = \frac{1}{2}.}$$

These values are not introduced as arbitrary fit choices. They define the canonical demonstration benchmark of the present paper:

$\eta_s = 1$corresponds to the minimal renormalized species-loading normalization,

$I_{\mathrm{sat}} = 1/2$identifies shell onset with the point at which realized local burden and residual support margin are of the same order.

With this benchmark, the shell proper distance becomes

$$\rho_s = \frac{\sqrt{\eta_s}}{\pi\sqrt{I_{\mathrm{sat}}}}\ell_P = \frac{1}{\pi\sqrt{1/2}}\ell_P = \frac{\sqrt{2}}{\pi}\ell_P.$$

Thus

$$\boxed{\rho_s \approx 0.450\,\ell_P.}$$

This places the shell at a Planck-scale proper distance from the classical horizon location, exactly as required by the finite-capacity strong-field logic.

11.2 Echo-delay formula in benchmark form

Using the canonical benchmark shell distance, the leading FCLET echo delay becomes

$$\Delta t_{\mathrm{echo}} \approx 4M\ln\left(\frac{8M}{\rho_s}\right).$$

Substituting $\rho_s = 0.450\,\ell_P$gives the explicit mass-dependent delay scale. The corresponding characteristic echo-frequency spacing is

$$\Delta f_{\mathrm{echo}} \sim \frac{1}{\Delta t_{\mathrm{echo}}}.$$

These quantities can now be evaluated directly.

11.3 Stellar-mass benchmark estimates

Using $M_\odot = 4.92549095\ \mu$sin geometric time units, the resulting FCLET benchmark values are:

Table 1. Canonical FCLET Schwarzschild-shell benchmark estimates

Mass M	ρ_s/ℓ_P	Δt_{echo}	Δf_{echo}
$10\ M_\odot$	0.450	18.24 ms	54.8 Hz
$30\ M_\odot$	0.450	55.37 ms	18.1 Hz
$60\ M_\odot$	0.450	111.57 ms	9.0 Hz

These values establish the first concrete FCLET strong-field benchmark window. A $30\ M_\odot$remnant, which lies in the mass range of the earliest LIGO binary-black-hole events, yields a characteristic FCLET echo delay of approximately

$$\boxed{\Delta t_{\text{echo}}(30\ M_\odot) \approx 55.4\ \text{ms},}$$

with characteristic frequency spacing

$$\boxed{\Delta f_{\text{echo}}(30\ M_\odot) \approx 18.1\ \text{Hz}.}$$

This is no longer a symbolic strong-field prediction. It is a concrete observational benchmark.

11.4 Scaling laws

The benchmark values above can be generalized immediately.

Since

$$\rho_s = \frac{\sqrt{\eta_s}}{\pi\sqrt{I_{\text{sat}}}}\ell_P,$$

the shell proper distance scales as

$$\boxed{\rho_s \propto \sqrt{\eta_s}\, I_{\text{sat}}^{-1/2}.}$$

The echo delay then scales as

$$\boxed{\Delta t_{\mathrm{echo}} \approx 4M \ln\left(\frac{8\pi M\sqrt{I_{\mathrm{sat}}}}{\sqrt{\eta_s}\,\ell_P}\right).}$$

Thus:

increasing η_s pushes the shell outward slightly in proper distance and shortens the logarithmic cavity depth,

increasing I_{sat} pulls the shell inward and increases the logarithmic delay,

increasing M increases the delay approximately linearly, up to the slow logarithmic correction.

This is the exact benchmark scaling law of the FCLET shell sector.

11.5 Reflectivity benchmark and ringdown visibility

To translate the cavity structure into a minimal observational template, we adopt the simplest benchmark shell reflectivity model,

$$\boxed{\mathcal{R}_s(\omega) = R_0, 0 < R_0 < 1,}$$

with constant reflectivity over the dominant ringdown band. The amplitude of the first echo is then suppressed relative to the primary ringdown by a factor of order R_0, while successive echoes acquire additional cavity and barrier suppression.

The present paper does not yet fit R_0 to data. Its purpose here is to establish the benchmark delay scale and the cavity frequency spacing. That is already sufficient to define a falsifiable observational window:

the shell location fixes the delay,

the cavity fixes the frequency spacing,

the reflectivity fixes the echo strength.

The next strong-field paper can therefore proceed directly to quasi-normal mode deformation and signal-template construction with explicit FCLET shell input rather than with abstract shell placeholders.

11.6 Observational meaning of the benchmark

The benchmark estimates above sharpen the status of the FCLET compact-object sector considerably.

First, the shell proper distance is no longer only parametrically "near Planckian." It is explicitly Planck-scale with a calculable prefactor.

Second, the echo delay lies in a range that is at least in principle comparable to ringdown follow-up analysis windows used in gravitational-wave searches.

Third, the frequency spacing falls directly into the low-frequency structure relevant to late-time post-merger analysis for stellar-mass remnants.

Fourth, the theory now makes a concrete benchmark statement:

For a $30\,M_\odot$ Schwarzschild-like FCLET shell remnant, the canonical benchmark delay is $\Delta t_{\mathrm{echo}} \approx 55.4$ ms.

That is the correct form of a testable strong-field prediction.

11.7 FCLET benchmark statement

The Schwarzschild-shell sector of FCLET can now be summarized in one benchmark theorem-like statement:

$$\eta_s = 1,\ I_{\mathrm{sat}} = \frac{1}{2} \Longrightarrow \rho_s \approx 0.450\,\ell_P,$$

$$\Delta t_{\mathrm{echo}}(10\,M_\odot) \approx 18.24\ \mathrm{ms},\ \Delta t_{\mathrm{echo}}(30\,M_\odot) \approx 55.37\ \mathrm{ms},\ \Delta t_{\mathrm{echo}}(60\,M_\odot) \approx 111.57\ \mathrm{ms}.$$

This is the first FCLET strong-field numerical benchmark table derived from the local microphysical burden prescription itself.

12. Species-Based Benchmark Estimate of η_s and the Resulting FCLET Echo Scale

The benchmark estimates of Section 11 established the first explicit FCLET strong-field timing window. But a Planck-scale shell and a logarithmic echo delay are not by themselves unique to FCLET. To turn the shell sector into a theory-specific benchmark, the species-loading coefficient η_s must be tied to microphysical field content rather than left as a purely symbolic placeholder.

This section does exactly that at benchmark level. It introduces a species-resolved definition of η_s, fixes a canonical scalar-normalized weighting convention, and shows explicitly how the resulting values modify the shell distance and echo-delay scale. The central outcome is structurally important: the echo delay depends only logarithmically on η_s, while the shell proper distance depends on $\sqrt{\eta_s}$. The immediate implication is that timing alone is only weakly discriminating, whereas shell reflectivity and quasi-normal mode deformation inherit a stronger microphysical dependence.

12.1 Species-resolved definition of η_s

In the heat-kernel realization of the FCLET coarse-graining map, the local renormalized entropy loading of a patch is the sum of the admissible contributions from the effective field content supported on that patch. The natural species-resolved form is therefore

$$\boxed{\eta_s = \xi_0 N_0 + \xi_{1/2} N_{1/2} + \xi_1 N_1 + \xi_{\text{other}} N_{\text{other}},}$$

where:

N_0 counts effective real scalar species,

$N_{1/2}$ counts effective Dirac fermion species,

N_1 counts effective vector species,

N_{other} denotes any additional microphysical sectors carried by the chosen field inventory,

ξ_a are the corresponding renormalized entropy-loading weights in the canonical FCLET prescription.

The precise values of the ξ_a coefficients remain tied to the chosen regularization and renormalization convention, but the benchmark structure of the theory does not require that every field-theoretic subtlety be resolved at once. It requires a fixed operational weighting convention from which explicit strong-field estimates can be produced and then refined.

We therefore impose the canonical scalar-normalized FCLET benchmark weights

$$\boxed{\xi_0 = 1, \xi_{1/2} = 2, \xi_1 = 2.}$$

This convention is not inserted as an arbitrary fit device. It is the minimal strong-field benchmark rule:

one real scalar defines the unit loading,

one Dirac fermion carries twice that loading,

one vector species carries twice that loading.

The resulting η_s then becomes a definite function of the chosen effective field inventory.

12.2 Canonical benchmark field inventories

Under the scalar-normalized weighting convention above, several benchmark microphysical inventories can be defined immediately.

Benchmark A: single real scalar

$$N_0 = 1, N_{1/2} = 0, N_1 = 0$$

so that

$$\boxed{\eta_s^{(A)} = 1.}$$

Benchmark B: single Dirac fermion

$$N_0 = 0, N_{1/2} = 1, N_1 = 0$$

so that

$$\boxed{\eta_s^{(B)} = 2.}$$

Benchmark C: single vector field

$$N_0 = 0, N_{1/2} = 0, N_1 = 1$$

so that

$$\boxed{\eta_s^{(C)} = 2.}$$

Benchmark D: minimal mixed sector

Take one real scalar, one Dirac fermion, and one vector:

$$N_0 = 1, N_{1/2} = 1, N_1 = 1.$$

Then

$$\boxed{\eta_s^{(D)} = 1 + 2 + 2 = 5.}$$

Benchmark E: enlarged mixed sector

For a moderate effective multiplet

$$N_0 = 2, N_{1/2} = 2, N_1 = 2,$$

we obtain

$$\boxed{\eta_s^{(E)} = 2 + 4 + 4 = 10.}$$

These five benchmark values already span the range needed to evaluate the sensitivity of the FCLET shell sector to microphysical field content:

$$\boxed{\eta_s \in \{1, 2, 5, 10\}.}$$

12.3 Shell distance as a function of field content

The shell proper distance is

$$\rho_s = \frac{\sqrt{\eta_s}}{\pi\sqrt{I_{\mathrm{sat}}}}\ell_P.$$

Retaining the canonical shell-onset threshold

$$\boxed{I_{\mathrm{sat}} = \frac{1}{2},}$$

this becomes

$$\boxed{\rho_s = \frac{\sqrt{2\eta_s}}{\pi}\,\ell_P.}$$

Thus the shell distance scales explicitly with the square root of the field-content loading.

Table 2. Species-based shell-distance benchmarks

Benchmark	$\boldsymbol{\eta_s}$	$\boldsymbol{\rho_s/\ell_P}$
A: single scalar	1	0.450
B: single Dirac fermion	2	0.637
C: single vector	2	0.637
D: scalar + Dirac + vector	5	1.007
E: enlarged mixed sector	10	1.424

This result is already significant. While the echo delay depends only logarithmically on η_s, the shell proper distance changes by more than a factor of three across this benchmark range. Any shell reflectivity model $\mathcal{R}_s(\omega)$tied to the microscopic shell structure will therefore inherit a correspondingly stronger field-content dependence.

12.4 Echo-delay scale as a function of field content

The benchmark echo law derived earlier reads

$$\Delta t_{\mathrm{echo}} \approx 4M\ln\left(\frac{8M}{\rho_s}\right).$$

Substituting the species-based shell distance gives

$$\boxed{\Delta t_{\mathrm{echo}} \approx 4M\ln\left(\frac{8\pi M\sqrt{I_{\mathrm{sat}}}}{\sqrt{\eta_s}\,\ell_P}\right).}$$

For the canonical threshold $I_{\mathrm{sat}} = 1/2$,

$$\boxed{\Delta t_{\mathrm{echo}} \approx 4M\ln\left(\frac{8\pi M}{\sqrt{2\eta_s}\,\ell_P}\right).}$$

This shows the dependence explicitly:

increasing $\eta_s$pushes the shell outward,

the cavity becomes slightly shorter,

the echo delay decreases logarithmically.

For a $30\,M_\odot$remnant, the benchmark values become:

Table 3. Species-based FCLET echo-delay benchmarks for $M = 30\,M_\odot$

Benchmark	η_s	ρ_s/ℓ_P	Δt_{echo}	Δf_{echo}
A: single scalar	1	0.450	55.37 ms	18.1 Hz
B: single Dirac fermion	2	0.637	54.96 ms	18.2 Hz
C: single vector	2	0.637	54.96 ms	18.2 Hz
D: scalar + Dirac + vector	5	1.007	54.42 ms	18.4 Hz
E: enlarged mixed sector	10	1.424	54.01 ms	18.5 Hz

These numbers make the observational situation transparent. The shell distance reacts noticeably to field content, but the delay reacts only weakly because the dependence is

logarithmic. A one-order-of-magnitude change in η_s shifts the $30\ M_\odot$ benchmark delay by only about 1.36 ms.

12.5 Why the echo delay alone is not yet FCLET-unique

This result is physically important and must be stated directly. A Planck-scale shell generically produces an echo delay of the form

$$\Delta t_{\mathrm{echo}} \sim 4M \ln\left(\frac{M}{\ell_P}\right),$$

up to order-unity factors inside the logarithm. FCLET does not escape that generic structure. The present benchmark calculation therefore does not claim that the delay scale alone is unique to FCLET.

What FCLET adds is not the existence of a logarithmic Planck-shell echo scale by itself, but the derivation of the shell position from local information burden,

$$I(r_s) = I_{\mathrm{sat}},$$

and the resulting field-content dependence carried by η_s. The timing scale is therefore a necessary but not sufficient discriminator.

This leads to the exact strong-field methodological conclusion:

("*In FCLET, echo timing is only weakly sensitive to species loading, whereas shell structure and reflectivity are much more sensitive.*")

The genuinely FCLET-specific observational content must therefore come from the combined package:

species-based shell position,

physically fixed saturation threshold,

shell reflectivity $\mathcal{R}_s(\omega)$,

resulting quasi-normal mode deformation and echo amplitude pattern.

12.6 Species dependence of the quasi-normal mode deformation

The mode-correction formula obtained earlier was

$$\delta\omega_n \propto \mathcal{R}_s(\omega_n^{\mathrm{GR}}) \exp\left(2i\omega_n^{\mathrm{GR}} r_{*,s}\right).$$

Since $r_{*,s}$depends on $\eta_s$through the shell offset, and $\mathcal{R}_s(\omega)$is expected to depend on the microphysics of the shell itself, the field-content dependence enters the strong-field spectrum through two distinct channels:

geometric channel: shell location,

boundary-response channel: shell reflectivity.

The geometric channel modifies the phase of the spectral correction only logarithmically. The boundary-response channel can be much stronger. That is why a future FCLET reflectivity paper will likely be more decisive observationally than the timing benchmark alone.

The present section therefore establishes the correct hierarchy:

$\eta_s$fixes the shell distance,

shell distance fixes the delay scale,

but $\mathcal{R}_s(\omega)$is the main gateway to theory-specific spectroscopic distinction.

12.7 FCLET benchmark statement with species content

The benchmark result of the Schwarzschild-shell sector can now be stated in a microphysically sharpened way:

$$\boxed{\eta_s = \xi_0 N_0 + \xi_{1/2} N_{1/2} + \xi_1 N_1 \Longrightarrow \rho_s = \frac{\sqrt{\eta_s}}{\pi\sqrt{I_{\mathrm{sat}}}}\ell_P,}$$

$$\boxed{\Delta t_{\mathrm{echo}} \approx 4M \ln\left(\frac{8\pi M\sqrt{I_{\mathrm{sat}}}}{\sqrt{\eta_s}\,\ell_P}\right).}$$

For the canonical benchmark threshold $I_{\mathrm{sat}} = 1/2$, a 30 $M_\odot$remnant gives a delay window in the narrow range

$$\boxed{54.0\ \mathrm{ms} \lesssim \Delta t_{\mathrm{echo}} \lesssim 55.4\ \mathrm{ms}}$$

across the benchmark species range $\eta_s \in \{1,2,5,10\}$.

This is the first species-based FCLET strong-field benchmark window.

12.8 Consequence for the next FCLET strong-field paper

The outcome of the present section is exact in strategic terms. The strong-field FCLET program no longer needs a generic Planck-shell timing estimate. It now needs the next decisive step:

compute η_s from a definite field inventory and regularization prescription,

derive I_{sat} from a physical shell-onset criterion rather than benchmark choice,

and construct $\mathcal{R}_s(\omega)$ from the shell microphysics itself.

Only then does the theory move from benchmark timing to genuinely distinctive ringdown spectroscopy.

The present section therefore does not close the strong-field problem. It sharpens it into a calculable final target.

13. Physical Shell-Onset Criterion for I_{sat}

The benchmark estimates of Sections 11 and 12 fixed the shell-onset threshold at

$$I_{\mathrm{sat}} = \frac{1}{2}$$

as the canonical demonstration value. That choice was operationally useful, but the strong-field sector becomes substantially stronger once the threshold is derived from the internal logic of the theory rather than inserted as a benchmark convention. This section provides that derivation.

The central result is exact: the FCLET saturation shell begins when realized local burden and residual support margin become equal. This condition fixes the shell-onset threshold uniquely at

$$\boxed{I_{\mathrm{sat}} = \frac{1}{2}.}$$

This is not a convenient choice. It is the physical shell-onset criterion implied by finite-capacity patch dynamics.

13.1 Residual support margin

The normalized local occupancy field is

$$I(x) = \frac{S_{\mathrm{eff}}(x)}{S_{\max}(x)}, 0 \le I(x) < 1.$$

The complementary quantity

$$\boxed{\mathcal{W}(x) = 1 - I(x)}$$

is the residual support margin of the patch. It measures how much admissible local capacity remains available.

The FCLET latency field is

$$\chi(x) = \frac{I(x)}{1 - I(x)} = \frac{I(x)}{\mathcal{W}(x)}.$$

This form makes the physical interpretation exact. The patch does not respond to local burden alone. It responds to the ratio between realized burden and what remains available.

That ratio defines the onset of strong nonlinearity.

13.2 Physical meaning of shell onset

A saturation shell is not the state in which the patch is already maximally filled. It is the state in which the local patch first ceases to behave as a weakly burdened domain and enters the self-reinforcing finite-capacity regime.

That transition occurs when the local burden is no longer small compared to the remaining support margin. In exact FCLET language, shell onset occurs when

$$\boxed{I(x) \sim \mathcal{W}(x).}$$

Before that point,

$$I(x) < \mathcal{W}(x),$$

and the patch remains support-dominated: the residual capacity exceeds the realized burden, so the latency response remains subcritical.

After that point,

$$I(x) > \mathcal{W}(x),$$

and the patch becomes burden-dominated: the realized burden exceeds the remaining support margin, so the nonlinear response amplifies rapidly and the system is driven toward saturation-adjacent shell structure.

The shell-onset threshold is therefore defined by the equality condition

$$\boxed{I_{\mathrm{sat}} = 1 - I_{\mathrm{sat}}.}$$

Solving gives

$$\boxed{I_{\text{sat}} = \frac{1}{2}.}$$

This is the physical shell-onset threshold of the theory.

13.3 Equivalent latency criterion

The same result follows directly from the latency field itself.

The shell begins when the patch exits the low-latency regime and enters the nonlinear regime in which latency cost is no longer perturbative. The natural crossover occurs at

$$\boxed{\chi = 1.}$$

Using the FCLET burden map,

$$\chi = \frac{I}{1 - I},$$

the condition $\chi = 1$gives

$$\frac{I}{1 - I} = 1 \Longrightarrow I = 1 - I \Longrightarrow I = \frac{1}{2}.$$

Thus the shell-onset criterion can be written equivalently as

$$\boxed{I_{\text{sat}} = \frac{1}{2} \Leftrightarrow \chi_{\text{sat}} = 1.}$$

This is a highly useful equivalence. It says that the shell does not begin at an arbitrary occupancy level, but precisely when the latency cost becomes equal to the residual support scale of the patch.

13.4 Why the shell does not begin at $I \ll 1$or $I \to 1$

The FCLET threshold must lie between the perturbative and asymptotically saturated limits.

If one chose

$$I_{\text{sat}} \ll 1,$$

then shell onset would occur while the patch is still transparently weakly loaded. That would destroy the distinction between weak-load perturbative sectors and strong-field shell sectors.

If one chose

$$I_{\mathrm{sat}} \to 1,$$

then shell onset would occur only at the point of near-complete capacity exhaustion. That would make the shell a terminal artifact rather than the finite-thickness strong-field transition structure required by the theory.

The physically correct threshold must therefore occur at the crossover between:

support-dominated patch behavior, and

burden-dominated patch behavior.

That crossover is exactly the equal-balance condition

$$I = \mathcal{W}.$$

Hence the threshold

$$\boxed{I_{\mathrm{sat}} = \frac{1}{2}}$$

is not merely plausible. It is the unique finite-capacity crossover point consistent with the FCLET burden map.

13.5 Shell threshold in entropy language

Using

$$I(x) = \frac{S_{\mathrm{eff}}(x)}{S_{\mathrm{max}}(x)},$$

the shell-onset condition becomes

$$\boxed{\frac{S_{\mathrm{eff}}(x)}{S_{\mathrm{max}}(x)} = \frac{1}{2}.}$$

Equivalently,

$$\boxed{S_{\mathrm{eff}}(x) = \frac{1}{2}\, S_{\mathrm{max}}(x).}$$

This gives the strongest physical interpretation of the threshold: the shell begins when the patch has realized one half of its admissible local information capacity. At that point the remaining support margin is also one half, and the latency cost reaches unity.

Thus the shell-onset condition is not merely a condition on I. It is an exact entropy-balance condition on the local causal patch itself.

13.6 Consequence for the shell proper distance

Substituting the physically derived threshold into the shell-distance formula,

$$\rho_s = \frac{\sqrt{\eta_s}}{\pi\sqrt{I_{\mathrm{sat}}}}\ell_P,$$

gives

$$\rho_s = \frac{\sqrt{\eta_s}}{\pi\sqrt{1/2}}\ell_P = \frac{\sqrt{2\eta_s}}{\pi}\ell_P.$$

Therefore

$$\boxed{\rho_s = \frac{\sqrt{2\eta_s}}{\pi}\,\ell_P.}$$

This result is now stronger than the benchmark version of Section 11. The shell distance is no longer tied to an inserted threshold parameter. It is tied to a threshold derived from the internal burden-support balance of FCLET itself.

The corresponding echo-delay law becomes

$$\boxed{\Delta t_{\mathrm{echo}} \approx 4M\ln\left(\frac{8\pi M}{\sqrt{2\eta_s}\,\ell_P}\right).}$$

Thus the strong-field timing window is now determined by only one genuinely unresolved microphysical loading factor, η_s. The shell threshold itself is fixed.

13.7 FCLET shell-onset theorem

The strong-field onset structure of the theory can therefore be summarized as follows:

("*A local FCLET patch enters shell*
– forming saturation onset when realized burden equals residual support margin.")

Equivalently,

$$\boxed{I_{\mathrm{sat}} = 1 - I_{\mathrm{sat}}, I_{\mathrm{sat}} = \frac{1}{2}, \chi_{\mathrm{sat}} = 1.}$$

This is the physical shell-onset theorem of the FCLET compact-object sector.

It removes the last arbitrariness from the shell threshold and sharpens the status of the benchmark timing results derived earlier. The only remaining microphysical freedom in the canonical Schwarzschild shell estimate is the species-loading coefficient η_s, not the shell-onset threshold itself.

13.8 Consequence for the next strong-field calculation

With I_{sat}now fixed by the internal balance structure of the theory, the next decisive task becomes exact and isolated:

$$\boxed{\text{compute } \eta_s \text{ from a definite field inventory and regularization prescription.}}$$

Once that is done, the shell distance, echo delay, and cavity spacing of the FCLET strong-field sector are no longer benchmark quantities. They become theory-specific numerical predictions.

The strong-field program is therefore now reduced to a sharply defined final microphysical target rather than a diffuse parameter ambiguity.

14. Final Strong-Field Prediction Window for FCLET Compact Objects

The preceding sections have now fixed every element of the FCLET shell sector except one: the species-loading coefficient η_s. The shell-onset threshold is no longer a benchmark insertion. It has been derived internally from the finite-capacity balance condition

$$I_{\mathrm{sat}} = \frac{1}{2}, \chi_{\mathrm{sat}} = 1.$$

The shell distance, echo delay, and characteristic cavity spacing are therefore no longer functions of two open parameters. They are functions of only one remaining microphysical loading factor. This sharply reduces the strong-field ambiguity of the theory and allows the FCLET compact-object sector to be expressed as a final prediction window.

14.1 Canonical one-parameter strong-field sector

With the shell threshold fixed, the shell proper distance is

$$\boxed{\rho_s = \frac{\sqrt{2\eta_s}}{\pi}\,\ell_P.}$$

The corresponding Schwarzschild shell offset is

$$\boxed{r_s - 2M \approx \eta_s\,\frac{\ell_P^2}{4\pi^2 M}.}$$

The tortoise-coordinate shell location is then

$$\boxed{r_{*,s} \approx 2M + 2M\ln\left(\frac{\eta_s\,\ell_P^2}{8\pi^2 M^2}\right),}$$

and the leading FCLET echo delay becomes

$$\boxed{\Delta t_{\text{echo}} \approx 4M\ln\left(\frac{8\pi M}{\sqrt{2\eta_s}\,\ell_P}\right).}$$

The characteristic echo-frequency spacing is therefore

$$\boxed{\Delta f_{\text{echo}} \sim \frac{1}{\Delta t_{\text{echo}}}.}$$

These relations define the canonical one-parameter strong-field prediction sector of FCLET. Once $\eta_s$is fixed from field content, the entire shell timing structure is fixed.

14.2 Field-content prediction window

The benchmark species analysis of Section 12 already showed that physically reasonable field-content choices produce a bounded range of η_s. Taking the canonical benchmark span

$$\boxed{\eta_s \in [1,10],}$$

the shell proper distance lies in the range

$$\boxed{0.450\,\ell_P \lesssim \rho_s \lesssim 1.424\,\ell_P.}$$

This means that the FCLET shell is not arbitrarily placed. It is confined to a narrow Planck-scale proper-distance window fixed by the microphysical burden structure of the theory.

The corresponding strong-field timing window for a Schwarzschild-like remnant of mass $M$is

$$\boxed{4M\ln\left(\frac{8\pi M}{\sqrt{20}\,\ell_P}\right) \lesssim \Delta t_{\text{echo}} \lesssim 4M\ln\left(\frac{8\pi M}{\sqrt{2}\,\ell_P}\right).}$$

For stellar-mass compact objects, this gives a narrow timing band rather than an unrestricted echo scale.

14.3 Representative prediction window for stellar-mass remnants

For the representative mass values $10\,M_\odot$, $30\,M_\odot$, and $60\,M_\odot$, the FCLET strong-field timing window becomes:

Table 4. Final FCLET strong-field timing window for canonical species range $\eta_s \in [1, 10]$

Mass M	ρ_s/ℓ_P range	Δt_{echo} range	Δf_{echo} range
$10\,M_\odot$	0.450–1.424	17.8–18.2 ms	54.9–56.2 Hz
$30\,M_\odot$	0.450–1.424	54.0–55.4 ms	18.1–18.5 Hz
$60\,M_\odot$	0.450–1.424	108.9–111.6 ms	9.0–9.2 Hz

These numbers show that the FCLET shell timing sector is already quite constrained once the shell-onset threshold is fixed physically. The remaining uncertainty is logarithmic in η_s, so even a broad species interval produces a narrow observational time window.

14.4 What is and is not distinctive in the timing window

The FCLET prediction window must be interpreted correctly.

It is distinctive in the following sense:

- the shell position is derived from local burden saturation rather than inserted as a free microscopic wall,
- the shell threshold is fixed internally by the equality of realized burden and residual support margin,
- the species-loading coefficient enters in a controlled and explicitly derived way,

the shell timing window is therefore tied to the theory's finite-capacity microphysics.

But it is not yet fully distinctive in the stronger sense of uniquely isolating FCLET from every other Planck-scale shell model through delay time alone. Because the delay depends logarithmically on shell position, many Planck-scale near-horizon models naturally fall into a similar timing band. The true discriminatory power of FCLET will therefore not come from timing alone.

That power must come from the combined observable package:

shell location,

shell reflectivity $\mathcal{R}_s(\omega)$,

quasi-normal mode deformation,

echo amplitude hierarchy,

consistency with the same $\eta_s$inferred from the underlying species inventory.

This is the exact strong-field logic of the theory.

14.5 FCLET prediction theorem for Schwarzschild-like remnants

The canonical strong-field prediction of FCLET can now be stated in compact theorem-like form:

$$\boxed{I_{\text{sat}} = \frac{1}{2} \Longrightarrow \rho_s = \frac{\sqrt{2\eta_s}}{\pi}\ell_P,}$$

$$\boxed{\Delta t_{\text{echo}} \approx 4M\ln\left(\frac{8\pi M}{\sqrt{2\eta_s}\,\ell_P}\right), \Delta f_{\text{echo}} \sim \frac{1}{\Delta t_{\text{echo}}}.}$$

For canonical field-content loading in the range $\eta_s \in [1,10]$, stellar-mass FCLET remnants lie in a narrow echo-delay window of order 10^{-2}–10^{-1} seconds and a corresponding low-frequency spacing window of order 10–10^2 hertz.

This is the final strong-field timing prediction window of the present paper.

14.6 Strong-field falsification target

The theory now has a sharp observational implication. For a compact-object merger producing a Schwarzschild-like remnant of mass M, the FCLET shell sector predicts that any shell-induced late-time structure must fall within the timing window defined above, up to corrections from spin, mode mixing, and the exact shell reflectivity profile.

This gives the theory a falsification target:

if high-SNR ringdown data systematically exclude shell-like late-time structure in the FCLET timing band while simultaneously excluding the corresponding quasi-normal mode deformation pattern, then the canonical Schwarzschild-shell realization of the theory is strongly constrained;

if a consistent shell-timing and shell-spectroscopy signature appears in that same band, the theory gains direct strong-field support.

The point is not that any one echo claim proves FCLET. The point is that FCLET now defines where its strong-field compact-object signatures must live.

14.7 Consequence for the next paper

The strong-field program is now reduced to one decisive remaining task: construct the shell reflectivity and mode-deformation sector from the same microphysical burden logic that fixed the shell location. That next calculation will determine whether FCLET produces observationally distinctive ringdown structure beyond the generic Planck-shell logarithmic timing scale.

The present paper therefore reaches a clear endpoint. It has:

defined the local burden variables microphysically,

specified the coarse-graining and patch logic operationally,

executed a worked Schwarzschild calculation,

derived the shell location,

fixed the shell threshold physically,

and produced the final timing window of the canonical strong-field sector.

The next strong-field paper can begin exactly where this one ends.

15. Consequences for the Existing FCLET Program

This specification paper sharpens every branch of the theory.

It removes the floating ambiguity in $\mathcal{C}_{\mathrm{cg}}$, fixes the patch normalization, defines the vacuum zero point, and turns regime-dependent patch choice into a single causal-selection rule.

The result is that FCLET's central burden variable is now not only microphysically motivated, but operationally fixed. That strengthens:

weak-field recovery,

cosmological burden interpretation,

strong-field saturation structure,

stochastic fluctuation meaning,

quantum-sector burden language,

and future data-driven numerical implementations.

The most important consequence is foundational: the theory's central field variables are no longer scheme-floating placeholders. They are specified local physical quantities.

16. Conclusion

We have completed the microphysical specification of the local information-capacity sector of the finite-capacity latency–erasure theory and carried that specification through to an explicit strong-field calculation.

The paper achieved four foundational results. First, it fixed the coarse-graining structure of the local burden sector by defining the FCLET entropy-selection operator as a concrete composition of admissible mode truncation, causal accessibility restriction, and finite-resolution distinguishability. Second, it removed the floating normalization ambiguity of the patch-capacity sector by fixing the canonical geometric factor to $\zeta_{\mathcal{P}} = 1$. Third, it imposed the canonical vacuum normalization $I_{\mathrm{vac}} = 0$in the renormalized Minkowski reference patch, thereby giving the burden field a clean physical zero point. Fourth, it replaced regime-by-regime patch choice with a single patch-selection principle based on minimal causal accessibility and capacity consistency.

These results transformed the local FCLET burden variables from structurally motivated quantities into operationally specified ones. The theory now possesses a fixed prescription for $S_{\mathrm{eff}}(x)$, $N_{\mathrm{loc}}(x)$, $N_{\max}(x)$, $I(x)$, and $\chi(x)$. The local substrate basis of the theory is therefore no longer incomplete. It is specified.

We then executed that prescription in a concrete geometry. In the Schwarzschild exterior patch, we derived an explicit local entropy content, an explicit occupancy profile $I(r)$, and an explicit latency profile $\chi(r)$. From these quantities we obtained the shell-onset condition, the shell radius, the shell proper distance, the shell tortoise-coordinate location, and the leading echo-delay law. The strong-field branch of FCLET is therefore no longer only conceptually motivated. It is calculable.

The shell threshold itself has also been fixed physically. The onset of shell formation is not an inserted benchmark convention, but the exact burden-support crossover of the finite-capacity patch:

$$I_{\mathrm{sat}} = 1 - I_{\mathrm{sat}}, I_{\mathrm{sat}} = \frac{1}{2}, \chi_{\mathrm{sat}} = 1.$$

With this result, the canonical FCLET shell sector becomes a one-parameter strong-field system controlled only by the species-loading coefficient η_s. The shell proper distance is therefore

$$\rho_s = \frac{\sqrt{2\eta_s}}{\pi}\ell_P,$$

and the corresponding echo-delay law is

$$\Delta t_{\text{echo}} \approx 4M\ln\left(\frac{8\pi M}{\sqrt{2\eta_s}\,\ell_P}\right).$$

We further showed that for canonical benchmark field-content loading, stellar-mass compact remnants occupy a narrow FCLET timing window in the late-time ringdown regime. This gives the theory its first explicit strong-field numerical benchmark.

At the same time, the paper clarified the exact observational hierarchy of the shell sector. The echo delay is a necessary strong-field consequence of the FCLET shell, but it is not by itself the most discriminating observable, since logarithmic timing windows are shared by a broader class of Planck-scale near-horizon shell models. The genuinely theory-specific content lies in the complete strong-field package: shell location derived from local burden saturation, species-resolved η_s, shell reflectivity $\mathcal{R}_s(\omega)$, quasi-normal mode deformation, and echo amplitude hierarchy. The timing window is therefore the entry point of the FCLET compact-object sector, not its final observational endpoint.

The structural significance of the present paper is decisive. The FCLET program now possesses:

a specified local coarse-graining prescription,

a fixed patch-capacity normalization,

a canonical vacuum burden baseline,

a unified patch-selection rule,

an explicit Schwarzschild-shell calculation,

a physically derived shell-onset threshold,

and a final one-parameter strong-field timing window.

This closes the operational microphysical specification of the local capacity sector and turns the compact-object shell branch into a predictive strong-field framework.

The next task is exact and sharply defined: compute $\eta_s$from a definite field inventory and derive the shell reflectivity sector $\mathcal{R}_s(\omega)$from the same local burden microphysics. Once that

is done, the FCLET strong-field branch will no longer provide only a timing window. It will provide a complete spectroscopic target.

The theory has therefore crossed an important threshold in this paper. Its local burden variables are specified, its strong-field shell is calculable, and its observational window is now explicit.

Appendix A. Canonical Patch Dictionary

$\mathcal{P}_{\mathrm{W}}$: weak-field local causal patch
$\mathcal{P}_{\mathrm{C}}$: cosmological horizon-scale patch
$\mathcal{P}_{\mathrm{S}}$: strong-field compact-object patch

Canonical rule:

$$\mathcal{P}(x) = \text{minimal accessible capacity-consistent causal domain.}$$

Appendix B. Vacuum Normalization Conventions

Canonical renormalized vacuum:

$$S_{\mathrm{eff}}^{\mathrm{vac,ren}} = 0, I_{\mathrm{vac}} = 0, \chi_{\mathrm{vac}} = 0.$$

Nonzero vacuum burden can be studied only as an extended background sector, not as the canonical baseline.

Appendix C. Transition Matching Examples

For overlapping weak-field and cosmological domains:

$$I_{\mathrm{W}}(x) \approx I_{\mathrm{C}}(x), \chi_{\mathrm{W}}(x) \approx \chi_{\mathrm{C}}(x).$$

For overlapping cosmological and strong-field domains:

$$I_{\mathrm{C}}(x) \approx I_{\mathrm{S}}(x), \chi_{\mathrm{C}}(x) \approx \chi_{\mathrm{S}}(x).$$

These are consistency requirements on admissible patch realization, not optional phenomenological fits.

Appendix D. Heat-Kernel Regularization Sketch for the Schwarzschild Patch

This appendix records the explicit regularization logic underlying the worked Schwarzschild-shell example of Section 10. The purpose is not to derive the full entanglement entropy from first principles for every field content and every spin sector, but to state the canonical FCLET prescription in concrete geometric form.

D.1 Euclidean near-horizon form

In the Schwarzschild exterior,

$$ds^2 = -f(r)\,dt^2 + f(r)^{-1}dr^2 + r^2 d\Omega^2, f(r) = 1 - \frac{2M}{r}.$$

Near the horizon, define

$$r = 2M + \delta r, 0 < \delta r \ll 2M.$$

Then

$$f(r) \approx \frac{\delta r}{2M}.$$

Introduce the proper radial distance $\rho$by

$$d\rho = \frac{dr}{\sqrt{f(r)}}.$$

To leading order one obtains

$$f(r) \approx \frac{\rho^2}{16M^2}.$$

After Euclidean continuation $t \to -i\tau$, the near-horizon metric becomes

$$ds_E^2 \approx d\rho^2 + \frac{\rho^2}{16M^2}\,d\tau^2 + (2M)^2 d\Omega^2.$$

Regularity requires $\tau$to be periodic with period

$$\beta_H = 8\pi M,$$

which reproduces the Hawking temperature

$$T_H = \frac{1}{8\pi M}.$$

The local Tolman-redshifted temperature at radius $r$is then

$$T_a(r) = \frac{T_H}{\sqrt{f(r)}} = \frac{1}{8\pi M\sqrt{f(r)}}.$$

This is equivalent to the local acceleration-temperature form used in the main text.

D.2 Heat-kernel entropy density

Let $\mathcal{O}$denote the reduced quadratic operator for the effective field content supported on the patch. The heat kernel is

$$K(s; x, x') = \langle x \mid e^{-s\mathcal{O}} \mid x' \rangle.$$

Its coincidence limit $K(s; x, x)$defines the local spectral density. The canonical FCLET coarse-graining uses a proper-time cutoff

$$s \geq s_0 = \Lambda_{\mathrm{cg}}^{-2}.$$

The regulated local entropy functional is then taken schematically as

$$S_{\mathrm{ent}}^{\mathrm{reg}}(\mathcal{P}) \sim \int_{s_0}^{\infty} \frac{ds}{s}\, \mathrm{Tr}_{\mathcal{P}} K(s),$$

where the trace is restricted to the patch degrees of freedom. This is the concrete realization of the admissible truncation map $\mathcal{T}_{\Lambda_{\mathrm{cg}}}$.

For a smooth patch boundary, the leading ultraviolet contribution is area-scaled:

$$\mathrm{Tr}_{\mathcal{P}} K(s) \sim \frac{A(\mathcal{P})}{(4\pi s)}\, \kappa_s + \cdots,$$

where $\kappa_s$is the species-dependent coefficient. Substitution gives the standard area-type divergence structure. FCLET removes the non-realizable divergence by:

cutoff selection,

vacuum subtraction,

distinguishability coarse-graining.

The renormalized effective entropy then takes the finite form

$$S_{\text{eff}}(\mathcal{P}) = \eta_s \, A(\mathcal{P}) \, T_a^2$$

used in Section 10. The coefficient $\eta_s$encodes the net contribution of the heat-kernel coefficients after renormalization and finite-resolution identification.

D.3 Canonical FCLET prescription

The Schwarzschild worked example therefore uses the following canonical rule:

$$\boxed{S_{\text{eff}}(r) = \eta_s \, A(r) \, T_a(r)^2}$$

with

$$A(r) = 4\pi r^2, T_a(r) = \frac{M}{2\pi r^2 \sqrt{f(r)}}.$$

Hence

$$S_{\text{eff}}(r) = \eta_s \, \frac{M^2}{\pi r^2 f(r)}.$$

This is the explicit finite local entropy content entering the FCLET burden field.

D.4 Species coefficient

The dimensionless coefficient $\eta_s$collects:

field multiplicity,

spin-dependent heat-kernel weights,

regulator-dependent finite renormalized contributions,

patch distinguishability normalization.

In the canonical FCLET prescription, $\eta_s$is not a floating fit constant introduced independently in each regime. It is the renormalized microphysical loading coefficient associated with the chosen field content and coarse-graining scheme. In future applications, $\eta_s$should be computed from the explicit species inventory of the theory.

For the present worked example, $\eta_s$is kept symbolic in order to display the exact dependence of $I(r)$, $\chi(r)$, and the shell radius on the renormalized local entropy loading.

D.5 Operational status

The heat-kernel regularization sketch given here is sufficient for the role of the present paper. It does not claim to replace a full field-by-field entanglement-entropy derivation. Its purpose is to demonstrate that the FCLET coarse-graining operator can be made explicit in a standard geometric setting and that the local burden variables can be calculated from it.

That purpose is fully achieved.

Appendix E. Echo Delay and Near-Horizon Matching Formulae

This appendix collects the explicit matching relations between the shell location, the tortoise coordinate, and the leading echo delay used in Section 10.

E.1 Near-horizon shell offset

Let the saturation shell radius be

$$r_s = 2M + \delta r_s, 0 < \delta r_s \ll 2M.$$

From Section 10, the near-horizon occupancy field gives

$$I(r_s) \approx \eta_s \frac{\ell_P^2}{16\pi^2 M^2 f(r_s)} = I_{\text{sat}}.$$

Therefore

$$f(r_s) = \eta_s \frac{\ell_P^2}{16\pi^2 M^2 I_{\text{sat}}}.$$

Using

$$f(r) \approx \frac{r - 2M}{2M}$$

near the horizon, one finds

$$\boxed{\delta r_s = r_s - 2M \approx \eta_s \frac{\ell_P^2}{8\pi^2 M I_{\text{sat}}}.}$$

This is the coordinate shell offset.

E.2 Proper shell distance

The proper radial distance from the horizon is

$$\rho = \int_{2M}^{r} \frac{dr'}{\sqrt{f(r')}}.$$

In the near-horizon regime,

$$f(r) \approx \frac{r-2M}{2M},$$

so

$$\rho \approx 2\sqrt{2M(r-2M)}.$$

Hence for the shell,

$$\rho_s \approx 2\sqrt{2M\delta r_s}.$$

Substituting δr_sgives

$$\boxed{\rho_s = \frac{\sqrt{\eta_s}}{\pi\sqrt{I_{\text{sat}}}}\,\ell_P.}$$

This is the canonical FCLET shell proper distance in the Schwarzschild example.

E.3 Tortoise-coordinate shell location

The Schwarzschild tortoise coordinate is

$$r_* = r + 2M\ln\left(\frac{r}{2M}-1\right).$$

At the shell location,

$$r_{*,s} = 2M + \delta r_s + 2M\ln\left(\frac{\delta r_s}{2M}\right).$$

Since $\delta r_s \ll 2M$, the logarithmic term dominates, so the shell sits at a large negative tortoise value.

Substituting the explicit shell offset,

$$\boxed{r_{*,s} \approx 2M + 2M\ln\left(\frac{\eta_s\,\ell_P^2}{16\pi^2 M^2 I_{\rm sat}}\right).}$$

This is the key location entering the cavity-delay calculation.

E.4 Leading echo delay

Let $r_{*,\rm peak}$denote the location of the exterior curvature barrier. Then the round-trip echo delay is

$$\Delta t_{\rm echo} = 2\left(r_{*,\rm peak} - r_{*,s}\right).$$

At leading logarithmic order,

$$\Delta t_{\rm echo} \approx 4M\ln\left(\frac{2M}{\delta r_s}\right) + \mathcal{O}(M).$$

Substituting the shell offset yields

$$\boxed{\Delta t_{\rm echo} \approx 4M\ln\left(\frac{16\pi^2 M^2 I_{\rm sat}}{\eta_s\,\ell_P^2}\right) + \mathcal{O}(M).}$$

Using the proper shell distance, this can be rewritten as

$$\boxed{\Delta t_{\rm echo} \approx 4M\ln\left(\frac{8M}{\rho_s}\right) + \mathcal{O}(M).}$$

This is the cleanest FCLET echo-delay formula for the explicit Schwarzschild shell model.

E.5 Echo spacing and cavity frequency

The characteristic cavity frequency spacing is set by the inverse delay scale:

$$\boxed{\Delta f_{\text{echo}} \sim \frac{1}{\Delta t_{\text{echo}}}.}$$

Equivalently, the angular-frequency spacing satisfies

$$\boxed{\Delta \omega_{\text{echo}} \sim \frac{2\pi}{\Delta t_{\text{echo}}}.}$$

Thus the same shell location that emerges from the local burden threshold determines the spectral spacing of the late-time ringdown structure.

E.6 Boundary-condition form

At the shell, the FCLET perturbation field obeys the mixed boundary condition

$$\Psi(r_{*,s}) \sim e^{-i\omega r_*} + \mathcal{R}_s(\omega) e^{+i\omega r_*},$$

where $\mathcal{R}_s(\omega)$is the shell reflectivity. This is the direct strong-field continuation of the finite-capacity shell structure derived from the microphysical burden calculation.

The classical Schwarzschild horizon is therefore replaced by a finite-capacity shell boundary with calculable location and calculable delay scale.

Appendix F. Numerical Conversion Conventions for the Benchmark Table

The values in Table 1 use the following conventions:

$$M_\odot = 4.92549095 \times 10^{-6} \text{ s}$$

in geometric time units, and

$$\ell_P = 1.616255 \times 10^{-35} \text{ m}.$$

The canonical benchmark shell distance is

$$\rho_s = \frac{\sqrt{2}}{\pi} \ell_P \approx 0.450 \, \ell_P.$$

The benchmark echo delay is then evaluated from

$$\Delta t_{\mathrm{echo}} \approx 4M \ln\left(\frac{8M}{\rho_s}\right),$$

with Mconverted into geometric length/time units in the standard way.

The frequency spacing is estimated by

$$\Delta f_{\mathrm{echo}} \sim \frac{1}{\Delta t_{\mathrm{echo}}}.$$

These conventions are sufficient for the benchmark-level strong-field estimates of the present paper.

Appendix G. Benchmark Numerical Conventions for the Species-Based Table

The values in Table 3 use the canonical shell-onset threshold

$$I_{\mathrm{sat}} = \frac{1}{2}$$

and the scalar-normalized species weights

$$\xi_0 = 1, \xi_{1/2} = 2, \xi_1 = 2.$$

The shell proper distance is evaluated from

$$\rho_s = \frac{\sqrt{\eta_s}}{\pi\sqrt{I_{\mathrm{sat}}}}\ell_P = \frac{\sqrt{2\eta_s}}{\pi}\ell_P.$$

For the 30 $M_\odot$benchmark mass we use

$$M = 30M_\odot = 30 \times 4.92549095 \times 10^{-6}\ \mathrm{s} = 1.47765 \times 10^{-4}\ \mathrm{s}.$$

The echo delay is then evaluated from

$$\Delta t_{\mathrm{echo}} \approx 4M \ln\left(\frac{8M}{\rho_s}\right),$$

and the frequency spacing is estimated by

$$\Delta f_{\mathrm{echo}} \sim \frac{1}{\Delta t_{\mathrm{echo}}}.$$

These conventions are sufficient for the benchmark strong-field estimates reported here.

Appendix H. Closed-Form Strong-Field Window Formulae

For the canonical FCLET shell threshold $I_{\mathrm{sat}} = 1/2$, the strong-field Schwarzschild-shell sector is summarized by the following closed-form relations:

$$\boxed{\rho_s = \frac{\sqrt{2\eta_s}}{\pi}\ell_P,}$$

$$\boxed{r_s - 2M \approx \eta_s \frac{\ell_P^2}{4\pi^2 M},}$$

$$\boxed{r_{*,s} \approx 2M + 2M\ln\left(\frac{\eta_s \ell_P^2}{8\pi^2 M^2}\right),}$$

$$\boxed{\Delta t_{\mathrm{echo}} \approx 4M\ln\left(\frac{8\pi M}{\sqrt{2\eta_s}\,\ell_P}\right),}$$

$$\boxed{\Delta f_{\mathrm{echo}} \sim \frac{1}{\Delta t_{\mathrm{echo}}}.}$$

These relations define the complete timing sector of the canonical FCLET Schwarzschild shell model.

Appendix I. Interpretation of the Narrow Timing Window

Because the echo delay depends logarithmically on shell distance, even order-of-magnitude changes in $\eta_s$shift the timing window only modestly. The shell proper distance is therefore more sensitive to microphysical field content than the delay itself.

This means:

timing is the first observational entry point,

reflectivity and spectroscopy are the stronger discriminators,

and species-resolved microphysics enters most sharply through the shell-response sector rather than through delay time alone.

This is not a weakness of FCLET. It is the exact observational hierarchy implied by the theory's strong-field structure.

Figure Captions

Figure 1. Local occupancy profile $I(r)$in the Schwarzschild exterior patch.
The figure shows the explicit FCLET local burden field in the Schwarzschild exterior,

$$I(r) = \eta_s \frac{\ell_P^2 M^2}{\pi^2 r^4 \left(1-\frac{2M}{r}\right)}.$$

Far from the compact object, the local patch is weakly loaded and the occupancy decays as r^{-4}. Toward the horizon, the redshift factor amplifies the local burden and drives the patch toward the finite-capacity saturation regime. The plot illustrates the exact transition from weak-load transparency to strong-field burden growth.

Figure 2. Latency profile $\chi(r)$and shell-onset condition in the Schwarzschild exterior.
The figure displays the derived FCLET latency field,

$$\chi(r) = \frac{I(r)}{1 - I(r)},$$

together with the shell-onset threshold defined by $I(r_s) = I_{\mathrm{sat}}$. In the far exterior region, $\chi(r) \approx I(r)$and remains perturbatively small. Near the strong-field boundary, the residual support margin $1 - I(r)$shrinks and the latency rises sharply. The shell radius $r_s$marks the onset of the saturation-adjacent regime and defines the compact-object boundary structure of the FCLET strong-field sector.

Figure 3. Echo cavity and delay structure in Schwarzschild tortoise coordinates.
The figure shows the effective strong-field cavity formed between the FCLET saturation shell at tortoise location $r_{*,s}$and the exterior curvature barrier near $r_{*,\mathrm{peak}}$. The round-trip travel time between these two structures defines the leading echo delay,

$$\Delta t_{\mathrm{echo}} = 2\left(r_{*,\mathrm{peak}} - r_{*,s}\right) \approx 4M \ln\left(\frac{8M}{\rho_s}\right) + \mathcal{O}(M).$$

The diagram summarizes the direct link between microphysical finite-capacity saturation, shell formation, and late-time strong-field spectroscopic signatures such as echo spacing and quasi-normal mode deformation.

Shell Reflectivity, Quasi-Normal Mode Deformation, and Echo Amplitude Hierarchy in the Finite-Capacity Latency–Erasure Theory

Frequency-Dependent Boundary Response of Saturation-Shell Compact Objects and the Strong-Field Spectroscopic Discriminator of FCLET

Ali Caner Yücel

Abstract

We develop the shell-reflectivity sector of the finite-capacity latency–erasure theory and derive the strong-field spectroscopic discriminator of the program. Earlier FCLET work established the local burden variables, completed the microphysical specification of the local information-capacity sector, derived the shell-onset condition $I_{\mathrm{sat}} = 1/2$, and obtained explicit Schwarzschild-shell benchmark estimates for the shell distance and echo-delay scale. What remained open was the boundary-response problem: once a finite-capacity saturation shell replaces the classical featureless horizon, how does that shell respond to incident perturbations?

This paper answers that question. We introduce the shell reflectivity function $R_s(\omega)$as the frequency-dependent response coefficient of the FCLET saturation shell and derive its relation to local burden saturation, residual support margin, finite-capacity dissipation, and delayed overwrite dynamics. In the FCLET compact-object sector, the shell is neither perfectly absorbing nor perfectly reflecting. It is a partially transmissive, frequency-selective boundary layer whose response is controlled by the same finite-capacity microphysics that fixed the shell location. We therefore construct the shell response operator, derive the mixed near-shell boundary condition for perturbation modes, and obtain the leading quasi-normal mode deformation generated by shell reflection and delayed reprocessing.

We show that the observationally decisive FCLET strong-field signature is not the logarithmic echo delay alone, since that timing scale is shared broadly by Planck-scale near-horizon shell models. The discriminator lies in the full spectroscopic package: shell reflectivity, echo amplitude hierarchy, cavity filtering, mode-dependent phase deformation, and damping modification. We derive the first general FCLET expressions for the reflected amplitude, echo-train suppression law, and complex frequency shift $\delta\omega_n$, and show how these

observables inherit species dependence through the shell loading parameter $\eta_s$and structural dependence through the shell-response scale ω_c.

The result is decisive for the strong-field completion of the theory. FCLET now advances from shell-location kinematics to shell-response spectroscopy. The compact-object branch no longer predicts only where a finite-capacity shell forms. It predicts how that shell reprocesses strong-field perturbations, how the ringdown spectrum departs from classical general relativity, and where the genuinely theory-specific observational signatures of FCLET must appear.

finite-capacity physics; shell reflectivity; quasi-normal modes; gravitational-wave echoes; compact objects; saturation shell; ringdown spectroscopy; FCLET; strong-field gravity; boundary response

1. Introduction

The strong-field branch of the finite-capacity latency–erasure theory has now reached a decisive stage. Earlier papers established that the classical horizon is replaced, in the saturation regime, by a finite-capacity shell structure generated by local burden growth and latency amplification. The local information-capacity sector was then specified microphysically, the shell-onset criterion was fixed internally by the balance condition $I_{\mathrm{sat}} = 1/2$, and an explicit Schwarzschild-shell calculation produced the first benchmark estimates for shell distance, echo-delay scale, and the associated timing window of the compact-object sector. Those results settled the kinematic side of the problem: FCLET now states where the shell forms and at what delay scale strong-field late-time structure should appear.

That, however, is not the decisive observational question.

The decisive question is how the shell responds.

A finite-capacity saturation shell is not a classical event horizon. A classical event horizon imposes a purely ingoing boundary condition and behaves, at linear perturbative level, as a featureless absorber. The FCLET shell does not. Its entire meaning lies in finite-capacity response. It is a burdened boundary layer with nontrivial internal realization cost, residual support margin, and local latency structure. Once perturbations reach such a shell, the correct physical problem is no longer merely geometric placement, but boundary reprocessing. One must determine what fraction of incident perturbation energy is absorbed, what fraction is reflected, what fraction is delayed and re-emitted, and how those processes depend on frequency.

That is the problem this paper solves.

The shell-response problem is central because it is the first place where FCLET can become observationally distinctive in a strong sense. A logarithmic echo-delay law of the form

$$\Delta t_{\mathrm{echo}} \sim 4M \ln\left(\frac{M}{\ell_P}\right)$$

is important, but it is not unique to FCLET. A wide class of Planck-scale near-horizon shell models produces a similar timing structure. Timing alone therefore does not isolate the theory. The decisive discriminator must lie elsewhere: in the detailed spectroscopic response of the shell. That response includes the shell reflectivity function $R_s(\omega)$, the resulting echo-amplitude hierarchy, the deformation of the quasi-normal mode spectrum, the modification of damping rates, and the frequency dependence of the shell's partial absorption and partial reflection.

The present paper constructs that sector.

We define the shell reflectivity function $R_s(\omega)$as the boundary-response coefficient of the FCLET saturation shell and show that it must be frequency dependent. The finite-capacity shell cannot act as a perfect mirror, because it remains a dissipative realization layer rather than an inert barrier. It also cannot act as a perfect absorber, because the same saturation structure that prevents featureless horizon formation necessarily generates nonzero reprocessing and return flux. The shell is therefore a partially reflective and partially dissipative interface. Its response must depend on the local burden state of the shell, on the species-loading coefficient η_s, on the shell-response frequency scale ω_c, and on the dissipative relaxation scale Γ_s.

From this starting point we derive the mixed shell boundary condition, the shell-barrier cavity transfer function, the general echo amplitude recursion law, and the leading complex mode shift of the ringdown spectrum. The resulting framework does more than attach an echo story to the theory. It identifies the real strong-field discriminator of FCLET: not timing alone, but the coupled structure of shell location, shell reflectivity, mode deformation, and echo hierarchy.

The paper is organized as follows. Section 2 explains why echo timing alone cannot serve as the unique FCLET discriminator and isolates the precise observational role of shell reflectivity. Section 3 establishes the shell as a finite-capacity boundary-response layer. Section 4 defines the reflectivity function $R_s(\omega)$. Section 5 derives the microphysical origin of partial reflection and partial absorption. Section 6 constructs the canonical shell boundary condition. Section 7 derives the shell-barrier transfer function. Section 8 develops the echo amplitude hierarchy. Section 9 obtains the quasi-normal mode deformation. Section 10 introduces benchmark reflectivity models. Section 11 identifies the dependence of shell response on species content and finite-capacity loading. Section 12 summarizes the observational windows of the strong-field sector. Section 13 clarifies the distinction between FCLET and generic Planck-shell echo models. Section 14 presents the final conclusion.

The strong-field program now moves beyond the question of shell existence. The shell has already been derived. The task now is to determine its response law. That response law is the gateway to ringdown spectroscopy, and ringdown spectroscopy is where FCLET must either distinguish itself or fail.

2. Why Echo Timing Alone Is Not the FCLET Discriminator

The Schwarzschild-shell benchmark developed earlier established the leading FCLET echo-delay law

$$\Delta t_{\mathrm{echo}} \approx 4M\ln\left(\frac{8\pi M}{\sqrt{2\eta_s}\,\ell_P}\right),$$

once the shell-onset threshold is fixed by the finite-capacity balance condition $I_{\mathrm{sat}} = 1/2$. This was an important result. It transformed the strong-field branch from conceptual shell kinematics into an explicit observational timing window. For stellar-mass remnants, the theory now predicts late-time structure in the millisecond to tenth-of-a-second regime. That is a real achievement. It places the compact-object branch of FCLET into direct contact with gravitational-wave ringdown analysis.

But that result is not yet the decisive discriminator of the theory.

The reason is structural. Any model that places a partially reflecting surface at a Planck-scale proper distance outside the classical horizon typically produces an echo-delay law with the same leading logarithmic structure. The logarithm originates from the near-horizon tortoise-coordinate stretching, not from the detailed microphysics of FCLET itself. Once the shell sits at proper distance $\rho_s \sim \ell_P$, the delay generically takes the form

$$\Delta t_{\mathrm{echo}} \sim 4M\ln\left(\frac{M}{\rho_s}\right),$$

up to order-unity factors inside the logarithm. That structure is broad. It belongs to the geometry of near-horizon cavities, not uniquely to the finite-capacity latency–erasure framework.

This point must be stated clearly because it defines the observational hierarchy of the theory.

FCLET does not claim uniqueness at the level of logarithmic timing alone. It claims a more exact and more physically meaningful distinction. The theory derives the shell location from local burden saturation, fixes the shell-onset threshold internally through the condition $I_{\mathrm{sat}} = 1/2$, and ties the shell proper distance to the species-loading coefficient η_s. These are already stronger statements than a generic hand-placed membrane model. But even that is not the final discriminator, because the delay depends only logarithmically on shell distance. Logarithms are weak filters. They compress a wide range of microscopic shell positions into a narrow range of timing predictions.

The decisive discriminator must therefore lie not in where the shell is placed alone, but in how the shell responds once it is there.

This leads directly to the reflectivity problem.

If a shell exists, then late-time structure depends on three layers of physics:

the shell location, which fixes the cavity size;

the shell response function, which fixes the fraction of perturbation energy reflected, absorbed, or delayed;

the interplay between shell response and the exterior curvature barrier, which fixes the echo hierarchy and the quasi-normal mode deformation.

The first layer is only weakly discriminating. The second and third are much stronger. A shell reflectivity function $R_s(\omega)$that is frequency independent, weakly frequency dependent, strongly cutoff dependent, or dissipative in a specific manner will produce very different mode shifts and echo-amplitude patterns even if the shell timing scale is nearly the same. That is why two theories can agree approximately on $\Delta t_{\mathrm{echo}}$and still be sharply distinguishable spectroscopically.

This observation has direct consequences for FCLET.

In the finite-capacity theory, the shell is not an inserted wall. It is the emergent response layer of a patch that has entered the burden-dominated regime. Its boundary behavior must therefore inherit the same microphysics that produced the shell location in the first place. The response coefficient $R_s(\omega)$cannot be arbitrary if the theory is internally coherent. It must depend on:

the shell burden state,

the remaining support margin,

the local latency cost,

the microphysical loading content encoded by η_s,

and the shell's dissipative overwrite dynamics.

That is precisely where FCLET can become genuinely distinctive.

The timing law tells us where to look in data. The reflectivity law tells us what to look for.

This distinction is the central methodological point of the present paper. The shell-delay calculation was necessary, but it was never the end of the strong-field program. It was the opening kinematic step. The true spectroscopic problem begins only now, with the construction of the shell reflectivity sector.

The conclusion of this section can therefore be stated exactly:

Echo timing is a necessary FCLET strong-field consequence, but not the decisive FCLET discriminator.

The decisive discriminator is the full shell-response package:

$$\boxed{R_s(\omega), \delta\omega_n, \text{echo amplitude hierarchy, and damping deformation.}}$$

The remainder of this paper constructs that package from the finite-capacity shell microphysics itself.

3. Finite-Capacity Shells as Boundary-Response Layers

The FCLET saturation shell is not a formal substitute for the classical horizon. It is a physical response layer generated by local burden saturation in a finite-capacity substrate. This distinction is decisive. A classical event horizon is defined by causal geometry alone and, at linear perturbative level, enforces a purely ingoing boundary condition. The FCLET shell is defined instead by finite-capacity microphysics. It forms when the local occupancy field reaches the burden-support crossover,

$$I_{\text{sat}} = \frac{1}{2}, \chi_{\text{sat}} = 1,$$

and therefore inherits the physical structure of the local burden variables rather than the featureless absorption law of the classical horizon.

This immediately changes the status of the near-boundary problem. Once a compact object enters the saturation-adjacent regime, the relevant strong-field interface is no longer a null surface with no internal response scale. It is a finite-thickness shell whose state is characterized by:

large local latency,

finite residual support margin,

nonzero microphysical loading,

and delayed overwrite dynamics.

A perturbation incident on such a layer does not encounter a purely geometric sink. It encounters a burdened response medium.

That response medium has three physically distinct channels.

First, part of the incident perturbation can be absorbed into the shell and dissipated through local overwrite dynamics. This is the finite-capacity analogue of irreversible loading.

Second, part of the incident perturbation can be reflected by the shell because the shell is not infinitely transparent once the local burden-support ratio reaches order unity. The shell therefore has nonzero impedance.

Third, part of the perturbation can be temporarily stored and then re-emitted with delay, because the shell is not only burdened but also latency-bearing. It is a reprocessing layer, not merely a barrier.

These three channels define the FCLET strong-field boundary logic. If $\mathcal{I}(\omega)$denotes the incident mode flux at frequency ω, then the shell response decomposes as

$$\boxed{\mathcal{I}(\omega) = \mathcal{A}_s(\omega) + \mathcal{R}_s(\omega) + \mathcal{D}_s(\omega),}$$

where:

$\mathcal{A}_s(\omega)$is the absorbed fraction,

$\mathcal{R}_s(\omega)$is the reflected fraction,

$\mathcal{D}_s(\omega)$is the delayed or reprocessed fraction.

At the level of amplitudes, the shell therefore behaves as a partially reflective and partially dissipative interface. This is the defining physical content of the FCLET shell. It is neither a perfect mirror nor a perfect absorber.

This point is not optional. A perfect mirror would contradict the finite-capacity dissipative logic of the shell. A perfect absorber would contradict the same finite-capacity logic from the other side, because a burdened shell with finite residual support margin cannot generically erase every incident perturbation without return structure. The shell must therefore interpolate between these extremes.

The most compact way to express this is to say that the shell behaves as a boundary-response layer with finite admittance. Let $\mathcal{Z}_s(\omega)$denote the effective shell impedance. Then reflection and absorption are not independent phenomenological decorations, but descendants of the shell's admittance structure. In FCLET language, that admittance depends on the local shell state itself:

$$\mathcal{Z}_s(\omega) = \mathcal{Z}_s(\omega; \eta_s, \chi_s, \Gamma_s, \omega_c),$$

where:

$\eta_s$is the shell loading coefficient inherited from microphysical field content,

$\chi_s$is the local shell latency,

$\Gamma_s$is the dissipative relaxation scale,

$\omega_c$is the shell response cutoff scale.

These are not arbitrary decorations. They are the minimal effective parameters required by the finite-capacity shell picture.

The shell must therefore be treated as a frequency-dependent response layer for a simple reason: different incident frequencies probe different aspects of the finite-capacity burden structure.

Low-frequency perturbations probe the collective shell response and can be reflected coherently.

Intermediate-frequency perturbations are partially reflected and partially reprocessed.

High-frequency perturbations are more strongly damped because they overload the shell's local response scale and are degraded by dissipative overwrite.

This is the strong-field continuation of FCLET's general logic: finite capacity implies nonlinear response, and nonlinear response implies frequency-selective boundary behavior.

The shell is therefore not only a location. It is an operator.

That statement marks the transition from shell kinematics to shell spectroscopy. The location $r_s$tells us where the shell forms. The response law tells us what the shell does. The latter is the spectroscopic heart of the compact-object branch.

This also clarifies the observational structure of the theory. Echo timing depends mainly on the shell location and the cavity size between the shell and the exterior barrier. But the amplitude, damping, and phase structure of the late-time signal depend on how the shell responds to frequency. That response is the first genuinely strong discriminant of FCLET. It is the part of the theory that can differ sharply even when the echo timing band overlaps with other Planck-scale shell models.

The conclusion of the present section is therefore exact:

In FCLET, the saturation shell is a finite-capacity boundary-response layer with partial reflection, partial absorption, and delayed reprocessing.

Everything that follows in the strong-field spectroscopic sector is a consequence of that fact.

4. Definition of the Shell Reflectivity Function $R_s(\omega)$

Once the shell is recognized as a boundary-response layer, its primary spectroscopic descriptor is the shell reflectivity function $R_s(\omega)$. This function is not an auxiliary notation. It is the strong-field observable interface between local shell microphysics and ringdown phenomenology.

Let a linear perturbation mode incident on the shell be described in tortoise-coordinate form near the shell location $r_{*,s}$by

$$\Psi(r_*, \omega) \sim A_{\mathrm{in}}(\omega)e^{-i\omega r_*} + A_{\mathrm{out}}(\omega)e^{+i\omega r_*}.$$

The shell reflectivity is then defined by the amplitude ratio

$$\boxed{R_s(\omega) = \frac{A_{\text{out}}(\omega)}{A_{\text{in}}(\omega)}.}$$

This is the exact boundary-response coefficient of the FCLET shell.

Its basic properties follow immediately.

First, $R_s(\omega)$is complex. Its magnitude controls the reflected amplitude, while its phase controls the boundary-induced phase shift. Therefore

$$\boxed{R_s(\omega) = \mid R_s(\omega) \mid e^{i\phi_s(\omega)}.}$$

Second, $R_s(\omega)$is frequency dependent. A finite-capacity shell is not transparent to all scales in the same way, because its local burden response has characteristic timescales and support margins. The shell therefore cannot assign the same response coefficient to arbitrarily slow and arbitrarily fast modes.

Third, $R_s(\omega)$is bounded by physical response consistency. If the shell is passive in the linear regime, then the reflected power cannot exceed the incident power. Hence

$$\boxed{0 \leq \mid R_s(\omega) \mid^2 \leq 1.}$$

The lower extreme corresponds to purely absorptive shell response at that frequency. The upper extreme corresponds to lossless reflection. FCLET generically predicts the interior of that interval.

Fourth, $R_s(\omega)$must be a shell-state function rather than a free detached coefficient. In the finite-capacity theory, shell response is controlled by the same variables that define shell formation in the first place. The minimal FCLET dependency structure is therefore

$$\boxed{R_s(\omega) = R_s(\omega; \eta_s, \chi_s, \Gamma_s, \omega_c),}$$

where:

$\eta_s$sets the microphysical loading content of the shell,

$\chi_s$sets the shell latency state,

$\Gamma_s$sets the dissipative relaxation scale,

$\omega_c$sets the shell response cutoff scale.

This is the exact FCLET meaning of shell reflectivity. It is not a wall reflectivity inserted from outside the theory. It is the boundary response of a finite-capacity, burden-saturated, latency-bearing shell.

This definition also makes clear why the shell reflectivity sector is the genuine discriminator of the theory. Echo timing depends predominantly on shell placement. But shell placement alone compresses into a logarithmic timing law. Reflectivity does not. Reflectivity can vary strongly across frequency even when shell location changes only weakly. The shell response law therefore carries much more theory-specific structure than the delay scale alone.

A useful equivalent quantity is the shell transmissivity $T_s(\omega)$, defined so that the non-reflected part of the mode flux is partitioned into transmission and dissipation. In the effective single-shell picture, however, the most important observable quantity remains $R_s(\omega)$, because it is the coefficient that enters directly into the cavity recursion law and the quasi-normal mode deformation.

The FCLET shell reflectivity function must satisfy two exact physical limits.

4.1 Weak-shell limit

If the shell burden is too small to sustain significant boundary response, then the shell approaches transparency and

$$\boxed{R_s(\omega) \to 0.}$$

This reproduces the classical absorptive limit in which the strong-field structure approaches horizon-like behavior.

4.2 Strong-shell limit

If the shell burden is large and the local support margin is small, then the shell becomes strongly reactive and

$$| R_s(\omega) |$$

can approach order unity in an appropriate frequency band. This is the regime in which strong echo structure and substantial quasi-normal mode deformation become possible.

The shell reflectivity is therefore the exact response measure of how far the compact-object boundary has moved away from classical horizon behavior.

To make this more concrete, it is useful to define the shell response in terms of the local FCLET variables themselves. Since the shell sits at the onset of the burden-dominated regime, the canonical shell values satisfy

$$I_s = I_{\mathrm{sat}} = \frac{1}{2}, \chi_s = 1,$$

at onset, and exceed these values deeper into the shell-support regime. The response law must therefore be an increasing function of burden dominance and a decreasing function of high-frequency overload. This leads to the general FCLET response form

$$\boxed{R_s(\omega) = \mathcal{F}\left(\frac{\omega}{\omega_c}, \eta_s, \chi_s, \Gamma_s\right),}$$

with the exact qualitative conditions

$$\frac{\partial \mid R_s \mid}{\partial \chi_s} > 0, \frac{\partial \mid R_s \mid}{\partial \eta_s} \text{ model dependent but generically nontrivial, } \frac{\partial \mid R_s \mid}{\partial \omega} < 0 \text{ at sufficiently large } \omega.$$

These conditions encode the finite-capacity logic of the shell:

larger burden and stronger latency increase boundary response,

sufficiently high frequency probes beyond the shell's coherent response scale and is therefore more strongly damped.

The exact analytical form of $\mathcal{F}$ will be modeled in later sections. What matters here is that the reflectivity function is now defined in principle and tied explicitly to the shell microphysics.

The final point of this section is methodological. Once $R_s(\omega)$ is defined, the shell problem becomes a standard boundary-response problem in wave mechanics—but with a nonstandard physical origin. The rest of the strong-field spectroscopic analysis follows from this coefficient:

the shell boundary condition,

the shell-barrier cavity transfer function,

the echo recursion hierarchy,

and the quasi-normal mode deformation.

The shell reflectivity function is therefore the correct starting point of the FCLET spectroscopic sector.

Its definition may be summarized compactly as

$\boxed{R_s(\omega) = \text{the complex, frequency-dependent reflection coefficient of the FCLET saturation shell, determined by shell loading, shell latency, and shell dissipation scales.}}$

That definition is the bridge from finite-capacity shell formation to observable ringdown structure.

5. Microphysical Origin of Partial Reflection and Partial Absorption

The shell reflectivity function $R_s(\omega)$cannot remain a purely formal boundary coefficient if the strong-field branch of FCLET is to be physically coherent. The shell is not an inserted membrane. It is the finite-capacity response layer generated when the local burden-support ratio crosses the shell-onset threshold. Its reflectivity must therefore arise from the microphysics of finite-capacity loading itself.

The correct starting point is the local shell state. At the shell, the normalized occupancy field has reached the burden-dominated regime,

$$I_s \gtrsim I_{\mathrm{sat}} = \frac{1}{2}, \chi_s \gtrsim 1,$$

so that the shell is no longer a weakly loaded transparent patch. It is a local domain in which realized burden is comparable to, or exceeds, the remaining support margin. This has two immediate physical consequences.

First, the shell cannot erase incident perturbations without cost. A perturbation mode reaching the shell must be processed by a substrate already operating near the crossover between support-dominated and burden-dominated behavior. The shell therefore has finite absorption capacity rather than infinite sink behavior.

Second, the shell cannot instantaneously re-equilibrate after loading. Because the shell is latency-bearing, incident perturbations excite delayed local response rather than zero-time dissipation. This automatically generates re-emission and therefore nonzero reflected structure.

These two facts are sufficient to force the shell into the regime of partial absorption and partial reflection.

5.1 Finite-capacity loading as impedance mismatch

The simplest physical interpretation is impedance mismatch. In the weak-load exterior, perturbations propagate in a region whose local capacity margin is large. At the shell, the same perturbations encounter a layer whose residual support margin is much smaller. The transition from one regime to the other creates a mismatch between the effective propagation properties of the exterior and those of the shell interior.

In ordinary wave systems, impedance mismatch generates reflection. In FCLET, the same is true, but the mismatch variable is not a mechanical stiffness or refractive index. It is the finite-capacity burden state of the shell. The shell reflectivity therefore increases as the shell becomes more burden dominated.

This gives the first exact qualitative rule:

$$\boxed{|\, R_s(\omega)\,| \text{ increases with shell burden dominance.}}$$

Equivalently, at fixed frequency,

$$\boxed{\frac{\partial \mid R_s \mid}{\partial \chi_s} > 0.}$$

That is the direct strong-field continuation of the FCLET burden logic.

5.2 Partial absorption from overwrite dissipation

Reflection is not the whole story. A finite-capacity shell is not lossless. It dissipates.

The microphysical origin of absorption lies in overwrite dynamics. Earlier FCLET papers introduced overwrite burden as the finite-response sector activated when local burden becomes large. In the shell regime, part of the incident perturbation must therefore be degraded into local shell excitation, dissipative processing, or delayed internal burden reorganization. This is the origin of the shell relaxation scale Γ_s.

Let $\tau_s$denote the characteristic shell relaxation time. Then

$$\boxed{\Gamma_s = \tau_s^{-1}}$$

is the shell dissipation scale. Modes with frequency $\omega \ll \Gamma_s$can be reprocessed quasi-adiabatically by the shell, whereas modes with $\omega \gg \Gamma_s$overload the shell's response channel and are more strongly degraded.

This implies the second exact qualitative rule:

The shell is partially absorptive because incident perturbations excite finite-capacity overwrite dissipation on timescale τ_s.

The shell is therefore not a conservative reflector. It is a lossy finite-capacity boundary layer.

5.3 Frequency dependence from finite response time

A shell with finite response time cannot respond identically to all frequencies. This is the origin of the response scale ω_c.

At low frequency, the shell has time to respond coherently to the incident mode. Reflection can therefore remain substantial.

At intermediate frequency, coherence weakens and part of the incoming perturbation is diverted into dissipative or delayed channels.

At high frequency, the shell cannot reorganize quickly enough to maintain coherent return structure, so the reflected fraction falls.

Thus the reflectivity function must satisfy

$$\boxed{|\, R_s(\omega)\,| \to 0 \text{as} \omega/\omega_c \to \infty,}$$

for any passive finite-capacity shell.

This gives the third exact qualitative rule:

The shell is frequency selective because finite-capacity reprocessing has a finite response bandwidth.

That bandwidth is the physical meaning of ω_c.

5.4 Canonical FCLET response ansatz

The microphysical rules above imply that the shell response must be:

burden dependent,

dissipative,

frequency selective.

The minimal FCLET reflectivity structure is therefore

$$\boxed{R_s(\omega) = R_0(\eta_s, \chi_s)\, \mathcal{G}\left(\frac{\omega}{\omega_c}, \frac{\omega}{\Gamma_s}\right),}$$

where:

R_0 is the low-frequency shell reflectivity amplitude,

$\mathcal{G}$ is the finite-response suppression factor.

This expression is general enough to accommodate multiple effective models while remaining explicitly tied to FCLET shell microphysics.

The lowest-order physical requirements are

$$0 \le R_0 \le 1,$$
$$\mathcal{G}(0,0) = 1,$$
$$|\, \mathcal{G}\,| \to 0 \text{for} \omega/\omega_c \to \infty \text{ or sufficiently strong dissipation.}$$

That is the exact minimal shell-response structure the theory requires.

5.5 Three canonical reflectivity channels

To understand the physics more transparently, it is useful to separate the shell response into three effective channels.

(i) Coherent reflection

A fraction of the incident perturbation is returned with definite phase relation. This is the true reflective part of the shell and is measured directly by $R_s(\omega)$.

(ii) Irreversible absorption

A fraction of the incident perturbation is dissipated into the shell's local overwrite dynamics and does not return coherently on the observation timescale.

(iii) Delayed re-emission

A fraction is temporarily stored in shell excitation and returned later, contributing to secondary delayed structure. In a coarse-grained effective description, this delayed channel may be absorbed into a frequency-dependent complex reflectivity.

Thus the shell reflectivity coefficient is best interpreted as an effective coarse-grained response function summarizing the coherent return channel after internal dissipation and delay have been integrated out.

This is why $R_s(\omega)$is complex rather than purely real.

5.6 Species loading and reflectivity amplitude

The shell loading parameter $\eta_s$enters the shell reflectivity in two ways.

First, it sets the shell distance through

$$\rho_s = \frac{\sqrt{2\eta_s}}{\pi}\ell_P.$$

Second, it modifies the shell's internal entropy-loading structure and therefore its reprocessing capacity. A shell with larger $\eta_s$is not merely farther from the classical horizon in proper distance. It is also microphysically denser in admissible loading content. That means $\eta_s$can affect both the low-frequency amplitude $R_0$and the cutoff/relaxation scales ω_c, Γ_s.

The exact dependence remains model specific, but the canonical FCLET expectation is

$$\boxed{R_0 = R_0(\eta_s, \chi_s), \omega_c \sim \rho_s^{-1}, \Gamma_s = \Gamma_s(\eta_s, \chi_s).}$$

This is enough to show that species loading affects the shell response more strongly than it affects the echo delay itself. That is one of the central reasons reflectivity is the true theory discriminator.

5.7 Why perfect absorption and perfect reflection are both excluded

It is useful to state explicitly why the FCLET shell cannot live at either extreme.

If the shell were perfectly absorbing,

$$R_s(\omega) = 0$$

for all frequencies, then the shell would be observationally indistinguishable from a classical horizon at linear level. That would contradict the finite-capacity logic that created the shell in the first place.

If the shell were perfectly reflecting,

$$| R_s(\omega) | = 1$$

for all frequencies, then the shell would behave as a rigid wall with no finite-capacity dissipation. That would contradict the overwrite and latency sectors of the theory.

The finite-capacity shell therefore lies strictly between those extremes:

$$\boxed{0 < | R_s(\omega) | < 1 \text{in the relevant frequency band.}}$$

This is not a phenomenological compromise. It is the direct consequence of finite-capacity microphysics.

5.8 Conclusion of the microphysical response analysis

The shell reflectivity sector of FCLET has a clear physical origin. Reflection arises because the shell is a burdened response layer with finite support margin, and absorption arises because the shell is a dissipative overwrite medium with finite relaxation time. Frequency dependence follows because finite-capacity processing has finite bandwidth.

The central conclusion of the present section can therefore be written as

$$\boxed{R_s(\omega) \text{ is the coarse-grained response coefficient of a burden-saturated, latency-bearing, dissipative shell.}}$$

It is this coefficient—not shell timing alone—that carries the distinctive strong-field information of the theory.

6. Canonical Boundary Condition at the Saturation Shell

Once the shell reflectivity function is defined, the perturbative strong-field problem becomes a boundary-value problem. The shell location is already fixed by the occupancy threshold, and

the shell response is now encoded in the complex coefficient $R_s(\omega)$. The next step is therefore to impose the correct boundary condition at the shell.

6.1 Near-shell mode structure

Let $r_{*,s}$denote the tortoise-coordinate location of the FCLET shell. In the near-shell region, the effective perturbation equation reduces to local plane-wave form, so that a mode of frequency $\omega$is written as

$$\Psi(r_*, \omega) \sim A_{\text{in}}(\omega)e^{-i\omega r_*} + A_{\text{out}}(\omega)e^{+i\omega r_*}.$$

The first term is the inward-directed component incident on the shell. The second term is the outward-directed component returned by the shell.

In classical Schwarzschild black-hole perturbation theory, the horizon condition requires

$$A_{\text{out}} = 0,$$

so that the near-horizon mode is purely ingoing. FCLET changes this exactly at the shell. The correct shell boundary condition is not purely ingoing, but mixed:

$$\boxed{\Psi(r_{*,s}, \omega) = e^{-i\omega r_{*,s}} + R_s(\omega)e^{+i\omega r_{*,s}}.}$$

This is the canonical FCLET shell boundary condition.

It states that the shell returns a reflected component with frequency-dependent amplitude and phase. The shell is therefore a genuine response boundary rather than a purely absorptive endpoint.

6.2 Derivative form of the boundary condition

Because the perturbation equation is second order, it is useful to write the corresponding derivative condition explicitly. Differentiating the near-shell mode gives

$$\boxed{\partial_{r_*}\Psi\,|_{r_{*,s}} = -i\omega e^{-i\omega r_{*,s}} + i\omega R_s(\omega)e^{+i\omega r_{*,s}}.}$$

The pair

$$\Psi(r_{*,s}), \partial_{r_*}\Psi(r_{*,s})$$

therefore carries the full shell response information at linear level.

This form is particularly useful in:

shooting methods for quasi-normal mode determination,

cavity transfer-function derivations,

and time-domain evolution schemes where shell reflection is imposed numerically.

6.3 Equivalent Robin-type representation

The mixed shell boundary condition may also be written in effective Robin form. Eliminating the explicit incident/reflected decomposition, one may write

$$\boxed{\partial_{r_*}\Psi\,|_{r_{*,s}} = \mathcal{B}_s(\omega)\,\Psi(r_{*,s}),}$$

where the shell admittance coefficient is

$$\boxed{\mathcal{B}_s(\omega) = -i\omega\,\frac{1 - R_s(\omega)e^{2i\omega r_{*,s}}}{1 + R_s(\omega)e^{2i\omega r_{*,s}}}.}$$

This representation is mathematically useful because it turns the shell into an effective frequency-dependent boundary operator. It also makes the analogy with dissipative boundary layers in ordinary wave systems explicit.

In the classical horizon limit $R_s(\omega) \to 0$, one recovers

$$\mathcal{B}_s(\omega) \to -i\omega,$$

which is precisely the purely ingoing Schwarzschild condition. The FCLET shell boundary therefore reduces continuously to the classical limit when the shell reflectivity vanishes. That is an important consistency check.

6.4 Constant and frequency-selective benchmark limits

The general boundary condition is defined by the full complex function $R_s(\omega)$, but two benchmark limits are especially useful.

Constant-reflectivity limit

If

$$R_s(\omega) = R_0,$$

with $0 < R_0 < 1$, then the shell is partially reflective with no frequency selection. This is the simplest benchmark model and already suffices to generate echo trains and quasi-normal mode shifts.

Frequency-selective limit

If

$$R_s(\omega) = R_0\, \mathcal{G}(\omega),$$

with $|\, \mathcal{G}(\omega)\,|$decreasing at large ω, then the shell behaves as a finite-bandwidth response layer. This is the more realistic FCLET case because it respects finite-capacity response limitations.

The formal boundary condition above is valid in both cases. Only the detailed mode structure changes.

6.5 Boundary condition and shell microphysics

The shell boundary condition is not arbitrary because the shell itself is not arbitrary. The shell location is fixed by the occupancy threshold, and the reflectivity function is fixed by shell burden, latency, and dissipation scales. The boundary condition therefore inherits the same physical content:

$$\boxed{\Psi(r_{*,s}) = \Psi(r_{*,s}; \eta_s, \chi_s, \Gamma_s, \omega_c).}$$

This is what makes the FCLET shell condition physically distinct from a hand-placed mirror model. The boundary law is not inserted independently of the shell microphysics. It is generated by it.

6.6 Cavity interpretation

Once the shell boundary condition is imposed, the compact-object exterior becomes an effective cavity. The shell is the inner response boundary, and the exterior curvature barrier near the photon-sphere region is the outer scattering boundary. Radiation trapped between these two structures undergoes repeated partial reflection and transmission.

This cavity interpretation follows immediately from the mixed shell boundary condition. It is not an extra hypothesis. The condition

$$\Psi(r_{*,s}) = e^{-i\omega r_*} + R_s(\omega) e^{+i\omega r_*}$$

already implies that energy returns from the shell to the exterior barrier. That return flow is what generates:

the echo hierarchy,

resonance filtering,

and quasi-normal mode deformation.

The shell boundary condition is therefore the exact entry point into FCLET ringdown spectroscopy.

6.7 Classical limit and FCLET deviation

The boundary condition also makes the deviation from classical GR completely explicit.

Classical GR

$$R_s(\omega) = 0 \Longrightarrow \Psi \sim e^{-i\omega r_*}.$$

FCLET shell

$$R_s(\omega) \neq 0 \Longrightarrow \Psi \sim e^{-i\omega r_*} + R_s(\omega) e^{+i\omega r_*}.$$

The entire strong-field observational distinction begins here. Everything that follows—echo amplitudes, damping shifts, mode deformations—follows from the single fact that the FCLET compact-object boundary is no longer purely ingoing.

6.8 Canonical FCLET shell boundary law

The boundary condition of the FCLET shell may therefore be summarized compactly as

$$\boxed{\Psi(r_{*,s}, \omega) = e^{-i\omega r_{*,s}} + R_s(\omega) e^{+i\omega r_{*,s}}, 0 <\mid R_s(\omega) \mid< 1 \text{ in the relevant band.}}$$

This is the canonical shell boundary law of the strong-field branch.

It is the correct starting point for the shell-barrier transfer function, the echo hierarchy, and the quasi-normal mode calculation.

7. Transfer Function of the Shell-Barrier Cavity

Once the mixed shell boundary condition is imposed, the exterior strong-field problem acquires the structure of a two-boundary cavity. The FCLET saturation shell defines the inner response boundary at tortoise location $r_{*,s}$, while the standard exterior curvature barrier near the photon-sphere region defines the outer scattering boundary. The ringdown signal is therefore no longer governed by a single absorptive end condition. It is governed by repeated wave transport between a frequency-dependent inner shell and a frequency-dependent outer barrier.

This immediately leads to a transfer-function description.

Let $R_b(\omega)$and $T_b(\omega)$denote, respectively, the reflection and transmission coefficients of the exterior curvature barrier. Let $R_s(\omega)$denote the shell reflectivity defined in the previous section. Let

$$L = r_{*,\mathrm{peak}} - r_{*,s}$$

be the cavity length in tortoise coordinates, where $r_{*,\mathrm{peak}}$is the effective location of the barrier peak. A mode that travels from the barrier to the shell and back acquires the round-trip phase

$$e^{2i\omega L}.$$

This is the exact geometric phase factor governing the shell-barrier cavity.

7.1 Single-pass response

Consider an incident exterior perturbation exciting the barrier region. The first contribution to the observed late-time outgoing response is the standard transmitted ringdown component, represented schematically by a baseline transfer function $T_{\mathrm{bh}}(\omega)$. This quantity includes the usual exterior propagation and barrier transmission structure of the GR problem.

Once the shell is introduced, however, the first shell-return contribution is obtained by:

transmission through the barrier toward the shell,

reflection at the shell,

propagation back across the cavity,

partial leakage through the barrier to infinity.

That process contributes a term proportional to

$$T_b(\omega)\, R_s(\omega)\, T_b(\omega)\, e^{2i\omega L}.$$

Thus the shell generates the first correction to the classical response through a round-trip cavity factor.

7.2 Multi-pass cavity recursion

The shell and the barrier are both partially reflective. Therefore the cavity does not end after one round trip. Once the shell-reflected wave returns to the barrier, a fraction leaks out and a fraction is reflected back inward by the barrier. That inward-reflected part then returns to the shell, is reflected again, and repeats the cycle.

The cavity therefore generates an infinite geometric recursion. The n-th round-trip contribution carries the factor

$$(R_b(\omega)\, R_s(\omega)\, e^{2i\omega L})^n.$$

Summing the entire cavity series gives the full shell-corrected transfer function

$$\boxed{\mathcal{T}(\omega) = \frac{T_{\mathrm{bh}}(\omega)}{1 - R_b(\omega) R_s(\omega) e^{2i\omega L}}.}$$

This is the canonical FCLET shell-barrier transfer function.

Its meaning is exact. The denominator encodes the cavity resonance structure, while the numerator retains the baseline excitation and leakage properties of the exterior geometry. Every strong-field shell signature of the theory—echoes, resonance combs, and quasi-normal mode shifts—is contained in this single expression.

7.3 Resonance condition

The shell-barrier cavity becomes resonant when the denominator approaches zero:

$$1 - R_b(\omega) R_s(\omega) e^{2i\omega L} \approx 0.$$

Equivalently,

$$\boxed{R_b(\omega) R_s(\omega) e^{2i\omega L} \approx 1.}$$

This is the resonance condition of the FCLET compact-object cavity. It determines the frequencies at which repeated shell-barrier reprocessing amplifies the late-time response.

This condition is immediately more informative than echo timing alone. Echo timing measures the cavity size. The resonance condition measures the coupled effect of cavity size, shell response, barrier response, and phase coherence. That is why spectroscopy is the stronger discriminator.

7.4 Classical limit

The shell-barrier transfer function must reduce continuously to the classical result when shell response vanishes. Indeed, if

$$R_s(\omega) \to 0,$$

then

$$\mathcal{T}(\omega) \to T_{\mathrm{bh}}(\omega).$$

Thus the FCLET cavity formalism contains the classical horizon problem as a smooth limit. This is an essential consistency check.

7.5 Finite-capacity interpretation of the denominator

The denominator

$$1 - R_b(\omega)R_s(\omega)e^{2i\omega L}$$

has a direct FCLET interpretation. The term $R_s(\omega)$carries the shell's finite-capacity response. The phase factor $e^{2i\omega L}$carries the geometric delay between shell and barrier. The barrier reflection $R_b(\omega)$closes the cavity. The combined factor therefore measures the extent to which the shell-barrier system can sustain repeated coherent burden reprocessing at frequency ω.

This is the exact strong-field analogue of the broader FCLET logic:

capacity determines response,

response determines delay,

delay plus recurrence determine observable structure.

7.6 Cavity filtering and frequency selection

Because both $R_s(\omega)$and $R_b(\omega)$are frequency dependent, the transfer function acts as a spectral filter. Some frequencies are strongly suppressed. Others are preferentially enhanced. The observed late-time spectrum is therefore not just delayed—it is filtered.

The finite-capacity shell thus contributes to the ringdown signal in two ways:

by introducing delayed return structure,

by selecting which frequencies survive repeated cavity transport.

This is already enough to see why FCLET can differ sharply from a model that predicts the same delay but a different shell response law.

7.7 Canonical cavity law

The strong-field cavity sector of FCLET may therefore be summarized by the exact relation

$$\boxed{\mathcal{T}(\omega) = \frac{T_{\mathrm{bh}}(\omega)}{1 - R_b(\omega)R_s(\omega)e^{2i\omega L}}, L = r_{*,\mathrm{peak}} - r_{*,s}.}$$

This is the correct transfer function for a saturation-shell compact object in the linear perturbative regime.

It is the natural bridge from shell reflectivity to both echo hierarchy and quasi-normal mode deformation.

8. Echo Amplitude Hierarchy and Delay Structure

The shell-barrier transfer function makes the late-time echo structure completely explicit. Once a perturbation is trapped between the exterior curvature barrier and the FCLET shell, the observed signal is naturally decomposed into a sequence of progressively delayed and progressively suppressed echoes. The crucial point is that this hierarchy is not appended phenomenologically. It follows directly from the cavity recursion law.

8.1 First echo

The first echo is generated by a single shell-barrier round trip. A perturbation transmitted inward through the barrier reflects once from the shell and then leaks back out through the barrier. Its amplitude therefore carries the leading factor

$$\boxed{A_1(\omega) \propto T_b(\omega)\, R_s(\omega)\, T_b(\omega)\, e^{2i\omega L}.}$$

The corresponding time delay is the round-trip cavity time

$$\boxed{\Delta t_{\text{echo}} = 2L = 2(r_{*,\text{peak}} - r_{*,s}).}$$

In the Schwarzschild-shell sector already derived earlier, this reproduces the logarithmic FCLET delay law.

8.2 Higher echoes

The second echo is generated after one additional reflection from the barrier and one additional reflection from the shell. Its amplitude therefore carries an extra factor of

$$R_b(\omega)\, R_s(\omega)\, e^{2i\omega L}.$$

Thus

$$\boxed{A_2(\omega) \propto T_b(\omega)\, R_s(\omega)\, R_b(\omega)\, R_s(\omega)\, T_b(\omega)\, e^{4i\omega L}.}$$

In the same way, the n-th echo carries the general structure

$$\boxed{A_n(\omega) \propto T_b(\omega)\,(R_b(\omega)R_s(\omega))^{n-1}R_s(\omega)\,T_b(\omega)\,e^{2in\omega L}.}$$

This is the canonical FCLET echo recursion law.

It can be written more compactly as

$$\boxed{A_n(\omega) \propto \mathcal{A}_0(\omega)\,(R_b(\omega)R_s(\omega))^{n-1}e^{2in\omega L},}$$

where $\mathcal{A}_0(\omega)$denotes the first-pass shell-coupled leakage amplitude. The physical interpretation is immediate:

each additional echo acquires one more factor of shell reflectivity,

one more factor of barrier reflectivity,

and one more round-trip phase.

8.3 Echo amplitude hierarchy

The ratio of successive echoes is therefore

$$\boxed{\frac{A_{n+1}(\omega)}{A_n(\omega)} \propto R_b(\omega)R_s(\omega)e^{2i\omega L}.}$$

At the level of magnitudes,

$$\boxed{\left|\frac{A_{n+1}}{A_n}\right| \sim |\,R_b(\omega)R_s(\omega)\,|.}$$

This is the exact FCLET echo-amplitude hierarchy law.

Its meaning is decisive. The shell response law enters the signal not only by creating delayed structure, but by controlling how quickly the echo train decays. The decay hierarchy is therefore a direct observable of shell reflectivity. This is one of the main reasons the echo amplitude structure is more discriminating than delay time alone.

8.4 Delay ladder

Each successive echo is delayed by one more cavity round trip. Thus the time of the n-th echo is approximately

$$\boxed{t_n \approx t_0 + n\,\Delta t_{\text{echo}},}$$

where t_0 is the onset time of the first shell-generated return signal. The late-time signal therefore forms a ladder in time:

equal spacing at leading order,

amplitude suppression governed by $R_b R_s$,

phase structure governed by ωL.

This is the cleanest time-domain signature of a finite-capacity shell cavity.

8.5 Frequency-domain comb structure

The time-domain ladder implies a frequency-domain comb. Because echoes are spaced approximately by Δt_{echo}, the corresponding angular-frequency spacing is

$$\boxed{\Delta\omega_{\mathrm{echo}} \sim \frac{2\pi}{\Delta t_{\mathrm{echo}}},}$$

or equivalently

$$\boxed{\Delta f_{\mathrm{echo}} \sim \frac{1}{\Delta t_{\mathrm{echo}}}.}$$

But the FCLET echo comb is not a pure equal-amplitude comb. It is filtered by:

the shell response $R_s(\omega)$,

the barrier response $R_b(\omega)$,

and the baseline transfer function $T_b(\omega)$.

Thus the spectrum is a weighted comb rather than a uniform one. This weighting is theory specific.

8.6 Role of shell dissipation

If the shell were purely conservative, the only suppression factor would come from geometric leakage and barrier filtering. But FCLET shells are dissipative. That means $|R_s(\omega)| < 1$even before one accounts for barrier leakage. Echo amplitudes therefore decay faster than they would in a lossless cavity.

This gives the finite-capacity echo hierarchy its characteristic form:

the shell produces echoes,

but it also damps them,

because the same microphysics that causes partial reflection also causes overwrite dissipation.

That dual role is a central FCLET feature.

8.7 Canonical benchmark echo laws

The simplest benchmark hierarchy arises when the shell reflectivity is taken constant over the dominant ringdown band:

$$R_s(\omega) = R_0, 0 < R_0 < 1.$$

Then

$$A_n(\omega) \propto \mathcal{A}_0(\omega)\,(R_b(\omega)R_0)^{n-1}e^{2in\omega L}.$$

If, more realistically, the shell response is frequency selective, for example

$$R_s(\omega) = R_0 e^{-\omega/\omega_c},$$

then the hierarchy becomes

$$A_n(\omega) \propto \mathcal{A}_0(\omega)\,(R_b(\omega)R_0 e^{-\omega/\omega_c})^{n-1}e^{2in\omega L}.$$

This immediately shows how FCLET shell microphysics shapes the late-time spectrum:

low-frequency components survive longer,

high-frequency echoes are suppressed more aggressively,

the echo train becomes softer as $n$increases.

That spectral softening is itself a potential discriminator.

8.8 Echo hierarchy as an FCLET observable

The final point of this section is methodological and observational.

A model that predicts only a shell location predicts only a delay. A model that predicts a shell response predicts an echo hierarchy. FCLET belongs to the second class. The hierarchy

$$A_n(\omega) \propto (R_b(\omega)R_s(\omega))^{n-1}e^{2in\omega L}$$

is therefore one of the first genuinely theory-structured strong-field observables of the program.

This matters because two models can agree on Δt_{echo} and still disagree sharply on:

the relative strength of the first and second echoes,

the suppression of higher echoes,

the frequency dependence of the echo train,

and the damping structure of the late-time signal.

That is exactly where FCLET can become distinguishable.

8.9 Canonical FCLET echo law

The echo sector of the theory may therefore be summarized compactly as

$$\boxed{t_n \approx t_0 + n\,\Delta t_{\mathrm{echo}}, \Delta t_{\mathrm{echo}} = 2L,}$$

$$\boxed{A_n(\omega) \propto \mathcal{A}_0(\omega)\,(R_b(\omega)R_s(\omega))^{n-1} e^{2in\omega L}.}$$

This is the canonical FCLET echo law.

It shows explicitly that the shell delay and the shell response are inseparable parts of the strong-field signal. Timing tells us where the echoes sit. Reflectivity tells us what the echoes look like.

9. Quasi-Normal Mode Deformation from Finite Shell Reflectivity

The echo hierarchy developed in the previous section describes the time-domain consequence of shell reprocessing. The frequency-domain consequence is equally important: the shell modifies the quasi-normal mode spectrum itself. This is the point at which the FCLET shell sector becomes a true spectroscopic framework rather than a delayed-signal kinematics.

In classical Schwarzschild perturbation theory, quasi-normal modes are determined by the outgoing condition at spatial infinity together with the purely ingoing condition at the horizon. In FCLET, the second of these is replaced by the mixed shell boundary condition

$$\Psi(r_{*,s}, \omega) = e^{-i\omega r_{*,s}} + R_s(\omega) e^{+i\omega r_{*,s}}.$$

That replacement is enough to shift both the oscillation frequency and the damping rate of the modes.

9.1 Resonance equation

The full shell-barrier transfer function is

$$\mathcal{T}(\omega) = \frac{T_{\mathrm{bh}}(\omega)}{1 - R_b(\omega)R_s(\omega)e^{2i\omega L}}, L = r_{*,\mathrm{peak}} - r_{*,s}.$$

The quasi-normal spectrum is determined by the poles of the transfer function. Therefore the FCLET mode condition is

$$\boxed{1 - R_b(\omega)R_s(\omega)e^{2i\omega L} = 0.}$$

This is the exact cavity resonance equation of the shell-modified compact object.

In the classical limit $R_s(\omega) \to 0$, the shell disappears and one recovers the usual GR boundary-value problem. In the FCLET case, however, the shell introduces a nonzero cavity return factor and therefore shifts the pole structure of the Green function.

9.2 Perturbative mode shift around GR

Let ω_n^{GR}denote the n-th quasi-normal mode of the corresponding classical Schwarzschild problem. For sufficiently weak shell response, the FCLET mode may be written as

$$\boxed{\omega_n^{\mathrm{FCLET}} = \omega_n^{\mathrm{GR}} + \delta\omega_n,}$$

with $|\delta\omega_n| \ll |\omega_n^{\mathrm{GR}}|$.

At leading order, the shell-induced correction inherits the standard cavity form

$$\boxed{\delta\omega_n \propto R_s(\omega_n^{\mathrm{GR}})\exp(2i\omega_n^{\mathrm{GR}}L).}$$

Since $L = r_{*,\mathrm{peak}} - r_{*,s}$, the correction is exponentially sensitive to the shell location and directly proportional to the shell reflectivity. This is the exact bridge between FCLET shell microphysics and ringdown spectroscopy.

The correction may be decomposed into its real and imaginary parts:

$$\boxed{\delta\omega_n = \Delta\omega_n^{(R)} + i\,\Delta\gamma_n^{(R)},}$$

so that

$$\boxed{\omega_n^{\mathrm{FCLET}} = (\omega_n^{\mathrm{GR}} + \Delta\omega_n^{(R)}) + i(\gamma_n^{\mathrm{GR}} + \Delta\gamma_n^{(R)}),}$$

where $\gamma_n^{\mathrm{GR}} < 0$is the classical damping rate.

Thus the shell changes both:

the oscillation frequency,

and the damping law.

This is why FCLET cannot be reduced to an echo-delay story. The shell deforms the mode spectrum before the late echo train is even isolated.

9.3 Phase sensitivity and shell location

The complex phase factor

$$e^{2i\omega_n^{\mathrm{GR}}L}$$

shows that the FCLET mode shift is highly sensitive to the shell position. Even when the shell sits only a Planck-scale proper distance from the classical horizon, the tortoise-coordinate cavity length $L$is logarithmically large, so the phase can be substantial.

That is the key reason a microscopically shifted shell can produce macroscopically visible spectral structure. The shell is close in proper distance but far in tortoise distance. This is the same mechanism that produces the delayed echo scale, now expressed in frequency-domain language.

9.4 Reflectivity controls mode deformation amplitude

If the shell were purely absorptive, $R_s(\omega) = 0$, then no shell-induced spectral deformation would survive. Conversely, if $|\ R_s(\omega)\ |$is appreciable in the relevant ringdown band, the quasi-normal spectrum shifts correspondingly.

The lowest-order scaling is therefore

$$\boxed{|\ \delta\omega_n\ | \propto |\ R_s(\omega_n^{\mathrm{GR}})\ |.}$$

This means the size of the FCLET spectroscopic deviation is controlled primarily by the shell response, not by the shell timing alone.

The shell reflectivity function is therefore the decisive frequency-domain discriminator of the theory.

9.5 Damping deformation and dissipative shells

A finite-capacity shell is dissipative, so $R_s(\omega)$is not generally a pure phase. Its magnitude is less than unity and its argument is frequency dependent. Therefore the shell modifies not only the phase of the returned perturbation, but also the effective damping structure of the cavity.

This gives a direct physical interpretation of the imaginary correction $\Delta\gamma_n^{(R)}$:

if the shell returns radiation coherently, damping is reduced relative to the purely absorptive case;

if the shell strongly dissipates perturbations, damping remains closer to the GR value;

if the shell response is strongly frequency selective, different overtones may be modified differently.

The FCLET shell therefore naturally predicts mode-dependent damping deformation.

9.6 Overtone sensitivity

Higher overtones probe shorter effective wavelengths and larger damping scales. They therefore sample the shell response differently from the fundamental mode. Since $R_s(\omega)$is frequency dependent, the FCLET shell does not generally shift all quasi-normal modes by the same relative factor.

This produces a characteristic spectroscopic fingerprint:

the fundamental mode feels the low-frequency shell response,

higher overtones feel more of the shell cutoff and dissipation structure.

Thus FCLET predicts not just a single ringdown shift, but a mode hierarchy of shifts.

That hierarchy is potentially much more diagnostic than the first echo delay alone.

9.7 Frequency-domain resonance picture

The shell-modified spectrum can also be understood through the resonance condition

$$1 - R_b(\omega)R_s(\omega)e^{2i\omega L} = 0.$$

Whenever the barrier reflectivity, shell reflectivity, and cavity phase align appropriately, the denominator approaches zero and the response is resonantly enhanced. The resulting poles define the FCLET quasi-normal spectrum.

This is the exact frequency-domain analogue of the time-domain echo train:

repeated shell-barrier reprocessing in time,

repeated phase-matched cavity resonance in frequency.

These are two representations of the same shell physics.

9.8 FCLET spectroscopic consequence

The central conclusion of this section may therefore be written in exact form:

The FCLET saturation shell deforms the quasi-normal spectrum through a complex, frequency-dependent shift proportional to $R_s(\omega_n^{\mathrm{GR}})e^{2i\omega_n^{\mathrm{GR}}L}$.

This is the first general spectroscopic statement of the strong-field branch.

It is stronger than the delay law because it depends directly on shell response rather than only on shell placement.

10. Benchmark Reflectivity Models

The previous sections established the general shell-response framework. To move from qualitative structure to explicit strong-field templates, one must choose benchmark forms for the reflectivity function $R_s(\omega)$. These forms are not yet the final microphysical derivation of shell response, but they are necessary intermediate models that make the FCLET spectroscopic sector calculable.

The purpose of the present section is therefore twofold:

to define a small set of canonical response models,

to display how different shell microphysics would project into different ringdown and echo signatures.

10.1 Model A: Constant reflectivity

The simplest benchmark model is

$$R_s(\omega) = R_0, 0 < R_0 < 1.$$

This model assumes that the shell response is approximately frequency independent over the dominant ringdown band. It is the minimal phenomenological shell-response model and is often sufficient for first-pass echo and mode-shift estimates.

Its advantages are obvious:

algebraic simplicity,

transparent dependence on shell amplitude,

easy insertion into cavity transfer functions.

Its limitation is equally clear:

it ignores finite-capacity bandwidth effects.

In FCLET language, Model A corresponds to the approximation in which the probed frequency range is narrow enough that the shell response scale $\omega_c$is effectively large compared with the dominant mode frequencies.

10.2 Model B: Exponential cutoff shell

A more realistic finite-capacity model is the exponential suppression form

$$\boxed{R_s(\omega) = R_0\, e^{-\omega/\omega_c}.}$$

Here:

$R_0$is the low-frequency reflectivity amplitude,

$\omega_c$is the shell response cutoff scale.

This model captures a basic FCLET expectation: high-frequency perturbations probe beyond the shell's coherent response bandwidth and are therefore more strongly damped.

The exponential model has three useful properties:

it is simple enough for analytic handling,

it suppresses high-frequency echoes naturally,

it gives overtone-dependent mode deformation in a transparent way.

In the FCLET shell context, one expects

$$\omega_c \sim \rho_s^{-1},$$

up to order-unity factors determined by shell microphysics. Since $\rho_s$itself depends on η_s, the cutoff model directly ties field content to spectroscopic response.

10.3 Model C: Relaxation / dispersive shell

A second physically motivated model is the relaxation-type reflectivity law

$$\boxed{R_s(\omega) = \frac{R_0}{1 + i\omega/\Gamma_s}.}$$

Here:

R_0 is again the low-frequency response amplitude,

Γ_s is the shell relaxation scale.

This model encodes a dissipative shell with finite response time $\tau_s = \Gamma_s^{-1}$. At low frequency, the shell responds coherently and $R_s(\omega) \approx R_0$. At higher frequency, the response acquires a phase lag and the magnitude is suppressed.

This is a very natural FCLET ansatz because the shell is explicitly a latency-bearing and overwrite-dissipative structure. The dispersive form therefore captures more directly than the exponential model the idea that shell response is delayed, not merely cut off.

10.4 Comparison of the benchmark models

The three benchmark forms represent three nested levels of approximation:

Model A:

$$R_s(\omega) = R_0$$

best suited for narrow-band first-pass estimates.

Model B:

$$R_s(\omega) = R_0 e^{-\omega/\omega_c}$$

best suited for finite-bandwidth shell suppression.

Model C:

$$R_s(\omega) = \frac{R_0}{1 + i\omega/\Gamma_s}$$

best suited for dissipative and phase-lagged shell response.

These are not competing arbitrary fits. They are progressively richer effective models of the same finite-capacity shell.

10.5 Echo hierarchy in the benchmark models

Substituting the benchmark forms into the echo hierarchy law

$$A_n(\omega) \propto \mathcal{A}_0(\omega)\,(R_b(\omega)R_s(\omega))^{n-1} e^{2in\omega L}$$

gives immediately:

Model A

$$A_n(\omega) \propto \mathcal{A}_0(\omega)\,(R_b(\omega)R_0)^{n-1}e^{2in\omega L}.$$

Model B

$$A_n(\omega) \propto \mathcal{A}_0(\omega)\,(R_b(\omega)R_0 e^{-\omega/\omega_c})^{n-1}e^{2in\omega L}.$$

Model C

$$A_n(\omega) \propto \mathcal{A}_0(\omega)\left(R_b(\omega)\frac{R_0}{1+i\omega/\Gamma_s}\right)^{n-1}e^{2in\omega L}.$$

These formulas show directly how shell microphysics shapes the observable echo train:

Model A controls only overall echo strength,

Model B adds spectral softening,

Model C adds both amplitude suppression and phase lag.

10.6 Mode shift in the benchmark models

The quasi-normal mode correction

$$\delta\omega_n \propto R_s(\omega_n^{\mathrm{GR}})e^{2i\omega_n^{\mathrm{GR}}L}$$

likewise becomes:

Model A

$$\delta\omega_n \propto R_0\, e^{2i\omega_n^{\mathrm{GR}}L}.$$

Model B

$$\delta\omega_n \propto R_0 e^{-\omega_n^{\mathrm{GR}}/\omega_c} e^{2i\omega_n^{\mathrm{GR}}L}.$$

Model C

$$\delta\omega_n \propto \frac{R_0}{1+i\omega_n^{\mathrm{GR}}/\Gamma_s}\, e^{2i\omega_n^{\mathrm{GR}}L}.$$

This makes the observational logic exact:

a constant-reflectivity shell produces a nearly uniform low-band deformation,

an exponential-cutoff shell suppresses high-frequency overtones,

a relaxation shell produces both overtone suppression and phase-lagged damping modification.

This is precisely the type of structure needed to distinguish FCLET from generic shell models that predict only a delay.

10.7 Physical interpretation of the benchmark parameters

The parameters entering the benchmark reflectivity models have direct FCLET meaning.

$$\boldsymbol{R_0}$$

The low-frequency shell reflectivity. It measures how strongly the shell returns perturbations when the frequency is low compared to the shell response scale.

$$\boldsymbol{\omega_c}$$

The shell cutoff scale. It marks the frequency above which coherent shell reflection begins to fail. In FCLET, the natural scaling is

$$\omega_c \sim \rho_s^{-1}.$$

$$\boldsymbol{\Gamma_s}$$

The shell relaxation scale. It measures the inverse timescale of dissipative shell re-equilibration and is therefore the natural parameter controlling overwrite-driven damping.

These parameters are not final free constants of the theory. They are placeholders for the next microphysical derivation. But they are already physically meaningful placeholders.

10.8 Canonical FCLET benchmark hierarchy

At the current stage of the strong-field program, the most natural benchmark order is:

Model A for first-pass cavity and timing estimates,

Model B for shell-bandwidth studies,

Model C for dissipative shell spectroscopy.

This hierarchy reflects the increasing microphysical realism of the shell-response description.

10.9 Conclusion of the benchmark-response sector

The benchmark reflectivity models accomplish something essential. They turn the FCLET shell from a location plus delay into a calculable spectroscopic object. The theory can now ask concrete questions:

how large is R_0?

does the shell suppress high-frequency overtones?

does it introduce phase-lagged damping?

what echo hierarchy results?

The exact microphysical derivation of $R_s(\omega)$remains the next decisive task. But that task is now sharply formulated rather than vague. The benchmark response sector defines the space in which the final FCLET shell spectroscopy must live.

The present section may therefore be summarized by the statement

FCLET shell spectroscopy is already calculable at benchmark level through a small family of physically interpretable reflectivity models.

That is enough to move the compact-object branch from shell timing to ringdown-response analysis.

11. Species Dependence, Loading Dependence, and Response Scales

The benchmark reflectivity models introduced in the previous section become physically meaningful only when their parameters are tied to the shell microphysics itself. In FCLET, that tie is not optional. The shell is not an inserted boundary of unknown composition. It is the strong-field realization of a burden-saturated causal patch. Its response must therefore inherit the same local variables that fixed the shell location in the first place.

The two most important microphysical inputs are:

the species-loading coefficient η_s,

the local shell burden state $\chi_s$or equivalently I_s.

These variables determine the shell thickness, the shell storage burden, the shell dissipation budget, and therefore the shell response scales.

11.1 Species loading and shell structure

Earlier FCLET strong-field analysis fixed the shell proper distance as

$$\rho_s = \frac{\sqrt{2\eta_s}}{\pi}\,\ell_P,$$

once the shell-onset threshold is set by

$$I_{\mathrm{sat}} = \frac{1}{2}.$$

This relation already shows that the shell position depends explicitly on field content through η_s. A shell with larger loading coefficient sits farther from the classical horizon in proper distance, even though the shift remains Planck scale.

That matters for spectroscopy because the shell response scale depends on shell size. A shell that extends farther in proper distance does not generically react to perturbations in the same way as a thinner shell. Thus $\eta_s$enters the reflectivity sector both geometrically and dynamically.

The first exact consequence is therefore

$\boxed{\eta_s \text{ controls shell placement and contributes directly to shell response scales.}}$

11.2 Loading dependence of the low-frequency reflectivity amplitude

The low-frequency shell reflectivity amplitude R_0measures the coherent return strength of the shell in the $\omega \to 0$regime. In FCLET, R_0must depend on shell burden dominance.

At shell onset one has

$$I_s = I_{\mathrm{sat}} = \frac{1}{2}, \chi_s = 1.$$

Deeper into the shell-support regime, the burden state can exceed onset values:

$$I_s > \frac{1}{2}, \chi_s > 1.$$

A more burden-dominated shell has less residual support margin and therefore behaves as a stronger impedance mismatch relative to the weak-load exterior. This tends to increase coherent reflection, at least in the low-frequency band where the shell can respond collectively.

The canonical FCLET expectation is therefore

$$\boxed{\frac{\partial R_0}{\partial \chi_s} > 0}$$

in the physically relevant shell regime.

This does not mean R_0 must grow to unity. Dissipation remains present. It means only that a more strongly loaded shell is generically more reflective than a marginal shell.

11.3 Response cutoff scale

The shell cutoff scale ω_c marks the frequency above which coherent reflection begins to fail. The simplest FCLET estimate follows from shell thickness alone. A boundary layer of proper width ρ_s cannot maintain coherent collective response at wavelengths much shorter than that width. The natural scaling is therefore

$$\boxed{\omega_c \sim \rho_s^{-1}.}$$

Substituting the shell distance gives

$$\boxed{\omega_c \sim \frac{\pi}{\sqrt{2\eta_s}}\,\ell_P^{-1}.}$$

This is one of the most important scaling laws of the shell-response sector. It shows that increasing species loading decreases the shell cutoff scale. A more heavily loaded shell is thicker in proper distance and therefore less capable of coherently reflecting higher-frequency perturbations.

Thus the same increase in η_s that slightly shifts shell location also softens the shell response spectrum.

That effect is much more distinctive than the echo timing itself, because the timing depends only logarithmically on shell location while the cutoff depends algebraically on $\sqrt{\eta_s}$.

11.4 Dissipative relaxation scale

The shell relaxation scale Γ_s measures how quickly shell excitations decay or re-equilibrate after loading. This is the strong-field descendant of FCLET overwrite dissipation. The exact microscopic formula remains to be derived, but the structure of the theory already constrains its dependence.

A shell with larger burden and stronger latency generally relaxes more slowly, because its local realization cost is larger. A shell with larger species-loading content can also support a richer internal reprocessing structure. These two effects pull in opposite directions:

more loading can increase internal channels,

but more burden can slow their effective realization.

The theory therefore expects

$$\boxed{\Gamma_s = \Gamma_s(\eta_s, \chi_s),}$$

with the exact functional form to be derived by the next microphysical shell paper. What matters here is that $\Gamma_s$is not independent of the shell's finite-capacity state. It is a derived response scale.

11.5 Species dependence of the benchmark reflectivity models

The three benchmark reflectivity forms introduced earlier can now be rewritten in explicitly FCLET form.

Model A

$$\boxed{R_s(\omega) = R_0(\eta_s, \chi_s).}$$

Model B

$$\boxed{R_s(\omega) = R_0(\eta_s, \chi_s)\, e^{-\omega/\omega_c(\eta_s)}.}$$

Model C

$$\boxed{R_s(\omega) = \frac{R_0(\eta_s, \chi_s)}{1 + i\omega/\Gamma_s(\eta_s, \chi_s)}.}$$

These are not merely benchmark models anymore. They are benchmark FCLET shell-response laws.

Their significance is immediate:

$\eta_s$shifts shell thickness and response bandwidth,

$\chi_s$shifts low-frequency reflectivity,

$\Gamma_s$determines dissipative phase lag and overtone suppression.

Thus the shell-response sector is where FCLET field content enters most sharply.

11.6 Why species loading affects spectroscopy more than timing

This point is decisive and must be stated explicitly.

The echo delay depends on shell location through a logarithm:

$$\Delta t_{\mathrm{echo}} \approx 4M \ln\left(\frac{8\pi M}{\sqrt{2\eta_s}\,\ell_P}\right).$$

Therefore even order-of-magnitude changes in η_s shift the delay only modestly.

By contrast, the shell cutoff scale satisfies

$$\omega_c \sim \eta_s^{-1/2},$$

and the shell distance satisfies

$$\rho_s \sim \eta_s^{1/2}.$$

These are algebraic dependences, not logarithmic ones. The shell-response spectrum is therefore more sensitive to field content than the shell timing scale.

This leads to the exact strong-field inference:

Species loading enters FCLET timing weakly, but enters FCLET shell spectroscopy much more strongly.

That is the main reason reflectivity and mode deformation are the true theory discriminators.

11.7 Loading dependence of quasi-normal mode deformation

The leading mode correction is

$$\delta\omega_n \propto R_s(\omega_n^{\mathrm{GR}}) e^{2i\omega_n^{\mathrm{GR}} L}.$$

The shell location L depends logarithmically on η_s, while the reflectivity depends directly on $\eta_s, \chi_s, \Gamma_s, \omega_c$. Therefore the field-content dependence of mode deformation is dominated, in practice, by shell response rather than shell placement.

The theory therefore predicts the following hierarchy:

shell timing gives the cavity scale,

shell response gives the deformation amplitude and spectral pattern.

This is the correct FCLET reading of the strong-field sector.

11.8 Strong-field shell-response hierarchy

The shell-response sector of FCLET may therefore be summarized by the following hierarchy of dependencies:

$$\eta_s \Longrightarrow \rho_s \Longrightarrow \omega_c,$$
$$(\eta_s, \chi_s) \Longrightarrow R_0, \Gamma_s,$$
$$(R_0, \omega_c, \Gamma_s) \Longrightarrow R_s(\omega),$$
$$R_s(\omega) \Longrightarrow \delta\omega_n,\ A_n(\omega),\ \text{echo hierarchy.}$$

This chain is the real strong-field microphysical architecture of the theory.

11.9 Conclusion of the species-loading analysis

The reflectivity sector is not detached from the rest of FCLET. It is the direct continuation of the same burden-capacity microphysics that fixed the shell onset and shell location. Species loading controls shell scale. Shell scale controls response bandwidth. Shell burden controls coherent reflectivity. Dissipative overwrite controls relaxation. All of these then feed into the observable ringdown spectrum.

The exact conclusion is

In FCLET, shell reflectivity is a microphysical descendant of species loading, shell burden, and finite-capacity response scales.

That is the essential content of the present section.

12. Strong-Field Observational Windows for FCLET

With the shell location, shell timing, shell reflectivity, and shell-response hierarchy now in place, the strong-field branch of FCLET can finally be expressed in observational language. The goal of this section is not yet to produce a full matched-filter data-analysis pipeline. It is to identify the precise windows in which the theory predicts departures from classical ringdown behavior.

These windows are of four kinds:

the echo-delay window,

the echo-amplitude window,

the quasi-normal mode deformation window,

the overtone and damping-modification window.

Taken together, these define the observational target space of the FCLET compact-object sector.

12.1 Echo-delay window

The first window is the timing window already derived earlier. For a Schwarzschild-like remnant of mass M, the shell delay scale is

$$\Delta t_{\mathrm{echo}} \approx 4M \ln\left(\frac{8\pi M}{\sqrt{2\eta_s}\,\ell_P}\right).$$

For canonical field-content loading $\eta_s \in [1,10]$, stellar-mass remnants lie in a narrow late-time delay band of order 10^{-2}–10^{-1} seconds. This is the first observational locator of the shell sector.

But as emphasized already, timing alone is not enough. It tells us where to look, not what the shell must look like.

12.2 Echo-amplitude window

The second window is the echo-amplitude hierarchy. The n-th echo satisfies

$$A_n(\omega) \propto \mathcal{A}_0(\omega)\,(R_b(\omega)R_s(\omega))^{n-1} e^{2in\omega L}.$$

This means the relative strength of successive echoes is a direct probe of shell reflectivity. A shell with weak low-frequency return produces rapidly decaying echoes. A shell with stronger coherent response produces a more persistent late-time train.

The amplitude window is therefore not universal. It is model specific, and in FCLET it is tied directly to the shell-response law. That makes it much more discriminating than delay time alone.

In practical observational terms, the theory predicts not simply a delayed feature, but a delayed feature with a specific amplitude falloff law.

12.3 Quasi-normal mode deformation window

The third window is the deformation of the mode spectrum itself. The FCLET shell shifts the quasi-normal frequencies according to

$$\delta\omega_n \propto R_s(\omega_n^{\mathrm{GR}}) e^{2i\omega_n^{\mathrm{GR}} L}.$$

This means the earliest post-merger ringdown may already depart slightly from the pure GR template before late echoes are separately identifiable. The effect is strongest when:

the shell reflectivity is appreciable in the dominant ringdown band,

the shell-barrier cavity phase is favorable,

and the overtone content of the event is sufficiently well resolved.

This gives the theory a direct spectroscopic prediction: ringdown should not only be followed by delayed structure; its early frequency and damping content may already carry a shell imprint.

That is one of the most important observational avenues for FCLET, because mode deformation can in principle be probed even when late-time echoes are weak.

12.4 Overtone and damping window

Because $R_s(\omega)$is frequency dependent, higher overtones and faster-damping components do not respond identically to the shell. The theory therefore predicts a fourth observational window: overtone-selective modification.

This can appear as:

stronger suppression of higher-frequency overtones,

frequency-dependent phase lags,

mode-dependent damping corrections,

and spectral softening of the late-time echo train.

A shell with exponential cutoff reflectivity, for example, suppresses higher-frequency return channels much more strongly than lower-frequency ones. A relaxation-type shell adds phase lag and dissipative damping in a mode-dependent way.

Thus the overtone structure of the post-merger signal can be as informative as the first-echo timing scale.

12.5 Observational hierarchy of the FCLET shell sector

The strong-field observational logic of FCLET is therefore hierarchical.

First layer: timing

$$\Delta t_{\mathrm{echo}}$$

locates the cavity scale.

Second layer: amplitude

$$A_n(\omega)$$

tests shell reflectivity and barrier-shell recurrence.

Third layer: spectroscopy

$$\delta\omega_n$$

tests shell-induced mode deformation.

Fourth layer: overtone response

frequency dependence of $R_s(\omega)$tests the shell bandwidth and dissipation structure.

This hierarchy is the correct way to compare the theory with data. The shell delay is only the first observable. The real diagnostic power comes from the combined package.

12.6 FCLET observational target region

The strong-field observational target region of the theory can therefore be stated as follows:

For compact − object mergers, FCLET predicts shell − induced structure in a narrow late
− time timing window, accompanied by model
− dependent echo amplitudes and mode
− dependent ringdown deformation.

This target region is not arbitrary. It is fixed by:

shell onset at $I_{\mathrm{sat}} = 1/2$,

shell location set by η_s,

cavity size set by $r_{*,s}$,

and shell response set by $R_s(\omega)$.

Thus the theory now defines not only a possible strong-field anomaly, but the exact observational region in which it must appear.

12.7 What a detection would require

A convincing FCLET-type strong-field signal would not consist of one delayed bump in the time series alone. It would require a consistent package:

a delay scale in the FCLET cavity window,

an echo-amplitude decay compatible with a passive finite-capacity shell,

a quasi-normal mode deformation consistent with the same shell location,

a frequency dependence compatible with one of the admissible shell-response laws.

Only a combined signal of that sort would qualify as genuine support for the compact-object branch of the theory.

This is another reason the shell-response sector is indispensable. It upgrades the theory from "delayed feature" language to internally linked spectroscopic structure.

12.8 What a null result would mean

The same hierarchy defines falsification pressure. A null result does not mean "no visible echo at all under any conditions." It means something sharper: if data exclude the FCLET timing band, the corresponding amplitude hierarchy, and the associated mode deformation pattern simultaneously, then the canonical shell realization of the theory is constrained.

This is exactly how the strong-field branch should be tested:

not by one indicator in isolation,

but by correlated shell observables.

That is the mature observational form of the FCLET compact-object sector.

12.9 Conclusion of the observational-window analysis

The strong-field branch of FCLET has now crossed the threshold from shell placement to observational targeting. The theory defines:

where late-time shell structure must occur,

how that structure must decay,

how ringdown frequencies must shift,

and why overtone structure matters.

The exact conclusion of the section is

$$FCLET\ predicts\ a\ correlated\ strong - field\ observational\ package\ consisting\ of\ shell\ timing, shell\ amplitude\ hierarchy, and\ shell - induced\ ringdown\ deformation.$$

This is the proper observational window of the theory.

13. Distinction from Generic Planck-Shell Echo Models

The strong-field compact-object literature already contains a broad class of models in which a partially reflective surface is placed at a microscopic proper distance outside the classical horizon. Such models generically predict a logarithmic echo-delay law, because the dominant

timing scale is controlled by the near-horizon tortoise stretching rather than by the detailed shell microphysics. This fact must be faced directly. The existence of a shell-induced delay in the approximate range

$$\Delta t_{\mathrm{echo}} \sim 4M\ln\left(\frac{M}{\ell_P}\right)$$

does not by itself isolate FCLET from the rest of the Planck-scale shell landscape.

That observation, however, does not weaken the present theory. It clarifies where its genuine distinctiveness lies.

FCLET is not a theory that begins by postulating a reflective membrane and then asking what ringdown signals follow. It is a theory in which the shell is derived from a finite-capacity burden architecture. The shell is not inserted. It emerges. That single difference reorganizes the entire strong-field problem.

The distinction from generic Planck-shell echo models can therefore be stated in four exact layers.

13.1 Shell location is derived, not postulated

In generic shell models, the shell location is often introduced as an external parameter:

a microscopic offset ϵ,

a proper-distance cutoff,

or a membrane placed by hand near the horizon.

In FCLET, the shell location is not introduced independently of the local field variables. It is derived from the saturation condition of the burden sector. The shell appears when the local patch reaches the burden-support crossover

$$I_{\mathrm{sat}} = \frac{1}{2}, \chi_{\mathrm{sat}} = 1,$$

and the shell distance follows from the microphysical burden variables as

$$\rho_s = \frac{\sqrt{2\eta_s}}{\pi}\,\ell_P.$$

Thus the shell is not a free near-horizon surface. It is a derived finite-capacity transition layer. That is the first decisive distinction.

13.2 The shell threshold is internal to the theory

Generic echo models frequently choose the shell offset without an internal saturation criterion. FCLET does not. The shell-onset condition is fixed by the internal logic of the burden map itself:

$$I_{\mathrm{sat}} = 1 - I_{\mathrm{sat}},$$

which yields

$$I_{\mathrm{sat}} = \frac{1}{2}.$$

The shell therefore begins where realized local burden equals residual support margin. This is not a phenomenological choice. It is the unique crossover point between support-dominated and burden-dominated patch behavior.

This matters because it means that FCLET does not merely say "put a shell somewhere near the horizon." It says **why** the shell begins where it does. The shell threshold is therefore part of the theory's dynamical architecture rather than a hidden auxiliary assumption.

13.3 Shell response is tied to finite-capacity microphysics

A generic Planck-shell model may assign a reflectivity coefficient $R(\omega)$to its shell. But in many such models, that coefficient is phenomenological at the point of introduction. In FCLET, the shell reflectivity sector is tied directly to the same variables that created the shell location:

species loading η_s,

shell burden state χ_s,

shell response scale ω_c,

shell relaxation scale Γ_s.

The shell response function

$$R_s(\omega) = R_s(\omega; \eta_s, \chi_s, \Gamma_s, \omega_c)$$

is therefore not an independent decorative attachment. It is the boundary-response descendant of the shell's finite-capacity state. That is the second decisive distinction.

A model that merely assumes a microscopic shell can reproduce echo timing. A model that derives shell response from local burden variables can reproduce a shell spectroscopy. FCLET belongs to the second class.

13.4 The theory predicts a correlated observational package

The strongest difference appears at the observational level. Generic shell models often predict one or two shell-like observables:

a delay scale,

perhaps a nominal reflectivity,

perhaps a generic echo train.

FCLET predicts a linked package:

shell location from burden saturation,

shell threshold from internal support-burden balance,

echo timing from the shell-barrier cavity,

reflectivity hierarchy from finite-capacity shell response,

quasi-normal mode deformation from the same reflectivity law,

overtone dependence from shell bandwidth and dissipation scales.

This means that the strong-field branch is constrained by internal consistency. One does not have the freedom to choose shell placement, shell threshold, and shell response independently without departing from the FCLET architecture. The shell observables must cohere because they descend from one burden-capacity structure.

That is the third decisive distinction.

13.5 Timing overlap does not imply theoretical equivalence

The most important methodological point can now be stated exactly. Suppose two theories predict similar echo delays for a $30\,M_{\odot}$ remnant. It does not follow that the theories are strongly equivalent in the ringdown sector. Similarity in delay can coexist with sharp differences in:

echo amplitude hierarchy,

overtone suppression,

damping modification,

mode deformation,

and shell reflectivity phase structure.

The reason is simple: timing depends mainly on shell placement and tortoise stretching, whereas spectroscopy depends on shell response.

Therefore, even if FCLET shares the broad logarithmic timing scale of other Planck-shell models, it need not share their strong-field spectroscopic signatures.

That is precisely where the theory becomes distinguishable.

13.6 What FCLET does and does not claim

The present strong-field analysis therefore makes two claims, one negative and one positive.

Negative claim

FCLET does **not** claim that a logarithmic Planck-shell echo delay is by itself unique to the theory.

Positive claim

FCLET **does** claim that the shell's location, onset, response law, and resulting spectroscopic hierarchy form a correlated structure that is specific to its finite-capacity microphysics.

That distinction is essential. It keeps the strong-field argument disciplined and prevents the theory from overstating what one timing formula alone can accomplish.

13.7 Exact discriminant of the theory

The decisive strong-field discriminator of FCLET may therefore be written as

FCLET is distinguished not by shell timing alone, but by the coupled structure of
(i) burden-derived shell location,(ii) internally fixed shell threshold,(iii) microphysically controlled shell reflectivity,
(iv) quasi-normal mode deformation,and (v) echo amplitude hierarchy.

This is the exact strong-field identity of the theory.

13.8 Final comparison statement

The comparison with generic Planck-shell echo models can therefore be summarized in one compact statement:

($FCLET\ does\ not\ merely\ place\ a\ shell\ near\ the\ horizon.\ It\ derives\ a\ shell\ from\ finite - capacity\ burden\ saturation\ and\ constrains\ its\ response\ through\ the\ same\ microphysics.$)

That is the reason the theory can move beyond shell kinematics into shell spectroscopy.

14. Conclusion

We have developed the shell-response sector of the finite-capacity latency–erasure theory and identified the true strong-field spectroscopic discriminator of the program.

Earlier FCLET papers established the local information-capacity variables, completed the microphysical specification of the burden sector, derived the shell-onset condition $I_{\mathrm{sat}} = 1/2$, and obtained explicit Schwarzschild-shell benchmark estimates for shell distance and echo timing. The present paper completed the next decisive step. It turned the shell from a kinematic surface into a boundary-response layer.

The central result is exact. The FCLET shell is neither a classical horizon nor a rigid mirror. It is a finite-capacity, burden-saturated, latency-bearing, dissipative response layer. Once that point is recognized, the correct strong-field problem is no longer merely where the shell sits, but how it responds to incident perturbations. That response is encoded in the shell reflectivity function

$$R_s(\omega),$$

which we defined as the complex, frequency-dependent return coefficient of the saturation shell and tied to shell burden, species loading, dissipation, and response bandwidth.

From this starting point we derived the canonical shell boundary condition, the shell-barrier transfer function, the echo-amplitude recursion law, and the leading quasi-normal mode deformation produced by shell reflection and cavity recurrence. These results establish the first general spectroscopic framework of the FCLET compact-object branch.

The theoretical significance of this step is substantial. The strong-field sector of FCLET no longer predicts only a shell location and a delay scale. It now predicts:

a shell response law,

a structured echo hierarchy,

overtone-sensitive shell filtering,

and a mode-dependent ringdown deformation.

This is the correct transition from shell timing to shell spectroscopy.

We also clarified the observational status of the delay scale itself. The logarithmic echo timing law is real and important, but it is not by itself the unique signature of the theory, since broad classes of Planck-scale near-horizon shell models share a similar timing structure. The genuine discriminator of FCLET lies deeper: in the correlated package of burden-derived shell location, internally fixed shell threshold, microphysically constrained shell reflectivity, and the resulting spectroscopic hierarchy of echoes and quasi-normal mode shifts.

That conclusion is a strength, not a weakness. It places the theory on exactly the right scientific footing. The compact-object branch is no longer built around a single delayed feature. It is built around a coupled strong-field structure that can be confronted with ringdown data in multiple mutually constraining ways.

The strong-field program is therefore now sharply focused. One task remains decisive: derive the shell reflectivity function $R_s(\omega)$from the shell microphysics at full field-theoretic level,

including explicit evaluation of the response scales $\omega_c$and $\Gamma_s$from a definite field inventory and a definite coarse-graining prescription. Once that step is completed, FCLET will no longer provide only a shell timing window and benchmark response models. It will provide a full strong-field spectroscopic target.

The theory has therefore crossed another threshold in this paper. It has moved beyond shell formation and beyond echo timing. It now possesses a shell-response framework.

That is the strong-field spectroscopic identity of FCLET.

Shell Perturbation Theory from the FCLET Action

Covariant Linearization, Gauge-Invariant Shell Modes, and the Derivation of the Reflectivity Sector in Saturation-Shell Compact Objects

Ali Caner Yücel
Independent Researcher
Gaziantep, Türkiye
alicaneryucel2@outlook.com

Abstract

We develop the perturbation-theoretic strong-field sector of the finite-capacity latency–erasure theory by deriving the shell reflectivity problem directly from the FCLET action. Earlier FCLET work established the local burden variables, fixed the shell-onset condition $I_{\mathrm{sat}} = 1/2$, derived the shell location, and obtained the echo-delay scale of saturation-shell compact objects. What remained open was the decisive strong-field problem: once a finite-capacity shell forms, how do perturbations propagate across it, what matching law does the shell impose, and how does the reflectivity function $R_s(\omega)$arise from the action itself?

This paper answers that question. We construct the strong-field FCLET action in a static spherically symmetric shell background, linearize the coupled metric-latency system,

$$g_{\mu\nu} = \bar{g}_{\mu\nu} + h_{\mu\nu}, \chi = \bar{\chi} + \delta\chi,$$

and derive the shell perturbation problem in covariant form. In the odd-parity sector, the scalar latency perturbation does not propagate as an independent axial degree of freedom, but it dresses the background shell structure and modifies the effective Regge–Wheeler problem through shell-localized coupling. In the strict thin-shell limit, this yields a shell-supported axial master equation with a localized interaction term, from which the first explicit FCLET shell reflectivity law is derived analytically.

We obtain

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s},$$

together with the corresponding transmission coefficient and shell response scale. The minimal axial thin-shell branch is therefore fully reflective in magnitude in the deep infrared, transparent in the ultraviolet, and governed by the crossover scale $\omega_c^{(\mathrm{ax,thin})} = \Lambda_s/2$. This

result establishes the first action-derived reflectivity sector of the FCLET compact-object program.

The paper also shows why the minimal branch is not the final physical shell-response sector of the theory. A realistic FCLET reflectivity law requires finite-thickness shell dynamics, coupled metric-latency perturbations, and dissipative internal shell channels. The present result is therefore both decisive and delimitative: it proves that $R_s(\omega)$is derivable from the perturbation problem rather than inserted phenomenologically, and it identifies exactly what must be added to obtain the fully physical shell-response law.

The strong-field FCLET program thus advances from shell kinematics to shell perturbation dynamics. The shell is no longer characterized only by where it forms and when its echoes return. It is now characterized by a derived boundary-response sector.

1. Introduction

The strong-field branch of the finite-capacity latency–erasure theory has now reached the point at which shell kinematics is no longer sufficient. Earlier FCLET work established that compact collapse does not terminate in a featureless classical horizon. Instead, the local burden field approaches the finite-capacity crossover, the shell-onset threshold is fixed internally by

$$I_{\mathrm{sat}} = \frac{1}{2}, \chi_{\mathrm{sat}} = 1,$$

and a saturation shell forms at a finite proper distance outside the classical horizon scale. From that shell geometry, the echo-delay law of the compact-object sector was derived, and the strong-field branch acquired its first explicit timing window. Those results closed the kinematic side of the problem. They determined where the shell forms and when late-time return structure should appear.

But they did not yet determine how the shell responds.

That is the decisive unresolved question. A shell location does not by itself define a strong-field theory. A shell reflectivity law does. Once a saturation shell exists, the compact-object boundary is no longer a purely absorptive horizon. It becomes a response layer. Perturbations incident on that layer must satisfy a boundary law, and that boundary law determines:

how much of the incoming mode is reflected,

how much is transmitted,

how much is dissipated,

and how the quasi-normal mode spectrum departs from the general-relativistic baseline.

The reflectivity problem is therefore not a secondary refinement. It is the central spectroscopic problem of the FCLET compact-object sector.

This paper derives that sector from the action itself.

The point of departure is exact. A genuine strong-field reflectivity law cannot be obtained by inserting an impedance analogy, by assigning a phenomenological mirror coefficient, or by choosing a shell response ansatz in isolation. Those procedures reintroduce the very arbitrariness that FCLET has spent the entire program eliminating. The shell reflectivity sector must instead emerge from the perturbation dynamics of the coupled field system. That means one must write the strong-field FCLET action, choose a shell background, linearize the metric-latency system around that background, identify the gauge-invariant perturbation variables, derive the shell matching law, and only then read off the reflectivity coefficient from the scattering solution.

That is what the present paper does.

The key structural fact of the theory is that the shell is not an external membrane. It is the finite-capacity response layer generated by local burden saturation. The same burden field that fixed the shell onset and shell position must therefore also control the shell's perturbative boundary behavior. This immediately implies two consequences.

First, the reflectivity coefficient $R_s(\omega)$is not an auxiliary parameter. It is a derived output of the shell perturbation problem.

Second, the shell-response problem must be parity sensitive. In the odd-parity axial sector, the scalar latency perturbation does not propagate as an independent axial mode. Instead, the shell burden profile modifies the background geometry and contributes to the shell matching problem through background dressing and shell-localized coupling. This makes the axial sector the natural first place to begin. It is technically cleaner than the polar sector and already sufficient to yield a nontrivial action-derived reflectivity law.

The present paper therefore begins with the minimal but exact strong-field perturbation problem: the axial shell sector in the thin-shell limit.

This turns out to be decisive. In that limit the shell-corrected Regge–Wheeler problem can be solved analytically. The reflectivity coefficient is no longer a guessed response function. It becomes an explicit derived quantity:

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}.$$

That result is both powerful and clarifying. It proves that the FCLET reflectivity sector can be derived from perturbation matching rather than postulated phenomenologically. At the same time, it shows that the strict thin-shell axial branch is too rigid to be the final physical shell-response law: the low-frequency reflectivity is unity in magnitude, which immediately indicates that finite-thickness shell dynamics and coupled metric-latency perturbations must be incorporated in the next step.

That is exactly the right scientific outcome. The theory does not pretend to have finished the shell-response problem before it has done so. It does the first real calculation, identifies the exact analytical branch it controls, and shows what remains.

The paper is organized as follows. Section 2 defines the FCLET strong-field action and the static shell background. Section 3 linearizes the metric-latency system. Section 4 constructs the odd-parity gauge-invariant perturbation sector. Section 5 derives the shell-localized effective coupling in the axial branch. Section 6 states the shell matching conditions. Section 7 derives the reflectivity sector explicitly and obtains the minimal axial thin-shell response law together with its low-frequency and high-frequency limits. Section 8 explains why the minimal branch does not yet exhaust the physical shell-response sector of the theory. Section 9 draws the immediate consequences for echoes and quasi-normal modes. Section 10 concludes.

The compact-object branch of FCLET therefore enters a new stage in this paper. The shell is no longer described only by where it forms and when it echoes. It is described by a derived perturbative response law.

That is the transition from shell kinematics to shell perturbation dynamics.

2. FCLET Action and Strong-Field Shell Background

The perturbation problem must begin from a definite field system. In the strong-field FCLET sector, the relevant degrees of freedom are the spacetime metric $g_{\mu\nu}$, the latency field χ, and whatever matter content Ψ_m sources or supports the shell background. The general effective action is therefore written as

$$\boxed{S[g,\chi,\Psi_m] = \int d^4x\sqrt{-g}\left[\frac{1}{16\pi G}R + \mathcal{L}_\chi(g,\chi,\nabla\chi) + \mathcal{L}_{\rm int}(g,\chi,\Psi_m) + \mathcal{L}_m(g,\Psi_m)\right].}$$

The specific content of the FCLET strong-field branch is carried by the latency sector $\mathcal{L}_\chi$. At the level required for the present perturbation analysis, the minimal effective form is

$$\boxed{\mathcal{L}_\chi = -\frac{1}{2}Z_\chi(\chi)\, g^{\mu\nu}\nabla_\mu\chi\nabla_\nu\chi - U(\chi),}$$

where:

$Z_\chi(\chi)$ is the effective shell-state-dependent kinetic factor,

$U(\chi)$ is the shell-support potential of the burden sector.

The interaction term $\mathcal{L}_{\rm int}$ encodes the effective coupling between the latency field and the matter or shell-support sector. Its detailed microscopic completion is not needed to derive the minimal axial thin-shell branch. What matters for the present purpose is that it supports a static, spherically symmetric shell background in which the latency field is nontrivial near the shell radius and asymptotes appropriately outside the shell-support region.

The Euler–Lagrange equations obtained from the action are

$$\boxed{G_{\mu\nu} = 8\pi G\left(T^{(\chi)}_{\mu\nu} + T^{(m)}_{\mu\nu} + T^{(\rm int)}_{\mu\nu}\right),}$$

together with the latency-field equation

$$\boxed{\nabla_\mu\left(Z_\chi(\chi)\nabla^\mu\chi\right) - \frac{1}{2}Z'_\chi(\chi)\,(\nabla\chi)^2 - U'(\chi) = \mathcal{J}_{\rm int},}$$

where $\mathcal{J}_{\rm int}$ is the interaction-sector source term.

These equations define the full FCLET strong-field field system. The perturbation theory of the shell must be derived by linearizing these equations around a static shell background.

2.1 Static spherically symmetric shell background

We take the background geometry to be static and spherically symmetric:

$$\boxed{d\bar{s}^2 = -\bar{A}(r)\,dt^2 + \bar{B}(r)\,dr^2 + r^2 d\Omega^2.}$$

The background latency field is likewise static and radial:

$$\boxed{\bar{\chi} = \bar{\chi}(r).}$$

This background represents the FCLET saturation-shell compact-object branch:

the exterior region is asymptotically Schwarzschild-like,

the shell region is the finite-capacity transition layer,

the shell onset is fixed by the burden-support crossover,

and the shell proper distance from the classical horizon scale is already determined by the earlier strong-field FCLET analysis.

The shell radius $r_s$is therefore not a free membrane position. It is the radius at which the background occupancy field reaches

$$I(r_s) = \frac{1}{2}.$$

Equivalently,

$$\chi(r_s) = 1.$$

This is the defining strong-field background condition of the shell.

2.2 Exterior and shell regions

The perturbation problem is most transparent when the background is viewed as consisting of three radial domains.

Exterior region

For $r > r_s$, the geometry is asymptotically Schwarzschild-like and the latency field relaxes outward. The compact object is observed from this region.

Shell region

In a narrow neighborhood of $r = r_s$, the burden field enters the strong crossover regime, the latency sector is order unity, and the local support margin is no longer large. This is the response layer of the theory.

Interior effective region

For $r < r_s$, the continuation of the effective solution depends on the particular shell-support completion being used. The present paper does not require a full interior microphysical completion. It requires only that the shell background admit a consistent thin-shell limit in the axial perturbation sector.

This is an important simplification. The first goal is not to solve the complete interior FCLET compact-object problem. It is to derive the shell reflectivity law in the first analytically tractable branch.

2.3 Thin-shell reduction

The full shell background has finite thickness in proper distance. But the first perturbative derivation is obtained most cleanly in the strict thin-shell reduction.

Let the shell thickness be Δr_s. In the limit

$$\Delta r_s \to 0$$

with finite integrated shell response strength, the shell-support sector reduces to a localized effective interaction at $r = r_s$. In tortoise coordinate r_*, this becomes a shell-supported distributional coupling. That is the origin of the delta-supported term that will later appear in the axial master equation.

The thin-shell limit is therefore not an arbitrary trick. It is the leading distributional reduction of a finite-thickness saturation shell background.

This matters conceptually. The shell-localized coupling used later in the perturbation equation is not a new postulate inserted by hand. It is the thin-shell image of the FCLET shell background itself.

2.4 Perturbation variables

The perturbation problem now begins from the standard linear split:

$$\boxed{g_{\mu\nu} = \bar{g}_{\mu\nu} + h_{\mu\nu}, \chi = \bar{\chi} + \delta\chi.}$$

The perturbation equations are then obtained by expanding the field system to first order in $h_{\mu\nu}$and $\delta\chi$.

At this stage the key structural point is already visible: the shell reflectivity law will not emerge from background geometry alone. It will emerge from the perturbation equations of the coupled metric-latency system on the shell background.

That is why the strong-field FCLET reflectivity problem is a true field-theoretic problem rather than a shell-placement problem.

2.5 Role of the odd-parity sector

The full perturbation system contains both even-parity and odd-parity sectors. The present paper begins with the odd-parity axial branch for a decisive reason.

A scalar background field $\bar{\chi}(r)$does not itself generate an independent odd-parity scalar mode. Therefore the axial perturbation sector is technically cleaner: the latency field enters the problem not as an independent propagating axial scalar degree of freedom, but through background dressing and shell-localized coupling. This makes the odd-parity sector the natural first place to derive an explicit analytical shell reflectivity law.

The axial sector is therefore not a secondary approximation. It is the first exact branch in which the action-derived shell response can be solved cleanly.

2.6 Outcome of the background setup

The background problem is now fixed.

We have:

a definite FCLET action,

a static shell background,

a background latency field,

a thin-shell reduction,

and a linear perturbation split.

The next step is therefore exact and unavoidable:
derive the linearized field equations of the metric-latency system and isolate the gauge-invariant axial perturbation sector.

That is the task of the next section.

3. Linearization of the Metric–Latency System

The shell reflectivity sector cannot be derived from the background solution alone. It emerges only after the coupled metric-latency system is linearized and the resulting perturbation structure is reduced to its gauge-invariant dynamical content. The purpose of the present section is therefore exact: to obtain the first-order field equations for perturbations around the

static FCLET shell background and to identify the structural role of the latency field in that linearized system.

We begin from the background split

$$g_{\mu\nu} = \bar{g}_{\mu\nu} + h_{\mu\nu}, \chi = \bar{\chi} + \delta\chi,$$

where:

$\bar{g}_{\mu\nu}$is the static spherically symmetric shell background,

$h_{\mu\nu}$is the metric perturbation,

$\bar{\chi}(r)$is the background latency profile,

$\delta\chi$is the linear latency perturbation.

The full field equations were written in the previous section as

$$G_{\mu\nu} = 8\pi G\left(T_{\mu\nu}^{(\chi)} + T_{\mu\nu}^{(m)} + T_{\mu\nu}^{(\mathrm{int})}\right),$$

together with the latency equation

$$\nabla_\mu\left(Z_\chi(\chi)\nabla^\mu\chi\right) - \frac{1}{2}Z'_\chi(\chi)(\nabla\chi)^2 - U'(\chi) = \mathcal{J}_{\mathrm{int}}.$$

Linearization now means expanding these equations to first order in $h_{\mu\nu}$and $\delta\chi$.

3.1 Linearized Einstein sector

The Einstein tensor expands as

$$G_{\mu\nu}[\bar{g} + h] = \bar{G}_{\mu\nu} + \delta G_{\mu\nu}[h] + \mathcal{O}(h^2).$$

Since the background already satisfies the exact shell equations, the zeroth-order terms cancel. The linearized gravitational equation is therefore

$$\boxed{\delta G_{\mu\nu}[h] = 8\pi G\left(\delta T_{\mu\nu}^{(\chi)} + \delta T_{\mu\nu}^{(m)} + \delta T_{\mu\nu}^{(\mathrm{int})}\right).}$$

The decisive new ingredient is the latency contribution $\delta T_{\mu\nu}^{(\chi)}$, because it carries both:

direct dependence on $\delta\chi$,

indirect dependence on the metric perturbation through variation of covariant derivatives, contractions, and the background shell profile $\bar{\chi}(r)$.

For the effective latency Lagrangian

$$\mathcal{L}_\chi = -\frac{1}{2} Z_\chi(\chi)\, g^{\mu\nu} \nabla_\mu \chi \nabla_\nu \chi - U(\chi),$$

the corresponding background stress tensor is

$$T^{(\chi)}_{\mu\nu} = Z_\chi(\chi)\, \nabla_\mu \chi \nabla_\nu \chi - g_{\mu\nu} \left[\frac{1}{2} Z_\chi(\chi) (\nabla\chi)^2 + U(\chi) \right].$$

Linearization gives a first-order perturbation of the form

$$\delta T^{(\chi)}_{\mu\nu} = \delta T^{(\chi)}_{\mu\nu}[h, \delta\chi; \bar{g}, \bar{\chi}].$$

Its detailed component structure is algebraically lengthy but conceptually straightforward: it is linear in $h_{\mu\nu}$and $\delta\chi$, with coefficients built from the background shell geometry and the background latency gradient $\bar{\chi}'(r)$.

This immediately shows why the shell perturbation problem is nontrivial. Even before parity decomposition, the metric and latency sectors are coupled at first order through the shell background itself.

3.2 Linearized latency equation

The latency field equation likewise expands as

$$\mathcal{E}_\chi[\bar{g} + h, \bar{\chi} + \delta\chi] = \bar{\mathcal{E}}_\chi + \delta\mathcal{E}_\chi[h, \delta\chi] + \mathcal{O}(h^2, h\delta\chi, \delta\chi^2).$$

Since the background satisfies the exact shell equation, the linearized latency equation is

$$\boxed{\delta\mathcal{E}_\chi[h, \delta\chi] = 0.}$$

In explicit form, this is a second-order wave-type equation for $\delta\chi$on the shell background, sourced and dressed by the metric perturbation. Schematically,

$$\boxed{\delta\mathcal{E}_\chi[h, \delta\chi] = \mathcal{D}_\chi\, \delta\chi + \mathcal{S}_\chi[h] = 0,}$$

where:

$\mathcal{D}_\chi$is the background-dependent scalar perturbation operator,

$\mathcal{S}_\chi[h]$is the metric-induced source term.

The structure of $\mathcal{D}_\chi$depends on:

the shell kinetic factor $Z_\chi(\bar{\chi})$,

its derivatives $Z'_\chi(\bar{\chi})$,

the shell-support potential $U(\bar{\chi})$,

and the radial shell profile $\bar{\chi}(r)$.

Thus the linearized latency sector is not an optional add-on. It is part of the full shell perturbation problem.

3.3 Coupled first-order system

Taken together, the linearized field equations define a coupled system:

$$\boxed{\delta G_{\mu\nu}[h] = 8\pi G\, \delta T_{\mu\nu}[h, \delta\chi],}$$
$$\boxed{\delta \mathcal{E}_\chi[h, \delta\chi] = 0.}$$

At this stage the theory has not yet chosen a perturbation basis. The fields $h_{\mu\nu}$and $\delta\chi$are still gauge-dependent objects. The next task is therefore not to solve the system directly, but to decompose it into parity sectors and isolate the gauge-invariant dynamical content.

That decomposition is particularly important in FCLET because the shell background carries a scalar profile $\bar{\chi}(r)$. The scalar background does not affect all perturbation sectors in the same way.

3.4 Parity decomposition and structural simplification

On a static spherically symmetric background, linear perturbations decompose into:

odd-parity (axial) sector,

even-parity (polar) sector.

This is the decisive structural split of the problem.

The reason it matters is simple. The background latency field $\bar{\chi}(r)$is a scalar depending only on radius. Therefore it does not generate an independent odd-parity scalar perturbation channel. In other words, there is no axial scalar harmonic content carried directly by $\delta\chi$.

This has a powerful consequence:

In the odd
− parity sector, the latency field enters through background dressing and shell coupling, not as an

independent propagating axial scalar mode.

That is why the axial branch is the correct first target of the theory. It is the cleanest nontrivial sector in which the shell reflectivity law can be derived analytically.

By contrast, the even-parity sector generically mixes metric perturbations and scalar perturbations much more directly. That sector is physically important, but technically more

complicated. It belongs to the next stage of the perturbation program rather than to the first exact derivation of $R_s(\omega)$.

3.5 Gauge structure

Before one can write a master equation, the gauge structure of the linearized system must be identified.

Under an infinitesimal diffeomorphism generated by vector field ξ^μ, the perturbations transform as

$$h_{\mu\nu} \to h_{\mu\nu} + \nabla_\mu \xi_\nu + \nabla_\nu \xi_\mu,$$
$$\delta\chi \to \delta\chi + \xi^\mu \nabla_\mu \bar{\chi}.$$

This makes clear that neither $h_{\mu\nu}$nor $\delta\chi$is directly observable. Physical shell response must therefore be extracted from gauge-invariant combinations.

In the odd-parity sector, this problem simplifies significantly because the scalar background does not supply an independent axial perturbation amplitude. As a result, one can construct an axial gauge-invariant master variable whose equation reduces to a shell-corrected Regge–Wheeler problem.

That will be the next step.

3.6 Background dressing versus propagating shell degrees of freedom

It is important to distinguish two different roles played by the latency field in the perturbation problem.

Background dressing

The shell profile $\bar{\chi}(r)$modifies the background geometry and therefore changes the effective potential seen by perturbations. This effect is already present even if $\delta\chi$does not appear as an independent dynamical mode in the chosen parity sector.

Propagating perturbative coupling

In the full coupled system, $\delta\chi$can in principle propagate and mix with metric perturbations. This is especially relevant in the polar sector and in finite-thickness shell dynamics.

The odd-parity axial branch isolates the first of these effects in its cleanest form. The shell reflectivity law derived in that branch therefore captures a genuine FCLET response effect, but not yet the full shell microphysics.

This distinction will later explain why the minimal branch yields a perfectly reflective low-frequency limit and why that result, though exact in the branch itself, is not yet the final physical shell-response law of the full theory.

3.7 Thin-shell reduction of the linearized system

The static shell background has finite thickness, but the first analytical branch is obtained by reducing the shell-support contribution to a distributional interaction in the strict thin-shell limit. At the level of the linearized perturbation problem, this means that the background-dressed shell contribution becomes localized at the shell radius $r = r_s$, or equivalently at $r_* = r_{*,s}$.

Thus the coupled system reduces, in the axial branch, to an effective master equation with shell-supported interaction. The full finite-thickness shell dynamics is thereby compressed into:

a localized coupling strength,

and corresponding jump conditions at the shell.

This reduction is not arbitrary. It is the leading distributional image of the shell background and therefore the correct first analytical approximation.

3.8 Outcome of the linearization

The result of the present section is exact in structure.

The FCLET shell perturbation problem is a coupled first-order system for $h_{\mu\nu}$and $\delta\chi$on a static shell background. In the odd-parity sector, the scalar latency perturbation does not propagate as an independent axial degree of freedom, which allows the shell problem to be reduced to a background-dressed axial master equation. In the thin-shell limit, this master equation acquires a shell-localized interaction term.

That is the precise mathematical doorway through which the first action-derived shell reflectivity law enters the theory.

The next task is therefore clear:
construct the odd-parity gauge-invariant sector explicitly and identify its master variable.

4. Odd-Parity Perturbations and Gauge-Invariant Variables

The linearized system derived in the previous section becomes analytically tractable only after a parity decomposition is performed and its gauge-invariant content is isolated. In the present paper we begin with the odd-parity sector because it is the cleanest nontrivial branch of the FCLET shell perturbation problem. It is nontrivial because the shell background modifies the axial propagation problem, but it remains technically manageable because the scalar latency perturbation does not furnish an independent axial propagating degree of freedom.

This section therefore does three things. First, it defines the odd-parity metric perturbations on the static shell background. Second, it identifies their gauge structure. Third, it constructs the gauge-invariant axial master variable that will carry the shell-response calculation.

4.1 Odd-parity harmonic decomposition

Let the static background metric be

$$d\bar{s}^2 = -\bar{A}(r)\,dt^2 + \bar{B}(r)\,dr^2 + r^2 d\Omega^2.$$

On this background, odd-parity perturbations are built from axial vector and tensor spherical harmonics. For each multipole (ℓ, m), the metric perturbation may be written in Regge–Wheeler form as

$$h_{\mu\nu}^{(\mathrm{odd})} = \sum_{\ell m} \begin{pmatrix} 0 & 0 & h_0^{\ell m}(t,r)\, S_\theta^{\ell m} & h_0^{\ell m}(t,r)\, S_\phi^{\ell m} \\ 0 & 0 & h_1^{\ell m}(t,r)\, S_\theta^{\ell m} & h_1^{\ell m}(t,r)\, S_\phi^{\ell m} \\ \mathrm{sym} & \mathrm{sym} & h_2^{\ell m}(t,r)\, S_{\theta\theta}^{\ell m} & h_2^{\ell m}(t,r)\, S_{\theta\phi}^{\ell m} \\ \mathrm{sym} & \mathrm{sym} & \mathrm{sym} & h_2^{\ell m}(t,r)\, S_{\phi\phi}^{\ell m} \end{pmatrix}.$$

Here $S_A^{\ell m}$ and $S_{AB}^{\ell m}$ are the standard odd-parity vector and tensor harmonics on the two-sphere.

The axial sector is therefore encoded in the triplet of radial-temporal amplitudes

$$h_0^{\ell m}(t,r), h_1^{\ell m}(t,r), h_2^{\ell m}(t,r).$$

For compactness, the (ℓ, m) labels will often be suppressed below.

4.2 Absence of an independent axial scalar mode

The background latency field is a scalar:

$$\bar{\chi} = \bar{\chi}(r).$$

Its perturbation transforms as a scalar on the two-sphere. Consequently, $\delta\chi$ decomposes into even-parity scalar harmonics, not odd-parity axial harmonics. There is therefore no independent odd-parity scalar perturbation channel associated directly with $\delta\chi$.

This point is decisive. It means that in the axial sector the shell latency field enters only through:

background modification of the geometry,

background-dependent effective couplings,

and, in the thin-shell reduction, shell-supported interaction terms.

It does **not** enter as an independent axial propagating scalar amplitude.

The precise structural statement is therefore

$$\boxed{\delta\chi^{(\mathrm{odd})} = 0 \text{ as an independent harmonic degree of freedom.}}$$

This is why the axial branch is the correct first sector for the derivation of an action-based reflectivity law.

4.3 Odd-parity gauge transformations

Under an infinitesimal diffeomorphism generated by vector ξ^{μ}, the metric perturbation transforms as usual:

$$h_{\mu\nu} \to h_{\mu\nu} + \bar{\nabla}_{\mu}\xi_{\nu} + \bar{\nabla}_{\nu}\xi_{\mu}.$$

In the odd-parity sector, the gauge generator takes the form

$$\boxed{\xi_{\mu}^{(\mathrm{odd})} = \sum_{\ell m} (0, 0, \Lambda^{\ell m}(t,r)\, S_{\theta}^{\ell m}, \Lambda^{\ell m}(t,r)\, S_{\phi}^{\ell m}).}$$

Under this transformation, the axial amplitudes change as

$$\boxed{h_0 \to h_0 - \partial_t \Lambda,}$$

$$\boxed{h_1 \to h_1 - \partial_r \Lambda + \frac{2}{r}\Lambda,}$$

$$\boxed{h_2 \to h_2 + 2\Lambda.}$$

These relations show explicitly that the individual functions $h_0, h_1, h_2$are gauge dependent. Any physically meaningful shell response calculation must therefore be expressed in terms of gauge-invariant combinations.

4.4 Regge–Wheeler gauge and gauge-invariant content

A standard simplification is to impose the axial Regge–Wheeler gauge

$$\boxed{h_2 = 0.}$$

This fully fixes the odd-parity angular gauge freedom for $\ell \geq 2$. In that gauge, the entire axial metric perturbation is carried by $h_0(t,r)$and $h_1(t,r)$.

However, the physical content of the theory should not be tied conceptually to a gauge choice. The better statement is that the axial branch admits a gauge-invariant master variable, and Regge–Wheeler gauge is merely the simplest coordinate representation of that invariant content.

Thus the goal is not just to set $h_2 = 0$, but to identify the invariant combination whose equation of motion will become the shell-corrected Regge–Wheeler equation.

4.5 Gauge-invariant axial master variable

For a static spherically symmetric background, the odd-parity metric perturbations can be reduced to a single gauge-invariant master field. In the present FCLET shell setting, the same

remains true in the axial branch, because no independent axial scalar perturbation is added by the latency sector.

We therefore define the gauge-invariant axial master variable $\Phi_{\ell m}(t,r)$by the standard Regge–Wheeler-type combination built from $h_0$and h_1. In Regge–Wheeler gauge this reduces to the familiar form

$$\boxed{\Phi_{\ell m}(t,r) = \frac{\bar{A}(r)}{r}\, h_1^{\ell m}(t,r),}$$

up to normalization conventions. More invariantly, one may regard $\Phi_{\ell m}$as the unique odd-parity master scalar constructed from the axial amplitudes and their first derivatives.

The exact normalization is not the central issue. What matters is that:

$\Phi_{\ell m}$is gauge invariant,

it captures the full dynamical content of the odd-parity sector,

and its equation of motion is second order and of Regge–Wheeler type.

For the rest of the paper we suppress $(\ell, m)$and write simply

$$\Phi(t,r).$$

4.6 Axial master equation on the shell background

The linearized Einstein sector in odd parity reduces to a single master equation for Φ. Because the background is not exactly vacuum Schwarzschild but an FCLET shell background dressed by $\bar{\chi}(r)$, the resulting equation is not the pure GR Regge–Wheeler equation. It takes the general form

$$\boxed{-\partial_t^2\Phi + \partial_{r_*}^2\Phi - V_{\mathrm{ax}}^{\mathrm{FCLET}}(r)\,\Phi = 0,}$$

where $r_*$is the tortoise coordinate associated with the background shell geometry, and $V_{\mathrm{ax}}^{\mathrm{FCLET}}(r)$is the FCLET axial effective potential.

This potential differs from the classical Regge–Wheeler potential in two ways.

First, the background metric functions $\bar{A}(r)$and $\bar{B}(r)$already differ from exact Schwarzschild because of shell support and burden dressing.

Second, in the thin-shell reduction the shell contributes a localized interaction term at $r = r_s$, or equivalently at $r_* = r_{*,s}$.

Thus the potential decomposes naturally as

$$\boxed{V_{\mathrm{ax}}^{\mathrm{FCLET}}(r) = V_{\mathrm{ext}}(r) + V_{\mathrm{shell}}(r).}$$

Here:

$V_{\rm ext}(r)$is the smooth exterior axial potential,

$V_{\rm shell}(r)$is the shell-supported correction.

In the strict thin-shell limit, the second term reduces to a distributional interaction:

$$\boxed{V_{\rm shell}(r_*) = \Lambda_s\, \delta(r_* - r_{*,s}),}$$

up to sign convention. With the convention adopted later in the scattering problem, the master equation becomes

$$\boxed{\frac{d^2\Phi}{dr_*^2} + [\omega^2 - V_{\rm ext}(r)]\Phi - \Lambda_s\, \delta(r_* - r_{*,s})\, \Phi = 0.}$$

This is the exact minimal axial thin-shell master equation already used in the later reflectivity derivation. The present section now shows where it comes from: it is the gauge-invariant odd-parity reduction of the linearized FCLET shell system.

4.7 Meaning of the shell coupling Λ_s

The parameter $\Lambda_s$is not an arbitrary membrane coefficient. It is the integrated axial shell-response strength produced by the thin-shell reduction of the background-dressed FCLET perturbation equations.

In a finite-thickness shell, the background burden profile $\bar{\chi}(r)$and the shell-support stress tensor modify the axial perturbation problem throughout a narrow radial layer. In the strict thin-shell reduction, that finite-thickness structure is compressed into a single effective shell coupling. Thus

$$\boxed{\Lambda_s = \int_{\rm shell} \mathcal{K}_{\rm ax}\,(r)\, dr_*}$$

schematically, where $\mathcal{K}_{\rm ax}(r)$denotes the effective axial shell-response density extracted from the linearized FCLET field equations.

This is the correct interpretation of Λ_s. It is the integrated axial shell strength of the background shell microphysics.

4.8 Frequency decomposition

Because the background is static, the master field can be Fourier decomposed as

$$\boxed{\Phi(t,r) = e^{-i\omega t}\, \Psi_\omega(r).}$$

Substituting into the master equation gives the stationary shell-corrected wave equation

$$\boxed{\frac{d^2\Psi_\omega}{dr_*^2} + [\omega^2 - V_{\mathrm{ext}}(r)]\Psi_\omega - \Lambda_s\,\delta(r_* - r_{*,s})\,\Psi_\omega = 0.}$$

This is the exact stationary scattering equation whose matching problem yields the first derived FCLET reflectivity law.

At this point the structure of the strong-field calculation is fully visible:

the action defines the shell background,

the shell background defines the linearized coupled system,

the odd-parity branch defines the gauge-invariant master variable,

and the thin-shell reduction produces a localized shell coupling.

The reflectivity problem is therefore now mathematically well posed.

4.9 Outcome of the odd-parity reduction

The main conclusion of the present section is exact:

$$("The\ odd - parity\ sector\ of\ the\ FCLET\ shell\ background\ reduces\ to\ a\ gauge - invariant\ master\ equation\ of\ Regge - Wheeler\ type\ with\ shell - localized\ coupling.")$$

This is the first fully controlled perturbative branch of the compact-object shell sector. It is technically simple enough to solve analytically, but rich enough to produce a nontrivial reflectivity law.

That is precisely why the axial thin-shell branch is the correct starting point of shell perturbation theory in FCLET.

The next task is therefore immediate:
make the shell-localized coupling explicit and derive the matching conditions it imposes at the saturation shell.

5. Thin-Shell Effective Coupling in the Axial Sector

The odd-parity reduction of the previous section showed that the FCLET shell perturbation problem can be written, in gauge-invariant form, as a Regge–Wheeler-type master equation with a shell-supported interaction term. The present section derives the meaning of that interaction term more precisely and fixes the thin-shell effective coupling that governs the first reflectivity calculation.

The central point is exact. The parameter $\Lambda_s$is not an auxiliary scattering constant inserted from outside the theory. It is the integrated axial response strength of the finite-capacity shell obtained by compressing the finite-thickness shell-support layer into its strict thin-shell image.

5.1 Finite-thickness shell and distributional reduction

Let the saturation shell occupy a narrow but finite radial layer centered at $r = r_s$. In the full background problem, the shell is not a geometric surface of zero thickness. It is a transition region in which:

the background occupancy field approaches the burden-support crossover,

the latency profile $\bar{\chi}(r)$varies rapidly,

and the stress-energy carried by the shell-support sector is concentrated.

In a finite-thickness treatment, the axial master equation therefore takes the form

$$\frac{d^2\Psi_\omega}{dr_*^2} + [\omega^2 - V_{\text{ext}}(r) - \Delta V_{\text{shell}}(r)]\Psi_\omega = 0,$$

where $\Delta V_{\text{shell}}(r)$is a sharply localized but regular shell contribution supported in a narrow neighborhood of r_s.

The strict thin-shell limit is obtained by shrinking the shell thickness while holding fixed its integrated response strength. In tortoise coordinate, this gives

$$\Delta V_{\text{shell}}(r_*) \longrightarrow \Lambda_s\, \delta(r_* - r_{*,s}),$$

with

$$\boxed{\Lambda_s = \int_{r_{*,s}-\epsilon}^{r_{*,s}+\epsilon} \Delta V_{\text{shell}}(r_*)\, dr_*}$$

in the $\epsilon \to 0$distributional limit.

This is the exact thin-shell definition of the FCLET axial shell coupling.

5.2 Origin of ΔV_{shell}

The shell-supported contribution ΔV_{shell}arises from the background-dressed linearized field equations. In the odd-parity branch, the scalar latency perturbation does not propagate as an independent axial degree of freedom, but the background shell profile still modifies the axial sector through:

derivatives of the background metric functions $\bar{A}(r), \bar{B}(r)$,

radial gradients of the background latency field $\bar{\chi}'(r)$,

and shell-support contributions to the effective stress tensor.

Thus the shell contribution to the axial potential is built from the background shell data rather than from an independent axial scalar wave.

At the effective level, the shell contribution may be written schematically as

$$\Delta V_{\mathrm{shell}}(r) = \mathcal{C}_1(r)\,\bar{\chi}'(r)^2 + \mathcal{C}_2(r)\,\bar{\chi}''(r) + \mathcal{C}_3(r)\,\delta T^{\mathrm{eff}}_{\mathrm{shell}}(r),$$

where the $\mathcal{C}_i(r)$are background-dependent coefficients fixed by the axial reduction of the linearized FCLET equations.

The exact coefficient functions depend on the specific effective action and shell-support sector chosen. But for the purpose of the thin-shell branch, their detailed radial form is less important than their integrated strength across the shell layer. It is that integrated strength that survives as Λ_s.

5.3 Shell coupling as integrated axial response strength

The thin-shell parameter $\Lambda_s$therefore has a clear physical meaning. It measures the total axial scattering weight carried by the saturation shell.

If the shell were absent, then

$$\Lambda_s = 0,$$

and the master equation would reduce to the standard exterior axial problem.

If the shell is present but weakly structured in the axial sector, then $|\,\Lambda_s\,|$is small and only weak shell reflection is induced.

If the shell is sharply burdened and strongly dressed in the axial channel, then $|\,\Lambda_s\,|$is larger and the shell responds more strongly.

Thus $\Lambda_s$is the first strong-field perturbative descendant of the shell-support background.

Its exact role can already be read from dimensional analysis. Since the delta distribution carries dimensions of inverse length in tortoise coordinate, $\Lambda_s$has dimensions of inverse length or frequency:

$$\boxed{[\Lambda_s] = [r_*^{-1}] = [\omega].}$$

This is why the derived reflectivity law later compares ωdirectly to Λ_s. The shell coupling is itself a response frequency scale.

5.4 Minimal effective shell action

The same result can be expressed at action level. In the thin-shell reduction, the shell contributes an effective quadratic surface term to the axial master action. Writing the axial master field as Φ, the minimal thin-shell effective action takes the form

$$S_{\mathrm{ax}}^{\mathrm{thin}} = \frac{1}{2}\int dt\, dr_*\left[(\partial_t\Phi)^2 - (\partial_{r_*}\Phi)^2 - V_{\mathrm{ext}}(r)\Phi^2\right] - \frac{1}{2}\int dt\, \Lambda_s\, \Phi(t, r_{*,s})^2.$$

Varying this action with respect to Φyields the distributional master equation

$$\frac{d^2\Psi_\omega}{dr_*^2} + [\omega^2 - V_{\mathrm{ext}}(r)]\Psi_\omega - \Lambda_s\, \delta(r_* - r_{*,s})\, \Psi_\omega = 0.$$

This is important conceptually. It shows that the thin-shell scattering problem is not merely a postulated jump equation. It follows from an effective shell action in the axial sector.

5.5 Sign of the coupling and shell behavior

The sign convention in the master equation matters. With the convention adopted here,

$$\frac{d^2\Psi_\omega}{dr_*^2} + [\omega^2 - V_{\mathrm{ext}}(r)]\Psi_\omega - \Lambda_s\, \delta(r_* - r_{*,s})\, \Psi_\omega = 0,$$

positive $\Lambda_s$corresponds to a repulsive shell-supported contribution in the effective scattering problem. This is precisely the sign needed for the minimal axial shell to act as a reflector at low frequency.

Thus the sign of $\Lambda_s$is not arbitrary if the shell is to represent a genuine finite-capacity boundary layer rather than an absorptive sink.

The branch studied in the present paper is therefore the **positive-coupling axial shell branch**:

$$\boxed{\Lambda_s > 0.}$$

This is the minimal FCLET shell-response branch compatible with nontrivial reflection.

5.6 Thin-shell validity window

The strict delta-shell reduction is not exact at all frequencies. It is the leading approximation to a finite-thickness shell background. Its validity requires that the shell thickness remain small compared with the exterior variation scale relevant to the axial wave:

$$\Delta r_{*,s}\, \omega \ll 1$$

for the modes treated in the local matching approximation.

This is exactly why the present result is a **minimal branch** rather than the final full-shell answer. The delta-shell model captures the first integrated response of the shell, but it cannot capture:

internal shell substructure,

multichannel dissipation,

coupled latency propagation inside a finite-thickness shell,

or parity-mixing effects beyond the axial reduction.

Still, within its validity window, it is a genuine action-derived approximation.

5.7 Relation to shell response scale

Because Λ_s has frequency dimension, it already defines a natural shell-response scale. Even before solving the matching problem, one can anticipate that:

modes with $\omega \ll \Lambda_s$ will experience the shell strongly,

modes with $\omega \gg \Lambda_s$ will resolve past the integrated shell barrier more easily.

This expectation will be confirmed exactly in the derived reflectivity law.

Thus the shell coupling does double duty:

it encodes the integrated shell strength,

and it sets the first response bandwidth of the minimal branch.

5.8 Outcome of the thin-shell coupling analysis

The result of the present section can be stated compactly.

The finite-thickness FCLET saturation shell reduces, in the odd-parity thin-shell limit, to a distributional axial interaction term whose integrated strength is

$$\boxed{\Lambda_s = \int_{\text{shell}} \Delta V_{\text{shell}}(r_*)\, dr_*.}$$

This parameter is the effective axial shell-response strength, has dimensions of frequency, and yields the shell-supported master equation

$$\boxed{\frac{d^2\Psi_\omega}{dr_*^2} + [\omega^2 - V_{\text{ext}}(r)]\Psi_\omega - \Lambda_s\, \delta(r_* - r_{*,s})\, \Psi_\omega = 0.}$$

That equation is the exact starting point of the first FCLET reflectivity derivation.

The next task is therefore immediate:
derive the shell matching conditions implied by this equation at $r_* = r_{*,s}$.

6. Matching Conditions at the Saturation Shell

The thin-shell axial reduction derived in the previous section compresses the finite-thickness FCLET saturation shell into a localized interaction supported at the shell position $r_* = r_{*,s}$. Once this reduction is made, the shell-response problem becomes a matching problem. The reflectivity law is not inserted by hand. It is the consequence of the discontinuity structure implied by the shell-supported master equation.

The starting point is the stationary axial wave equation

$$\frac{d^2\Psi_\omega}{dr_*^2} + [\omega^2 - V_{\mathrm{ext}}(r)]\Psi_\omega - \Lambda_s\, \delta(r_* - r_{*,s})\, \Psi_\omega = 0.$$

Because the shell is localized, the behavior of Ψ_ω at the shell is not arbitrary. It is fixed by the distributional structure of the equation itself.

6.1 Continuity of the master field

The first matching condition is continuity of the master field across the shell. A delta-supported potential does not force the field itself to jump; it forces only a discontinuity in its first derivative. Therefore

$$\boxed{\Psi_\omega(r_{*,s}^+) = \Psi_\omega(r_{*,s}^-).}$$

This is the first shell matching law.

Its physical meaning is exact. The shell is a localized response layer, not a singular excision surface. The axial perturbation remains well defined as a field variable across the shell position, even though its radial derivative changes discontinuously because of the integrated shell response.

It is useful to write this condition compactly as

$$\boxed{[\Psi_\omega]_s = 0\,,}$$

where the shell jump operator is defined by

$$[X]_s \equiv X(r_{*,s}^+) - X(r_{*,s}^-).$$

6.2 Jump condition for the radial derivative

The second matching condition is obtained by integrating the master equation across an infinitesimal neighborhood of the shell. Let

$$x = r_* - r_{*,s}.$$

Integrating from $-\epsilon$to $+\epsilon$and taking $\epsilon \to 0$, the smooth terms vanish in the limit while the delta-supported term survives. One obtains

$$\int_{-\epsilon}^{+\epsilon} \frac{d^2\Psi_\omega}{dx^2}\, dx - \Lambda_s \int_{-\epsilon}^{+\epsilon} \delta(x)\, \Psi_\omega(x)\, dx = 0.$$

Therefore

$$\Psi'_\omega(r_{*,s}^+) - \Psi'_\omega(r_{*,s}^-) = \Lambda_s\, \Psi_\omega(r_{*,s}).$$

Thus the exact derivative jump condition is

$$\boxed{[\partial_{r_*}\Psi_\omega]_s = \Lambda_s\, \Psi_\omega(r_{*,s}).}$$

This is the second shell matching law.

Together with continuity of the master field, it completely specifies the shell response in the minimal axial thin-shell branch.

6.3 Interpretation of the jump law

The derivative jump condition is the mathematical encoding of shell impedance in the present branch. A smooth exterior potential modifies propagation continuously. A localized shell modifies propagation impulsively. The finite jump in $\partial_{r_*}\Psi_\omega$measures the integrated scattering strength of the shell.

The meaning of the coefficient $\Lambda_s$is therefore now completely concrete. It is the coefficient relating:

the value of the perturbation at the shell,

to the jump in its radial flux derivative.

In this sense, the shell is not imposed by a guessed boundary reflectivity. It is imposed by a derived jump law.

This is the first real strong-field payoff of the perturbation formalism.

6.4 Local shell scattering form

To prepare the reflectivity calculation, it is convenient to rewrite the shell problem locally. Define again

$$x = r_* - r_{*,s}.$$

In the immediate shell neighborhood, the smooth exterior potential $V_{\text{ext}}(r)$is negligible at leading order in the local matching problem, so the wave equation reduces to

$$\frac{d^2\Psi_\omega}{dx^2} + \omega^2\Psi_\omega - \Lambda_s\,\delta(x)\,\Psi_\omega = 0.$$

The shell matching conditions then read

$$\boxed{\Psi_\omega(0^+) = \Psi_\omega(0^-),}$$
$$\boxed{\Psi'_\omega(0^+) - \Psi'_\omega(0^-) = \Lambda_s\,\Psi_\omega(0).}$$

These are the exact local shell scattering conditions of the minimal axial branch.

6.5 Exterior/interior mode decomposition

The shell matching problem must be solved by specifying the mode on both sides of the shell.

For the exterior side $x > 0$, the physically relevant solution is a superposition of incoming and reflected waves:

$$\boxed{\Psi_+(x) = A_{\rm in}(\omega)e^{-i\omega x} + A_{\rm out}(\omega)e^{+i\omega x}.}$$

For the inner side $x < 0$, the minimal transmitted branch is taken to be ingoing:

$$\boxed{\Psi_-(x) = A_{\rm tr}(\omega)e^{-i\omega x}.}$$

This is the simplest strong-field branch consistent with the idea that part of the incident perturbation is transmitted into the shell-interior channel while another part is returned to the exterior.

The shell reflectivity and transmission coefficients are then defined by

$$\boxed{R_s(\omega) = \frac{A_{\rm out}(\omega)}{A_{\rm in}(\omega)}, T_s(\omega) = \frac{A_{\rm tr}(\omega)}{A_{\rm in}(\omega)}.}$$

At this point the response problem is completely well posed.

6.6 Continuity equation in amplitude form

Applying continuity of the master field at $x = 0$gives

$$A_{\rm in} + A_{\rm out} = A_{\rm tr}.$$

Dividing by $A_{\rm in}$, one obtains

$$\boxed{1 + R_s(\omega) = T_s(\omega).}$$

This is the first amplitude relation imposed by the shell.

6.7 Jump equation in amplitude form

Now apply the derivative jump condition. The derivatives are

$$\Psi'_+(0) = -i\omega A_{\mathrm{in}} + i\omega A_{\mathrm{out}},$$
$$\Psi'_-(0) = -i\omega A_{\mathrm{tr}}.$$

Substituting into the jump law gives

$$(-i\omega A_{\mathrm{in}} + i\omega A_{\mathrm{out}}) - (\quad -i\omega A_{\mathrm{tr}}) = \Lambda_s(A_{\mathrm{in}} + A_{\mathrm{out}}).$$

Dividing by A_{in}, this becomes

$$-i\omega + i\omega R_s + i\omega T_s = \Lambda_s(1 + R_s).$$

Using the continuity relation $T_s = 1 + R_s$, one obtains

$$2i\omega R_s = \Lambda_s(1 + R_s).$$

This is the exact algebraic shell-response equation of the minimal axial branch.

The reflectivity law itself will be extracted in the next section. For the present section, what matters is that the shell matching problem closes exactly and analytically.

6.8 Robin form of the shell matching law

It is also useful to express the shell condition directly as an effective Robin law at the shell. Since

$$[\partial_{r_*}\Psi_\omega]_s = \Lambda_s\,\Psi_\omega(r_{*,s}),$$

the shell acts as a frequency-independent localized admittance layer in the strict thin-shell axial approximation. This is the distributional version of an effective Robin boundary operator.

In the local scattering problem, that Robin structure is what produces a nonzero reflected mode without the need to postulate one externally.

This is conceptually important. Reflection in FCLET appears here as a consequence of shell matching, not as a chosen phenomenological membrane coefficient.

6.9 Classical limit

The shell matching laws also recover the classical limit correctly. If the shell coupling vanishes,

$$\Lambda_s \to 0,$$

then the derivative jump disappears:

$$[\partial_{r_*}\Psi_\omega]_s \to 0.$$

The shell becomes transparent, the reflected amplitude vanishes, and the problem reduces to the ordinary smooth background propagation problem. Thus the FCLET shell branch contains the classical absorptive limit continuously.

This is an essential consistency check.

6.10 Outcome of the shell matching problem

The exact outcome of the present section is the following pair of shell laws:

$$\boxed{[\Psi_\omega]_s = 0\,,}$$
$$\boxed{[\partial_{r_*}\Psi_\omega]_s = \Lambda_s\,\Psi_\omega(r_{*,s}).}$$

These relations completely determine the localized axial shell response in the thin-shell approximation.

They are the mathematical heart of the first FCLET reflectivity derivation. Once the exterior/interior mode decomposition is inserted into these equations, the shell reflectivity and transmission coefficients follow uniquely.

That is the task of the next section.

7. Derivation of the Reflectivity Sector

The shell matching problem derived in the previous section is now complete in formal structure. The master field is continuous across the shell, its radial derivative satisfies a shell-supported jump law, and the exterior/interior mode decomposition has been fixed. Nothing further needs to be assumed. The reflectivity sector now follows directly from the shell matching equations themselves.

This is the decisive point of the present paper. The shell reflectivity coefficient is not introduced phenomenologically, not inferred from a membrane analogy, and not postulated as an external response law. It is obtained by solving the shell scattering problem defined by the axial master equation and its shell matching conditions. In this sense, the reflectivity sector is not an auxiliary addition to the FCLET strong-field branch. It is a derived output of the perturbation problem.

The derivation proceeds in three steps. First, the exact minimal axial thin-shell reflectivity law is obtained analytically. Second, its low-frequency limit is extracted and the zero-frequency

response R_0 is identified. Third, its high-frequency behavior is analyzed and the shell response scale ω_c is read off explicitly. These three results together define the complete leading-order shell response of the minimal axial branch.

The subsections that follow therefore do not merely decorate the shell picture. They produce the first exact action-derived FCLET response law of the compact-object sector.

7.1 Minimal Axial Thin-Shell Reflectivity

The full FCLET shell-response problem ultimately requires finite-thickness shell dynamics and the coupled perturbation system of the metric and latency sectors. Before that complete problem is solved, however, it is both legitimate and informative to isolate the minimal axial branch of the theory in the strict thin-shell limit. This branch already yields a nontrivial reflectivity law and shows, in exact analytical form, why the shell-response problem cannot be reduced to shell placement alone.

We therefore begin with the odd-parity axial sector and model the shell as a localized effective coupling in tortoise-coordinate space. Let $r_{*,s}$ denote the shell location and let the axial master field be $\Psi(r_*, t)$. In the thin-shell approximation, the shell-corrected master equation is taken to be

$$\frac{d^2\Psi}{dr_*^2} + [\omega^2 - V_{\mathrm{ext}}(r)]\Psi - \Lambda_s\, \delta(r_* - r_{*,s})\, \Psi = 0,$$

where $V_{\mathrm{ext}}(r)$ is the exterior axial effective potential and Λ_s is the shell-localized coupling strength. This is the minimal FCLET axial shell model: the shell contributes a localized response term, while the exterior remains governed by the ordinary smooth barrier structure.

To derive the shell reflectivity, define the local shell coordinate

$$x = r_* - r_{*,s}.$$

In the immediate shell neighborhood, the exterior potential is smooth and may be neglected at leading order in the local scattering problem. The master equation reduces to

$$\frac{d^2\Psi}{dx^2} + \omega^2\Psi - \Lambda_s\, \delta(x)\, \Psi = 0.$$

We now solve this as a one-dimensional scattering problem.

For $x > 0$, corresponding to the exterior side of the shell, we write the mode as an incident plus reflected wave,

$$\Psi_+(x) = e^{-i\omega x} + R_s(\omega)\, e^{+i\omega x}.$$

For $x < 0$, corresponding to the inward side of the shell, we take the minimal transmitted branch to be ingoing:

$$\Psi_-(x) = T_s(\omega)\, e^{-i\omega x}.$$

The first matching condition is continuity of the master field at the shell:

$$\Psi_+(0) = \Psi_-(0).$$

This gives

$$1 + R_s(\omega) = T_s(\omega).$$

The second matching condition follows from integrating the delta-supported equation across the shell:

$$\Psi'_+(0) - \Psi'_-(0) = \Lambda_s\, \Psi(0).$$

Using

$$\Psi'_+(0) = -i\omega + i\omega R_s(\omega), \Psi'_-(0) = -i\omega T_s(\omega),$$

we obtain

$$-i\omega + i\omega R_s + i\omega T_s = \Lambda_s(1 + R_s).$$

Substituting the continuity relation $T_s = 1 + R_s$, this becomes

$$2i\omega R_s = \Lambda_s(1 + R_s).$$

Solving for the shell reflectivity gives

$$\boxed{R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}.}$$

The corresponding transmitted amplitude is

$$\boxed{T_s^{(\mathrm{ax,thin})}(\omega) = \frac{2i\omega}{2i\omega - \Lambda_s}.}$$

These are the first explicit shell-response coefficients derived from the minimal axial thin-shell branch of FCLET.

The physical content of this result is immediate. The reflected amplitude is frequency dependent, so even the simplest shell realization already behaves as a nontrivial boundary-response layer rather than as a purely absorptive horizon replacement. The shell is reflective at low frequency and progressively more transparent at high frequency.

The squared reflection coefficient is

$$\boxed{|\, R_s^{(\mathrm{ax,thin})}(\omega)\,|^2 = \frac{\Lambda_s^2}{4\omega^2 + \Lambda_s^2}.}$$

Thus,

$$|\, R_s^{(\mathrm{ax,thin})}(\omega)\,|^2 \to 1 \mathrm{as} \omega \to 0,$$

and

$$|\, R_s^{(\mathrm{ax,thin})}(\omega)\,|^2 \to 0 \mathrm{as} \omega \to \infty.$$

The shell therefore acts as a low-pass reflector in the minimal axial branch.

In particular, the low-frequency limit gives

$$\boxed{R_0^{(\mathrm{ax,thin})} \equiv \lim_{\omega \to 0} R_s^{(\mathrm{ax,thin})}(\omega) = -1.}$$

Hence

$$\boxed{|\, R_0^{(\mathrm{ax,thin})}\,| = 1.}$$

This is a strong and revealing result. In the strict thin-shell axial approximation, the FCLET shell is perfectly reflective in magnitude at zero frequency, with a phase reversal. The small-ω expansion is

$$R_s^{(\mathrm{ax,thin})}(\omega) = -1 - \frac{2i\omega}{\Lambda_s} + \mathcal{O}(\omega^2),$$

showing that the shell begins from unit-magnitude reflection and acquires a frequency-dependent phase correction controlled by Λ_s.

The corresponding response scale is therefore

$$\boxed{\omega_c^{(\mathrm{ax,thin})} \sim \frac{\Lambda_s}{2}.}$$

This gives the minimal axial branch an exact interpretation: $\Lambda_s$is the shell-response scale controlling the transition from low-frequency reflection to high-frequency transparency.

The significance of this result is twofold.

First, it demonstrates that FCLET shell reflectivity can indeed be derived from a perturbation problem rather than assigned phenomenologically. Even this minimal branch produces an explicit analytical expression for $R_s(\omega)$.

Second, it shows equally clearly that shell-localized coupling alone is not enough to identify the physically admissible reflectivity sector of the full theory. A unit-magnitude low-frequency reflectivity is mathematically consistent in the strict axial thin-shell limit, but it is unlikely to represent the full shell microphysics once finite-thickness structure, coupled latency perturbations, and dissipative internal channels are restored.

The conclusion is therefore exact:

("*The minimal axial thin shell branch provides the first derived FCLET reflectivity law, but it does not yet exhaust the physical shell response sector of the theory.*")

Its proper role is foundational. It proves that the reflectivity problem is tractable and that $R_s(\omega)$can be obtained from shell matching rather than inserted by hand. At the same time, it establishes the necessity of the next step: finite-thickness shell perturbation dynamics and coupled metric-latency response.

7.2 Low-Frequency Reflectivity $R_0$and the Shell Response Limit

The minimal axial thin-shell branch derived in the previous subsection already contains a decisive low-frequency result. Since

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s},$$

the zero-frequency shell reflectivity is

$$\boxed{R_0^{(\mathrm{ax,thin})} \equiv \lim_{\omega\to 0} R_s^{(\mathrm{ax,thin})}(\omega) = -1.}$$

Hence

$$\boxed{|\, R_0^{(\mathrm{ax,thin})} \,| = 1.}$$

This means that, in the strict thin-shell axial limit, the FCLET shell is perfectly reflective in magnitude at low frequency, with a phase reversal of π. The physical interpretation is exact. Very long-wavelength axial perturbations do not resolve the shell's internal fine structure.

They encounter the shell as a coherent boundary-response layer and are therefore returned almost entirely.

This result is important because it is the first genuinely derived low-frequency reflectivity statement in the strong-field branch of FCLET. The shell is no longer discussed only in qualitative terms. Even the minimal perturbative realization already yields an explicit R_0.

At the same time, the result must be interpreted correctly. The value

$$R_0^{(\mathrm{ax,thin})} = -1$$

is not yet the final low-frequency reflectivity of the full theory. It is the low-frequency reflectivity of the **minimal axial thin-shell branch**. That distinction matters. The derivation has intentionally excluded:

finite-thickness shell structure,

coupled latency-field perturbations $\delta\chi$,

dissipative internal shell channels,

and even-parity mode coupling.

All of these effects can reduce the magnitude of low-frequency reflection away from unity once the full shell microphysics is restored.

The role of the present result is therefore foundational rather than terminal. It proves that $R_0$is in principle derivable from shell matching and that the low-frequency reflectivity need not be inserted phenomenologically. But it also shows, with equal force, that shell-localized axial coupling by itself is too rigid to represent the physically admissible shell response sector of the complete theory.

This point becomes especially clear when the low-frequency expansion is written explicitly. Expanding the exact result for small ω,

$$R_s^{(\mathrm{ax,thin})}(\omega) = -\frac{1}{1-\frac{2i\omega}{\Lambda_s}},$$

gives

$$\boxed{R_s^{(\mathrm{ax,thin})}(\omega) = -1 - \frac{2i\omega}{\Lambda_s} + \mathcal{O}(\omega^2).}$$

Thus the first correction to the zero-frequency limit is purely imaginary and linear in ω. The shell begins from perfect reflection in magnitude and acquires a frequency-dependent phase lag controlled by the shell-response scale Λ_s. The magnitude itself remains close to unity until ωbecomes comparable to Λ_s.

This allows the low-frequency regime to be stated precisely:

$$\boxed{\omega \ll \Lambda_s \Longrightarrow R_s^{(\mathrm{ax,thin})}(\omega) \approx -1.}$$

The shell therefore behaves as a coherent axial reflector throughout the deep infrared regime of the minimal branch.

This also clarifies an important methodological point for the FCLET program. The low-frequency shell response is not determined directly by the shell location $r_s$alone. It is determined by the **shell matching law**. Two theories can agree on shell position and yet differ sharply in R_0if their shell perturbation dynamics differ. The reflectivity problem is therefore irreducible. It cannot be replaced by shell kinematics alone.

The conclusion of the present subsection may be written in exact form:

("*In the minimal axial thin − shell branch of FCLET, the low − frequency shell response is fully reflective in magnitude, with* " $R\_0 = -1.$)

This is the first derived low-frequency reflectivity result of the program.

But it is also a warning. Because the result is so rigid, it immediately signals that a realistic shell-response sector must go beyond the strict thin-shell axial approximation and include finite-thickness and coupled-shell dynamics.

7.3 High-Frequency Transparency and the Scale ω_c

The same axial thin-shell branch that yields perfect reflection in the deep infrared also yields progressive transparency at high frequency. This is the second decisive feature of the derived shell response.

From the exact reflection coefficient,

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s},$$

the squared reflection magnitude is

$$| R_s^{(\mathrm{ax,thin})}(\omega) |^2 = \frac{\Lambda_s^2}{4\omega^2 + \Lambda_s^2}.$$

This expression immediately shows that the reflected power decreases monotonically with frequency. In particular,

$$\boxed{|\, R_s^{(\mathrm{ax,thin})}(\omega)\,|^2 \to 0 \mathrm{as} \omega \to \infty.}$$

Thus the minimal FCLET axial shell is not a broadband mirror. It is a **frequency-selective reflector**: highly reflective in the infrared, increasingly transparent in the ultraviolet.

This behavior has an exact physical interpretation. Shorter-wavelength perturbations probe the shell more locally and therefore pass more easily through the idealized localized coupling. In the strict delta-shell limit, there is no extended shell thickness to support broadband coherent return. The shell therefore loses its reflective strength as the probing frequency rises.

The characteristic crossover occurs when the two terms in the denominator become comparable:

$$2\omega \sim \Lambda_s.$$

This identifies the axial thin-shell response scale

$$\boxed{\omega_c^{(\mathrm{ax,thin})} \sim \frac{\Lambda_s}{2}.}$$

Equivalently, the shell is strongly reflective for

$$\omega \ll \omega_c^{(\mathrm{ax,thin})},$$

and strongly transparent for

$$\omega \gg \omega_c^{(\mathrm{ax,thin})}.$$

This is the first derived FCLET shell bandwidth law.

A more quantitative statement can be obtained from the half-power condition. Define the response scale as the frequency at which the reflected power falls to one half of its zero-frequency value:

$$|\, R_s^{(\mathrm{ax,thin})}(\omega_{1/2})\,|^2 = \frac{1}{2}.$$

Using the explicit formula gives

$$\frac{\Lambda_s^2}{4\omega_{1/2}^2 + \Lambda_s^2} = \frac{1}{2},$$

hence

$$4\omega_{1/2}^2 = \Lambda_s^2,$$

so that

$$\boxed{\omega_{1/2} = \frac{\Lambda_s}{2}.}$$

Thus the natural shell-response scale is not only order-of-magnitude defined; it is the exact half-power frequency of the minimal branch.

This result is important for two reasons.

First, it proves that FCLET shell response is not merely "some reflectivity." It has a derived frequency structure. The shell is reflective only in a finite band.

Second, it establishes the exact meaning of the parameter Λ_s. In the minimal axial thin-shell branch, Λ_s is not just a coupling coefficient. It is the **spectral stiffness** of the shell. Larger Λ_s pushes the reflectivity band to higher frequencies. Smaller Λ_s makes the shell transparent more quickly.

The transmitted amplitude confirms the same interpretation. Since

$$T_s^{(\mathrm{ax,thin})}(\omega) = \frac{2i\omega}{2i\omega - \Lambda_s},$$

one finds

$$|\, T_s^{(\mathrm{ax,thin})}(\omega)\,|^2 = \frac{4\omega^2}{4\omega^2 + \Lambda_s^2}.$$

Therefore

$$\boxed{|\, T_s^{(\mathrm{ax,thin})}(\omega)\,|^2 \to 0 \mathrm{as} \omega \to 0,}$$

and

$$\boxed{|\, T_s^{(\mathrm{ax,thin})}(\omega)\,|^2 \to 1 \mathrm{as} \omega \to \infty.}$$

This is the exact complement of the reflection law. The shell blocks low-frequency axial modes and transmits high-frequency ones. The minimal branch therefore behaves as a strong-field frequency filter.

That filtering has direct consequences for echoes and ringdown. In the cavity picture, low-frequency components are preferentially returned by the shell and can therefore participate in repeated shell-barrier cycling. High-frequency components leak through the shell more easily and are correspondingly less important in the late-time echo train. The shell thus induces not only delay, but also **spectral softening** of the repeated-return structure.

This point is central for the later strong-field observational analysis. A shell with nontrivial $\omega_c$does not just produce echoes at fixed spacing. It weights those echoes by frequency. The late-time signal therefore carries both geometric and spectral information.

The conclusion of the present subsection may be stated compactly as

$$("The\ minimal\ axial\ thin-shell\ branch\ of\ FCLET\ defines\ a\ low-pass\ shell\ -response\ law\ with\ crossover\ scale\ "\ \omega\_c\hat{}((\mathrm{ax},\mathrm{thin})\ ) = \Lambda\_s/2.)$$

Together with the previous subsection, this gives the full leading shell-response structure of the minimal branch:

low-frequency reflectivity:

$$R_0^{(\mathrm{ax,thin})} = -1,$$

high-frequency transparency:

$$|\ R_s^{(\mathrm{ax,thin})}(\omega)\ |^2 \to 0,$$

response bandwidth:

$$\omega_c^{(\mathrm{ax,thin})} = \Lambda_s/2.$$

These results complete the minimal analytical shell-response profile of the axial thin-shell sector.

They also sharpen the next task. Because the minimal branch is both fully reflective in the deep infrared and fully transparent in the ultraviolet, it captures the existence of a shell-response sector but not yet the physically complete FCLET shell dynamics. That completion requires finite-thickness shell structure and coupled metric-latency perturbations, to which we now turn.

8. Limits of the Minimal Branch and the Need for Finite-Thickness Shell Dynamics

The minimal axial thin-shell branch is exact within its own assumptions. It provides the first action-derived shell reflectivity law of the FCLET compact-object program, and for that reason it is already a major step forward. But its very success makes its limitations fully

visible. The branch is analytically tractable because it compresses the entire shell microphysics into a single localized coupling Λ_s. That same simplification is also the reason it cannot yet represent the full physical response sector of the theory.

The need to move beyond the minimal branch is not an aesthetic preference. It is forced by the structure of the derived result itself.

8.1 Why the minimal branch is too rigid

The defining result of the minimal branch is

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}.$$

This gives

$$R_0^{(\mathrm{ax,thin})} = -1, \mid R_0^{(\mathrm{ax,thin})} \mid = 1.$$

Thus the shell is perfectly reflective in magnitude in the deep infrared.

This is mathematically consistent, but physically too rigid to be accepted as the final FCLET shell-response law. A shell that is fully reflective at low frequency and purely transparent at high frequency is the natural behavior of a single-channel delta-supported barrier. It is not yet the behavior of a burdened, latency-bearing, internally dissipative shell with finite thickness and coupled field content.

The minimal branch therefore proves the existence of a reflectivity sector, but not yet its final physical form.

8.2 Missing finite-thickness structure

The strict thin-shell limit replaces the real shell profile by a distributional surface. This erases:

the radial variation of the shell burden across the shell thickness,

the finite-width latency gradient profile,

the possibility of internal standing structure within the shell,

and any sublayer dependence of shell dissipation.

In a finite-thickness shell, perturbations can interact with the shell over a nonzero radial domain rather than at a point. This can soften the response, distribute the coupling over scale, and reduce the rigidity of the delta-barrier result.

In particular, finite thickness allows:

frequency-dependent dephasing within the shell,

partial destructive interference of return channels,

and richer internal absorption dynamics.

These effects can reduce the low-frequency reflectivity magnitude below unity and alter the precise response scale.

That is why the next strong-field perturbation step must be a finite-thickness shell analysis.

8.3 Missing coupled latency perturbations

The second major limitation of the minimal branch is that it does not include propagating shell perturbations of the latency sector itself. In the odd-parity branch, the scalar latency perturbation does not appear as an independent axial harmonic mode. But the full shell microphysics still involves the coupled metric-latency system. In a finite-thickness treatment, shell-internal latency response can feed back into the effective shell admittance even when the asymptotic axial scattering problem remains parity reduced.

In other words, the minimal branch captures **background dressing** but not yet **dynamical shell reorganization**.

That missing channel is exactly where finite-capacity dissipation, delayed overwrite response, and internal shell relaxation should enter more realistically. The shell reflectivity of the full theory must therefore depend not only on the integrated shell strength but also on the shell's internal dynamical response.

This is the first place where the parameters $\Gamma_s$and more refined response functions should arise from actual perturbation dynamics rather than from benchmark modeling.

8.4 Missing dissipative channels

The minimal branch is conservative at the level of shell matching. It redistributes incoming amplitude between reflection and transmission, but it does not include explicit internal loss channels beyond what is encoded kinematically by the scattering coefficients.

A realistic FCLET shell, however, is not conservative in that narrow sense. The shell is a finite-capacity overwrite medium. It should therefore possess:

delayed reprocessing,

internal excitation storage,

irreversible or quasi-irreversible dissipation,

and possibly mode conversion within the shell-support layer.

These channels are absent in the strict one-channel axial delta-shell problem. Their absence is precisely why $|R_0| = 1$emerges so rigidly.

A fully physical shell-response theory must therefore enlarge the perturbation problem beyond the single-channel axial branch.

8.5 Missing polar sector

The present paper began with the odd-parity sector because it is the cleanest nontrivial branch. That remains the correct choice. But the full shell perturbation theory must eventually include the even-parity sector as well.

In the polar branch, the scalar latency perturbation couples more directly to the metric perturbations. That sector is therefore likely to be the first place where shell-internal burden dynamics enters explicitly into the observable response. In particular, it is plausible that the physically softened low-frequency reflectivity law of the full theory will emerge only once the polar and scalar channels are analyzed together.

Thus the minimal axial branch is the correct beginning, but it cannot be the end.

8.6 What the minimal branch has already accomplished

These limitations must not obscure what the minimal branch has already achieved.

It has shown that:

the shell reflectivity law can be derived from a perturbation equation,

the shell matching problem closes analytically,

a response scale $\omega_c$is already defined,

and shell response is a genuine action-derived sector rather than a phenomenological appendage.

That is already a decisive gain. The theory has crossed from shell kinematics into shell perturbation dynamics.

The purpose of the present section is therefore not to weaken the result, but to locate it correctly inside the larger program.

8.7 The next exact task

The next step can now be stated with precision.

The strong-field FCLET program must move from:

a strict thin-shell axial model,

to:

a finite-thickness shell,

with coupled metric-latency perturbations,

and explicit dissipative shell dynamics.

This means solving the shell perturbation problem in a layer of nonzero width, matching outer and inner solutions across that layer, and allowing the shell response to depend on internal shell mode structure rather than on a single integrated coupling alone.

Only at that stage can the theory produce the fully physical shell reflectivity law.

8.8 Conclusion of the minimal-branch analysis

The exact conclusion of the present section is

$$\begin{aligned} &The\ minimal\ axial\ thin-shell\ branch\ establishes\ the\ existence\ of\ an\ action\\ &\quad -derived\ FCLET\ reflectivity\ sector,\ but\ its\ perfect\ low\\ &\quad -frequency\ reflectivity\ signals\ the\ need\ for\ finite\\ &\quad -thickness\ and\ coupled-shell\ dynamics. \end{aligned}$$

That is the correct interpretation of the result.

The theory has not failed to derive shell response. It has derived the first exact branch of it. And the very structure of that branch now identifies the next perturbative problem without ambiguity.

9. Consequences for Echoes and Quasi-Normal Modes

The minimal axial thin-shell branch does not yet provide the full physical shell-response law of FCLET. But it already has immediate and nontrivial strong-field consequences. Once the shell reflectivity coefficient is derived rather than postulated, the compact-object branch acquires its first action-based statements about:

late-time echo structure,

spectral filtering,

and quasi-normal mode deformation.

These consequences are limited to the minimal axial sector, but they are real. Their value lies precisely in that fact. They show what follows directly from the first derived shell-response law and, at the same time, they indicate which observational features cannot yet be regarded as final until finite-thickness and coupled-shell dynamics are added.

9.1 Echo generation in the minimal axial branch

The first and most direct consequence of the derived reflectivity law is that the shell-barrier cavity becomes physically operative. Once the shell has nonzero reflectivity, a perturbation transmitted inward through the exterior curvature barrier is no longer lost irreversibly into a classical horizon-like sink. A fraction of it is returned by the shell, propagates back toward the barrier, and produces the first delayed echo.

In the minimal axial thin-shell branch, the shell reflectivity is

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s},$$

so the first echo amplitude already inherits a nontrivial frequency weighting. The shell is strongly reflective for

$$\omega \ll \Lambda_s,$$

and increasingly transparent for

$$\omega \gg \Lambda_s.$$

Therefore the echo train of the minimal branch is not merely delayed. It is **frequency filtered**.

This is the first exact spectroscopic consequence of the shell perturbation problem.

9.2 Low-frequency dominance of late-time echoes

Because the minimal axial shell behaves as a low-pass reflector, the late-time echo train is naturally dominated by lower-frequency components. The reason is simple. High-frequency components leak through the shell more efficiently, while low-frequency components are more strongly returned to the exterior cavity.

Thus the late-time signal is predicted to soften spectrally with echo number. The first echo carries the broadest range of shell-returned frequencies. Later echoes are progressively more dominated by the portion of the spectrum that survives repeated shell-barrier cycling.

This implies that the minimal FCLET axial branch predicts not only an echo-delay ladder, but also a **late-time spectral reddening** of the echo train.

That is already more informative than a pure timing estimate.

9.3 Echo-amplitude hierarchy in the minimal branch

Earlier shell-cavity analysis showed that the n-th echo obeys the schematic law

$$A_n(\omega) \propto \mathcal{A}_0(\omega)\,(R_b(\omega)R_s(\omega))^{n-1}e^{2in\omega L},$$

where $R_b(\omega)$is the curvature-barrier reflectivity and $L$is the shell-barrier cavity length in tortoise coordinates.

Substituting the minimal axial shell response gives

$$\boxed{A_n^{(\mathrm{ax,thin})}(\omega) \propto \mathcal{A}_0(\omega)\left(R_b(\omega)\,\frac{\Lambda_s}{2i\omega-\Lambda_s}\right)^{n-1} e^{2in\omega L}.}$$

This is the exact minimal-branch echo hierarchy.

Its physical interpretation is immediate:

low-frequency echoes are more persistent,

high-frequency echoes are damped more strongly by shell transparency,

and the shell response scale Λ_s directly controls the spectral survival of repeated echoes.

Thus Λ_s is not merely a shell coupling in the master equation. It is an observable hierarchy parameter of the echo train.

9.4 First-echo versus late-echo structure

The minimal branch also predicts a qualitative distinction between the first echo and later echoes.

The first echo is generated after a single shell reflection and one return through the barrier. Its amplitude therefore depends on the shell reflectivity only once. Later echoes accumulate repeated factors of

$$R_b(\omega)\, R_s^{(\mathrm{ax,thin})}(\omega).$$

This means the first echo can remain visible across a broader frequency band, while the later echoes are driven increasingly toward the shell's low-frequency response sector. The resulting late-time signal is not expected to be a simple equal-shape pulse train. It should exhibit:

decreasing amplitude,

increasing spectral softness,

and cavity-phase modulation.

This is the first strong indication that FCLET echo phenomenology must be treated spectroscopically rather than as a mere delayed copy of the initial ringdown pulse.

9.5 Quasi-normal mode deformation in the minimal branch

The shell response does not only produce echoes. It also modifies the mode spectrum itself.

The general shell-induced mode shift has the form

$$\delta\omega_n \propto R_s(\omega_n^{\mathrm{GR}}) e^{2i\omega_n^{\mathrm{GR}} L}.$$

In the minimal axial thin-shell branch this becomes

$$\boxed{\delta\omega_n^{(\mathrm{ax,thin})} \propto \frac{\Lambda_s}{2i\omega_n^{\mathrm{GR}} - \Lambda_s}\, e^{2i\omega_n^{\mathrm{GR}} L}.}$$

This is the first explicit FCLET action-derived quasi-normal mode correction law.

The shell therefore modifies the mode spectrum in a way controlled by:

the shell-response scale Λ_s,

the shell-barrier cavity length L,

and the classical GR mode frequency ω_n^{GR}.

This result is particularly important because it shows that the shell affects the signal even before late-time echoes are isolated as separate pulses. The mode spectrum itself is shifted.

9.6 Low-frequency mode sensitivity

In the regime

$$|\,\omega_n^{\mathrm{GR}}\,| \ll \Lambda_s,$$

the minimal reflectivity approaches

$$R_s^{(\mathrm{ax,thin})}(\omega_n^{\mathrm{GR}}) \approx -1.$$

Therefore the leading low-frequency axial modes are maximally sensitive to the shell in the minimal branch. Their mode shifts inherit a near-unit shell-response factor in magnitude.

This is a strong result, but it must be interpreted carefully. It does **not** mean that the full physical FCLET shell must strongly deform all low-frequency ringdown modes at the same level. It means only that the strict axial thin-shell branch predicts maximal low-frequency response unless finite-thickness and dissipative shell channels moderate it.

Thus the minimal branch provides an upper-structure response, not yet the final observational amplitude of the full theory.

9.7 High-frequency overtone suppression

At high frequency, the reflectivity decreases as

$$|\,R_s^{(\mathrm{ax,thin})}(\omega)\,|^2 = \frac{\Lambda_s^2}{4\omega^2 + \Lambda_s^2}.$$

Therefore higher-frequency overtones and shorter-wavelength shell probes are suppressed more strongly in the shell-return channel. This has two immediate spectroscopic consequences.

First, the shell-induced deformation of higher overtones is weaker than that of lower-frequency modes.

Second, the echo train is progressively depleted of higher-frequency content as repeated cavity cycles accumulate.

Thus the minimal branch predicts an overtone hierarchy:

stronger shell influence on lower-frequency modes,

weaker shell influence on higher-frequency modes.

This is the exact opposite of a frequency-blind membrane model and is one of the first concrete ways in which the derived FCLET shell-response sector already departs from purely ad hoc echo prescriptions.

9.8 What the minimal branch can already falsify

Even before the full shell-response problem is solved, the minimal axial branch already defines a falsifiable structure.

If a strong-field event were to show:

no shell-like late-time structure in the FCLET timing window,

no low-frequency-favored echo hierarchy,

and no corresponding axial mode deformation pattern,

then the minimal axial thin-shell realization would be under pressure.

This does not yet falsify the full FCLET shell program, because the full theory still requires finite-thickness and coupled-shell dynamics. But it does falsify a definite branch of that program.

That is scientifically valuable. The theory is no longer a single undifferentiated possibility. It now contains explicit perturbative realizations that can be tested separately.

9.9 What the minimal branch cannot yet claim

The opposite must also be stated clearly.

The minimal axial thin-shell branch cannot yet claim to provide:

the final low-frequency reflectivity of the full theory,

the final shell dissipation law,

the full even-parity response sector,

or the final numerical echo amplitudes relevant to realistic multimode ringdown data.

Those require:

finite-thickness shell structure,

coupled metric-latency perturbations,

and explicit shell-internal dissipative channels.

Thus the present consequences are exact **within the minimal branch**, but not yet final for the full compact-object sector.

This is a strength, not a weakness. It is the correct scientific placement of the result.

9.10 Strong-field significance of the derived branch

The derived branch already changes the status of the FCLET compact-object program. Before this calculation, shell response was a structural expectation. After this calculation, at least one nontrivial shell-response law is known exactly.

This means the program now possesses:

a shell location,

a shell threshold,

a shell timing law,

and a first action-derived shell reflectivity sector.

That is a major transition. The compact-object branch has crossed from shell kinematics into shell perturbation dynamics.

9.11 Conclusion of the strong-field consequence analysis

The exact conclusion of the present section is

$$("The\ minimal\ axial\ thin-shell\ branch\ already\ predicts\ a\ frequency-filtered\ echo\ hierarchy\ and\ a\ shell-induced\ quasi-normal\ mode\ deformation.")$$

These are the first genuine observational consequences of an action-derived FCLET reflectivity law.

They are not yet the final strong-field predictions of the theory, but they are already real predictions of a definite perturbative branch. That is the correct scientific threshold for the present paper.

10. Conclusion

We have developed the first action-derived shell perturbation branch of the finite-capacity latency–erasure theory and used it to obtain the first explicit reflectivity law of the FCLET compact-object sector.

Earlier FCLET work established the strong-field shell background, fixed the shell-onset threshold through the internal burden-support balance condition

$$I_{\mathrm{sat}} = \frac{1}{2}, \chi_{\mathrm{sat}} = 1,$$

and derived the shell location and echo-delay scale of saturation-shell compact objects. Those results completed the kinematic side of the strong-field program. What remained open was the perturbative response problem: once a shell forms, what boundary law does it impose on

incident perturbations, and how does the shell reflectivity sector emerge from the action itself?

This paper answered that question at the first exact perturbative level.

Starting from the FCLET action, we defined the static strong-field shell background and linearized the coupled metric-latency system around it. We then isolated the odd-parity sector, showed that the scalar latency perturbation does not propagate there as an independent axial harmonic mode, and reduced the shell problem to a gauge-invariant axial master equation. In the strict thin-shell limit, the finite-thickness shell-support layer compressed into a shell-localized coupling of strength Λ_s, yielding the shell-supported axial wave equation

$$\frac{d^2\Psi_\omega}{dr_*^2} + [\omega^2 - V_{\text{ext}}(r)]\Psi_\omega - \Lambda_s\,\delta(r_* - r_{*,s})\,\Psi_\omega = 0.$$

From the matching conditions implied by this equation, the shell reflectivity and transmission coefficients followed uniquely. The minimal axial thin-shell branch therefore yielded the first exact FCLET shell-response law,

$$R_s^{(\text{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}, T_s^{(\text{ax,thin})}(\omega) = \frac{2i\omega}{2i\omega - \Lambda_s}.$$

This result is structurally decisive. The reflectivity sector is no longer a phenomenological insertion. It is a derived output of the shell perturbation problem.

The derived branch also revealed the first exact spectral properties of the shell. In the deep infrared,

$$R_0^{(\text{ax,thin})} = \lim_{\omega\to 0} R_s^{(\text{ax,thin})}(\omega) = -1,$$

so the shell is fully reflective in magnitude at zero frequency in the minimal axial branch. At high frequency, the reflected power falls as

$$|\, R_s^{(\text{ax,thin})}(\omega)\,|^2 = \frac{\Lambda_s^2}{4\omega^2 + \Lambda_s^2},$$

and the shell becomes progressively transparent. The branch therefore defines a low-pass shell-response law with crossover scale

$$\omega_c^{(\text{ax,thin})} = \frac{\Lambda_s}{2}.$$

This is the first exact FCLET shell bandwidth result.

We then drew the immediate observational consequences. The minimal branch already predicts:

a frequency-filtered echo hierarchy,

low-frequency dominance of repeated shell-barrier returns,

and a shell-induced quasi-normal mode deformation of the form

$$\delta\omega_n^{(\mathrm{ax,thin})} \propto \frac{\Lambda_s}{2i\omega_n^{\mathrm{GR}} - \Lambda_s}\, e^{2i\omega_n^{\mathrm{GR}} L}.$$

Thus the compact-object branch of FCLET no longer speaks only about where a shell forms and when a delayed return may occur. It now possesses a derived perturbative response sector.

At the same time, the paper identified the exact limit of the result. The minimal axial thin-shell branch is not yet the full physical shell-response law of the theory. Its perfect low-frequency reflectivity in magnitude shows that shell-localized coupling alone is too rigid to encode the complete shell microphysics. A realistic FCLET shell-response sector must still include:

finite-thickness shell structure,

coupled metric-latency perturbations beyond the strict axial reduction,

explicit dissipative internal shell channels,

and eventually the even-parity sector.

This is not a weakness of the present result. It is its most valuable scientific consequence. The perturbation problem has now advanced far enough to show exactly what the next step must be.

The strong-field FCLET program therefore stands in a new position after this paper. It has:

a derived shell background,

a derived shell threshold,

a derived shell timing law,

and now a derived perturbative shell-response branch.

That is a major threshold. The compact-object sector has moved from shell kinematics into shell perturbation dynamics.

The next task is exact and sharply defined: derive the finite-thickness coupled shell-response law of the metric-latency system and determine how the full physical reflectivity sector departs from the minimal axial thin-shell limit. Once that is done, the theory will no longer provide only the first derived branch of shell response. It will provide the full shell spectroscopy of FCLET compact objects.

The present paper therefore marks the first exact entry of the theory into that spectroscopic regime.

Appendix A. Axial Harmonic Decomposition

This appendix records the odd-parity harmonic structure used in the main text and fixes notation for the gauge-invariant axial sector.

A.1 Spherical background split

On a static spherically symmetric background, the metric is written as

$$d\bar{s}^2 = \bar{g}_{ab}(x^c)\, dx^a dx^b + r^2(x^c)\, \gamma_{AB}\, dx^A dx^B,$$

where:

$x^a = (t, r)$are coordinates on the orbit space,

$x^A = (\theta, \phi)$are angular coordinates on the unit two-sphere,

$\gamma_{AB}$is the standard metric on S^2.

For the present shell background,

$$\bar{g}_{ab} dx^a dx^b = -\bar{A}(r)\, dt^2 + \bar{B}(r)\, dr^2.$$

A.2 Axial vector harmonics

Let $Y_{\ell m}(\theta, \phi)$be the ordinary scalar spherical harmonics. The odd-parity vector harmonics are defined by

$$\boxed{S_A^{\ell m} = \epsilon_A{}^B \nabla_B Y_{\ell m},}$$

where $\epsilon_{AB}$is the Levi-Civita tensor on the unit two-sphere and $\nabla_A$is the covariant derivative compatible with γ_{AB}.

They satisfy:

odd parity under $(\theta, \phi) \mapsto (\pi - \theta, \phi + \pi)$,

transversality on the sphere,

orthogonality to even-parity polar vector harmonics.

A.3 Axial tensor harmonics

The odd-parity tensor harmonics are defined by

$$\boxed{S_{AB}^{\ell m} = \frac{1}{2}\left(\nabla_A S_B^{\ell m} + \nabla_B S_A^{\ell m}\right).}$$

These furnish the angular tensor basis of the odd-parity sector for $\ell \geq 2$.

A.4 Metric perturbation in axial form

The general odd-parity metric perturbation can be written as

$$h_{\mu\nu}^{(\mathrm{odd})} = \sum_{\ell m} \begin{pmatrix} 0 & 0 & h_0^{\ell m} S_\theta^{\ell m} & h_0^{\ell m} S_\phi^{\ell m} \\ 0 & 0 & h_1^{\ell m} S_\theta^{\ell m} & h_1^{\ell m} S_\phi^{\ell m} \\ \mathrm{sym} & \mathrm{sym} & h_2^{\ell m} S_{\theta\theta}^{\ell m} & h_2^{\ell m} S_{\theta\phi}^{\ell m} \\ \mathrm{sym} & \mathrm{sym} & \mathrm{sym} & h_2^{\ell m} S_{\phi\phi}^{\ell m} \end{pmatrix}.$$

The three amplitudes h_0, h_1, h_2 are functions only of (t, r).

A.5 Axial gauge transformation

Under an odd-parity gauge generator

$$\xi_\mu^{(\mathrm{odd})} = (0,0,\Lambda S_\theta, \Lambda S_\phi),$$

the axial amplitudes transform as

$$\begin{aligned} h_0 &\to h_0 - \partial_t \Lambda, \\ h_1 &\to h_1 - \partial_r \Lambda + \frac{2}{r}\Lambda, \\ h_2 &\to h_2 + 2\Lambda. \end{aligned}$$

Thus h_0, h_1, h_2 are gauge dependent, while the Regge–Wheeler master combination is gauge invariant.

A.6 Regge–Wheeler gauge

The axial gauge may be fixed by imposing

$$\boxed{h_2 = 0.}$$

In this gauge, the odd-parity sector is carried by h_0 and h_1, and the master field may be represented directly in terms of them.

Appendix B. Distributional Shell Matching Formulae

This appendix records the shell-matching relations used in the derivation of the reflectivity law.

B.1 Distributional master equation

The minimal axial thin-shell branch is governed by

$$\frac{d^2\Psi_\omega}{dr_*^2} + [\omega^2 - V_{\text{ext}}(r)]\Psi_\omega - \Lambda_s\,\delta(r_* - r_{*,s})\,\Psi_\omega = 0.$$

Define

$$x = r_* - r_{*,s}.$$

Near the shell, the local equation reduces to

$$\frac{d^2\Psi_\omega}{dx^2} + \omega^2\Psi_\omega - \Lambda_s\,\delta(x)\Psi_\omega = 0.$$

B.2 Continuity of the field

Because the shell is represented by a delta-supported potential rather than a delta-prime structure, the field remains continuous:

$$\boxed{\Psi_\omega(0^+) = \Psi_\omega(0^-).}$$

Equivalently,

$$\boxed{[\Psi_\omega]_s = 0.}$$

B.3 Jump in the derivative

Integrating the local equation across the shell gives

$$\int_{-\epsilon}^{+\epsilon} \Psi_\omega''(x)\,dx - \Lambda_s \int_{-\epsilon}^{+\epsilon} \delta(x)\,\Psi_\omega(x)\,dx = 0.$$

Taking $\epsilon \to 0$yields

$$\boxed{\Psi_\omega'(0^+) - \Psi_\omega'(0^-) = \Lambda_s\,\Psi_\omega(0).}$$

Equivalently,

$$\boxed{[\partial_{r_*}\Psi_\omega]_s = \Lambda_s\,\Psi_\omega(r_{*,s}).}$$

This is the shell jump law of the minimal branch.

B.4 Scattering form

Take the mode decomposition

$$\Psi_+(x) = A_{\mathrm{in}} e^{-i\omega x} + A_{\mathrm{out}} e^{+i\omega x}, x > 0,$$
$$\Psi_-(x) = A_{\mathrm{tr}} e^{-i\omega x}, x < 0.$$

Continuity gives

$$A_{\mathrm{in}} + A_{\mathrm{out}} = A_{\mathrm{tr}}.$$

The derivative jump gives

$$(-i\omega A_{\mathrm{in}} + i\omega A_{\mathrm{out}}) - (-i\omega A_{\mathrm{tr}}) = \Lambda_s (A_{\mathrm{in}} + A_{\mathrm{out}}).$$

Dividing by $A_{\mathrm{in}}$and defining

$$R_s(\omega) = \frac{A_{\mathrm{out}}}{A_{\mathrm{in}}}, T_s(\omega) = \frac{A_{\mathrm{tr}}}{A_{\mathrm{in}}},$$

one obtains

$$1 + R_s = T_s,$$
$$2i\omega R_s = \Lambda_s (1 + R_s).$$

Hence

$$\boxed{R_s(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}, T_s(\omega) = \frac{2i\omega}{2i\omega - \Lambda_s}.}$$

These are the exact shell coefficients of the minimal axial thin-shell sector.

Appendix C. Low-Frequency Expansion of the Reflectivity Law

This appendix records the infrared expansion of the derived reflectivity law and its associated response scales.

C.1 Exact reflectivity and transmission

The exact coefficients are

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s},$$
$$T_s^{(\mathrm{ax,thin})}(\omega) = \frac{2i\omega}{2i\omega - \Lambda_s}.$$

C.2 Zero-frequency limit

The shell reflectivity at zero frequency is

$$\boxed{R_0^{(\mathrm{ax,thin})} = \lim_{\omega\to 0} R_s^{(\mathrm{ax,thin})}(\omega) = -1.}$$

Thus

$$\boxed{|\, R_0^{(\mathrm{ax,thin})} \,| = 1.}$$

The shell is therefore fully reflective in magnitude in the deep infrared of the minimal branch.

C.3 Infrared expansion

Rewrite the exact result as

$$R_s^{(\mathrm{ax,thin})}(\omega) = -\frac{1}{1 - \dfrac{2i\omega}{\Lambda_s}}.$$

For $|\,\omega\,| \ll \Lambda_s$, the geometric expansion gives

$$\boxed{R_s^{(\mathrm{ax,thin})}(\omega) = -1 - \frac{2i\omega}{\Lambda_s} - \frac{4\omega^2}{\Lambda_s^2} + \mathcal{O}(\omega^3).}$$

Likewise,

$$\boxed{T_s^{(\mathrm{ax,thin})}(\omega) = -\frac{2i\omega}{\Lambda_s} + \frac{4\omega^2}{\Lambda_s^2} + \mathcal{O}(\omega^3).}$$

This shows explicitly that the shell begins as an almost perfect reflector and acquires transmission only as the probing frequency rises.

C.4 Reflected-power law

The reflected power is

$$\boxed{|\, R_s^{(\mathrm{ax,thin})}(\omega) \,|^2 = \frac{\Lambda_s^2}{4\omega^2 + \Lambda_s^2}.}$$

The transmitted power is

$$\boxed{|\, T_s^{(\mathrm{ax,thin})}(\omega) \,|^2 = \frac{4\omega^2}{4\omega^2 + \Lambda_s^2}.}$$

Thus:

$|R_s|^2 \to 1$ and $|T_s|^2 \to 0$ as $\omega \to 0$,

$|R_s|^2 \to 0$ and $|T_s|^2 \to 1$ as $\omega \to \infty$.

C.5 Half-power response scale

Define $\omega_{1/2}$ by

$$|R_s(\omega_{1/2})|^2 = \frac{1}{2}.$$

Then

$$\frac{\Lambda_s^2}{4\omega_{1/2}^2 + \Lambda_s^2} = \frac{1}{2}$$

implies

$$\boxed{\omega_{1/2} = \frac{\Lambda_s}{2}.}$$

This gives the exact half-power shell-response scale of the minimal branch.

C.6 Interpretation

The minimal axial thin-shell branch therefore defines a low-pass shell-response law:

infrared reflection,

ultraviolet transparency,

response scale $\Lambda_s/2$.

This completes the first analytical shell-response profile of the FCLET compact-object program.

Evaluation of Λ_s from the Shell Burden Profile and the First Numerical Reflectivity Estimate

Abstract

We derive the axial shell-coupling coefficient Λ_s of the finite-capacity latency–erasure theory directly from the strong-field shell background and thereby convert the previously derived reflectivity law

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}$$

into a numerically evaluable strong-field prediction. Earlier FCLET work established the shell background, fixed the shell-onset threshold $I_{\mathrm{sat}} = 1/2$, derived the shell location, obtained the echo-delay scale, and then derived the first action-based shell reflectivity law in the odd-parity thin-shell sector. What remained open was the background-to-response bridge: the shell reflectivity law was known analytically, but its coupling scale Λ_s had not yet been evaluated from the shell burden profile itself. The present paper closes that gap.

We begin from the FCLET strong-field background with static shell profile $\bar{\chi}(r)$ and derive the shell contribution to the odd-parity master operator by linearizing the metric-latency system in the axial sector. This yields an explicit shell kernel $\mathcal{K}_{\mathrm{ax}}(r)$, constructed from the shell-dressed background geometry, the radial gradient structure of $\bar{\chi}(r)$, and the shell-support sector of the effective stress tensor. In the strict thin-shell limit, the integrated axial shell coupling is then

$$\Lambda_s = \int_{\mathrm{shell}} \mathcal{K}_{\mathrm{ax}}(r)\, dr_*.$$

We evaluate this expression for a Schwarzschild-like FCLET shell background and obtain the first numerical estimate of Λ_s, and therefore the first numerical axial reflectivity profile $R_s(\omega)$ in the observationally relevant low-frequency regime. This converts the shell-response sector from a formally derived law into a numerically testable strong-field prediction.

The result completes the first closed derivational sequence of the FCLET compact-object program: shell onset, shell location, echo timing, shell perturbation law, and shell-response scale now form a single calculable chain. The strong-field sector of the theory no longer states only where a shell forms and how it scatters in principle. It now begins to determine how strongly that shell responds in practice.

1. Introduction

The strong-field compact-object branch of the finite-capacity latency–erasure theory has now reached a sharply defined stage of development. Earlier FCLET work established that classical horizon formation is replaced, in the saturation regime, by a finite-capacity shell structure generated by local burden growth and latency amplification. The shell-onset threshold was fixed internally by the burden-support balance condition

$$I_{\mathrm{sat}} = \frac{1}{2}, \chi_{\mathrm{sat}} = 1,$$

the shell location was derived from the strong-field burden profile, and the shell-barrier cavity of the Schwarzschild-like branch yielded the first explicit echo-delay scale of the theory. Those results completed the kinematic architecture of the compact-object sector. They determined where the shell forms and when shell-induced late-time structure must appear.

The next question is more exact and more difficult:

What is the shell coupling that actually determines the magnitude of the response?

That question is not secondary. It is the remaining bottleneck of the strong-field program.

The previous perturbation paper derived the first action-based reflectivity law of the minimal axial thin-shell branch,

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s},$$

and thereby crossed a decisive threshold. The shell reflectivity sector ceased to be merely structural. It became perturbatively derivable. But that same result also exposed the exact unresolved quantity in the problem: the shell coupling Λ_s itself. Without Λ_s, the reflectivity law remains analytically correct but numerically incomplete. One can state its functional form, its low-frequency limit, and its response bandwidth in symbolic terms, but one cannot yet evaluate the actual response of the shell in a given frequency band.

This is the point at which the compact-object program becomes genuinely quantitative.

The shell coupling is not an independent phenomenological constant to be chosen by taste. It must be derived from the shell background. In the axial sector, the strong-field shell contributes to the gauge-invariant master equation through a localized shell kernel that arises from:

background dressing of the shell geometry,

radial gradients of the background latency profile,

and the shell-support stress structure carried by the FCLET strong-field solution.

In the strict thin-shell limit, the integrated effect of that shell kernel is precisely the axial shell-coupling coefficient:

$$\Lambda_s = \int_{\mathrm{shell}} \mathcal{K}_{\mathrm{ax}}(r)\, dr_*.$$

The present paper computes that quantity.

This is the exact missing bridge between shell background and shell response. Once Λ_s is known, the previously derived reflectivity law becomes numerically evaluable. At that point

the theory no longer states only that a shell exists and that such a shell must reflect. It begins to state how strongly it reflects.

The significance of this step is substantial. A strong-field theory is not completed by deriving a shell location alone. It is completed when the shell location and the shell perturbation sector are linked quantitatively. In FCLET language, the chain must close:

$$\bar{\chi}(r) \;\longrightarrow\; \mathcal{K}_{\mathrm{ax}}(r) \;\longrightarrow\; \Lambda_s \;\longrightarrow\; R_s(\omega).$$

That is the chain completed in the present paper.

The goal here is deliberately limited and therefore exact. We do not attempt the full coupled even-parity shell spectroscopy, the full finite-thickness shell-mode catalog, or the final multimode ringdown template problem. Those belong to later stages of the strong-field program. The present paper solves the first numerically evaluable branch: the axial shell coupling of the Schwarzschild-like FCLET shell background in the thin-shell limit. That branch is the correct next target because it is:

technically controlled,

physically nontrivial,

and directly connected to the already derived reflectivity law.

The paper is organized as follows. Section 2 explains why $\Lambda_s$is now the single most important unresolved strong-field quantity. Section 3 fixes the FCLET shell background and its radial burden profile. Section 4 derives the axial reduction of the linearized shell operator. Section 5 constructs the shell kernel $\mathcal{K}_{\mathrm{ax}}(r)$. Section 6 takes the thin-shell limit and identifies the integrated shell coupling Λ_s. Section 7 specifies the Schwarzschild-like benchmark shell background. Section 8 obtains the first numerical estimate of Λ_s. Section 9 converts that result into a numerical reflectivity profile. Section 10 evaluates the low-frequency shell response in the observationally relevant band. Section 11 discusses the consequences for echoes and axial mode deformation. Section 12 concludes.

The compact-object branch of FCLET therefore enters a new quantitative phase in this paper. The shell perturbation law is already known. What remains is to give that law numerical content. That is the task now completed.

2. Why Λ_sIs the Remaining Strong-Field Bottleneck

The strong-field development of FCLET has proceeded in a disciplined sequence. The shell was not introduced as an ad hoc membrane; it was derived from finite-capacity burden saturation. The shell-onset threshold was fixed internally. The shell location was obtained from the background shell profile. The shell-barrier geometry then produced the echo-delay scale. Finally, the first perturbative shell-response branch was derived in the odd-parity thin-shell sector, yielding the exact axial reflectivity law

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}.$$

That derivation was decisive because it showed that shell reflectivity in FCLET need not be postulated phenomenologically. It can be obtained from shell matching in a gauge-invariant perturbation problem.

But that success also made the remaining bottleneck completely transparent.

The unresolved quantity is no longer the form of the reflectivity law. The unresolved quantity is the shell coupling that feeds it.

This point can be stated exactly:

The strong-field axial reflectivity law is known. The unresolved quantity is the shell coupling Λ_s that gives it numerical content.

That is the current status of the compact-object program.

The bottleneck is real because every observable consequence of the minimal axial thin-shell branch depends on Λ_s. The low-frequency reflectivity limit, the response bandwidth, the filtering of repeated shell-barrier returns, and the shell-induced quasi-normal mode deformation are all governed by the same coefficient. Without Λ_s, the theory can say:

what the response law looks like,

how it behaves as $\omega \to 0$,

how it behaves as $\omega \to \infty$,

but it cannot yet say:

how large the shell response is at a given physical frequency,

where the spectral crossover lies numerically,

or how strongly the shell modifies the observable axial sector in a конкрет background.

In that sense, Λ_s is the unique missing number of the minimal axial branch.

This is also the point at which the program becomes methodologically clean. Earlier in the strong-field development, it was tempting to speak in terms of generic shell reflectivity models, response scales, or effective dissipative parameters. Those models were useful as scaffolding. But once the axial reflectivity law itself was derived from the perturbation problem, the program no longer needed to guess its central response function. It needed to compute the shell coupling that appears in it. The remaining problem is therefore not phenomenological fitting. It is background-to-response derivation.

That is why Λ_s is the bottleneck.

The physical meaning of this coefficient makes the point even sharper. In the thin-shell reduction, the shell coupling is defined by the integrated shell kernel:

$$\Lambda_s = \int_{\text{shell}} \mathcal{K}_{\text{ax}}(r)\, dr_*.$$

Thus Λ_s measures the total axial scattering strength carried by the shell-support layer. It is the integrated imprint of the shell burden profile on the odd-parity master operator. A theory that has not yet computed Λ_s has not yet completed the bridge between:

shell background,

shell perturbation dynamics,

and shell observables.

By contrast, once Λ_s is known, the chain closes immediately:

$$\bar{\chi}(r) \;\to\; \mathcal{K}_{\text{ax}}(r) \;\to\; \Lambda_s \;\to\; R_s(\omega).$$

That is why the present calculation is not merely a refinement. It is the decisive next closure step of the strong-field branch.

The bottleneck also clarifies what this paper does **not** need to do. It does not need to solve the full even-parity sector. It does not need the final finite-thickness dissipative shell-response law in every channel. And it does not need the full multimode ringdown catalog. Those are later tasks. The present bottleneck is narrower and therefore more tractable: compute the axial shell coupling of the already derived strong-field background and thereby turn the first perturbative reflectivity law into a numerical strong-field estimate.

In this sense the status of the program is now exact. The shell exists. The shell location is known. The shell timing law is known. The axial shell-response law is known. The only remaining missing ingredient in that branch is the shell coupling itself.

This is the reason the present paper is necessary, and it is the reason it can be so sharply focused. Its goal is not to broaden the strong-field program. Its goal is to close its current axial bottleneck.

3. FCLET Strong-Field Background and Shell Profile

The axial shell coupling Λ_s cannot be computed in abstraction from the background that generates it. The shell kernel $\mathcal{K}_{\text{ax}}(r)$ is not a free scattering potential. It is the thin-shell image of the strong-field FCLET background itself. The present section therefore fixes the background geometry, the shell burden profile, and the shell-width conventions that will feed directly into the construction of the axial shell operator.

The strong-field shell background is characterized by three fields:

the static spherically symmetric metric,

the background latency field $\bar{\chi}(r)$,

and the shell-support stress sector that sustains the transition layer.

What matters for the present paper is not the full microscopic completion of the shell interior. What matters is the shell-support layer itself: the narrow region in which the burden field crosses the saturation threshold and the background geometry departs from the pure vacuum exterior.

3.1 Static shell background

We write the background metric in the standard static spherical form

$$\boxed{d\bar{s}^2 = -\bar{A}(r)\,dt^2 + \bar{B}(r)\,dr^2 + r^2 d\Omega^2.}$$

The corresponding tortoise coordinate is defined by

$$\boxed{\frac{dr_*}{dr} = \sqrt{\frac{\bar{B}(r)}{\bar{A}(r)}}.}$$

The background latency field is radial and static:

$$\boxed{\bar{\chi} = \bar{\chi}(r).}$$

The shell radius r_s is not introduced externally. It is fixed by the FCLET shell-onset condition,

$$\boxed{I(r_s) = \frac{1}{2}, \bar{\chi}(r_s) = 1.}$$

Thus the shell is the radius at which realized burden and residual support margin become equal. This is the unique strong-field crossover point of the background solution.

3.2 Exterior, shell, and interior domains

For the present calculation it is useful to separate the background into three radial regions.

Exterior region

For $r > r_s + \Delta/2$, the metric is Schwarzschild-like to leading order and the latency field relaxes outward. The exterior observer sees this region as the effective strong-field vacuum outside the shell.

Shell region

For

$$r_s - \frac{\Delta}{2} \le r \le r_s + \frac{\Delta}{2},$$

the burden profile changes rapidly, the latency field is order unity, and shell-support stress is concentrated. This is the only region that contributes directly to the shell kernel $\mathcal{K}_{\mathrm{ax}}(r)$.

Interior effective region

For $r < r_s - \Delta/2$, the detailed continuation depends on the chosen compact-object completion. The present paper does not require its full microphysical specification. It requires only that the shell-support layer admit a controlled thin-shell reduction.

The shell thickness parameter Δ is therefore the key background scale of the present problem.

3.3 Schwarzschild-like exterior benchmark

The first numerical branch of the paper will use a Schwarzschild-like exterior background. Accordingly, outside the shell we write

$$\boxed{\bar{A}_{\mathrm{ext}}(r) = 1 - \frac{2M}{r}, \bar{B}_{\mathrm{ext}}(r) = \left(1 - \frac{2M}{r}\right)^{-1},}$$

up to shell-induced corrections that are parametrically small outside the transition layer.

This is the correct benchmark because the shell-support contribution is strongly localized. The exterior curvature barrier and the shell-barrier cavity are already defined most naturally in a Schwarzschild-like geometry, and the previous FCLET strong-field papers used the same benchmark to derive the shell timing law.

The background shell problem is therefore not a generic spherical problem. It is a Schwarzschild-like shell problem with a localized finite-capacity transition layer.

3.4 Shell burden profile

The shell kernel must be built from the shell background profile itself. To do that, the shell burden profile must be made explicit.

The exact FCLET shell solution is expected to be determined by the full strong-field field equations. For the present paper, however, a controlled benchmark profile is both sufficient and necessary. The profile must satisfy four conditions:

it must be centered at $r = r_s$,

it must cross $\bar{\chi}(r_s) = 1$,

it must vary over shell width Δ,

it must approach distinct exterior and interior values smoothly.

The minimal benchmark profile satisfying these conditions is the hyperbolic-tangent shell:

$$\boxed{\bar{\chi}(r) = \chi_{\text{out}} + \frac{\chi_{\text{in}} - \chi_{\text{out}}}{2}\left[1 - \tanh\left(\frac{r - r_s}{\Delta}\right)\right].}$$

For the canonical shell-onset normalization used throughout the strong-field FCLET branch, we take

$$\boxed{\chi_{\text{out}} = 0, \chi_{\text{in}} = 2,}$$

so that

$$\boxed{\bar{\chi}(r) = 1 - \tanh\left(\frac{r - r_s}{\Delta}\right).}$$

This benchmark profile satisfies

$$\bar{\chi}(r_s) = 1,$$

as required.

Its first derivative is

$$\boxed{\bar{\chi}'(r) = -\frac{1}{\Delta}\,\text{sech}^2\left(\frac{r - r_s}{\Delta}\right),}$$

and its second derivative is

$$\boxed{\bar{\chi}''(r) = \frac{2}{\Delta^2}\,\text{sech}^2\left(\frac{r - r_s}{\Delta}\right)\tanh\left(\frac{r - r_s}{\Delta}\right).}$$

These are the exact gradient data that will enter the shell kernel construction below.

3.5 Shell profile in tortoise coordinate

Because the perturbation problem is formulated in tortoise coordinate, the shell profile must ultimately be expressed in r_*. Near the shell, we define the local tortoise-width parameter

$$\boxed{\Delta_* \equiv \sqrt{\frac{\bar{B}(r)}{\bar{A}(r)}}\;\Big|_{r_s}\Delta.}$$

Then, to leading order across the narrow shell layer,

$$r - r_s \approx \sqrt{\frac{\bar{A}}{\bar{B}}}\,|_{r_s}\,(r_* - r_{*,s}),$$

and the shell profile may be written locally as

$$\boxed{\bar{\chi}(r_*) = 1 - \tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).}$$

The corresponding derivatives become

$$\boxed{\partial_{r_*}\bar{\chi} = -\frac{1}{\Delta_*}\,\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right),}$$

$$\boxed{\partial_{r_*}^2\bar{\chi} = \frac{2}{\Delta_*^2}\,\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).}$$

This is the form directly suited to shell-kernel integration.

3.6 Shell-support stress benchmark

The shell background is not sustained by the latency gradient alone. In the strong-field FCLET branch, the shell is a burden-supported transition layer, so the shell-support stress sector must be localized wherever the shell gradients are localized. For the benchmark reduction used here, we take the shell-support contribution to the effective stress tensor to share the same radial support as the burden gradient and to scale with the shell gradient energy density.

Thus we write the benchmark shell-support density as

$$\boxed{\bar{\rho}_{\mathrm{shell}}(r_*) = \sigma_s\left(\partial_{r_*}\bar{\chi}\right)^2,}$$

where σ_s is a dimensionless shell-support coefficient of the background sector. With the explicit shell profile above,

$$\boxed{\bar{\rho}_{\mathrm{shell}}(r_*) = \frac{\sigma_s}{\Delta_*^2}\,\mathrm{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).}$$

This is not a phenomenological scattering ansatz. It is a benchmark background closure rule: the shell-support stress is concentrated where the shell burden gradient is concentrated.

This is the minimal background model needed to compute the shell kernel.

3.7 Thin-shell parameter regime

The present paper aims to compute the integrated shell coupling in the strict thin-shell branch. The relevant regime is therefore

$$\boxed{\Delta_* \ll L_{\mathrm{ext}},}$$

where L_{ext} is any exterior curvature scale over which the smooth axial potential varies appreciably near the shell. In the Schwarzschild-like branch this includes, in particular, the local redshift length and the cavity scale to the barrier region.

In this regime:

the shell profile is sharply localized,

the shell kernel is narrow,

and the integrated shell coupling Λ_s captures the leading shell-response content.

Thus the thin-shell limit is not a guess. It is the asymptotic regime of a narrow burden-supported transition layer.

3.8 What Section 3 has fixed

At this stage the background problem is fully specified for the purposes of the axial coupling calculation.

We now have:

a Schwarzschild-like exterior geometry,

a shell radius fixed by $\bar{\chi}(r_s) = 1$,

a benchmark shell profile $\bar{\chi}(r)$,

explicit first and second shell gradients,

a tortoise-width scale Δ_*,

and a shell-support density localized on the same layer.

This is enough to build the axial shell kernel.

The next task is therefore precise:
derive the odd-parity shell contribution to the linearized master operator and isolate the kernel $\mathcal{K}_{\mathrm{ax}}(r)$ whose integral defines Λ_s.

4. Axial Reduction of the Linearized Shell Operator

The shell coupling Λ_s is defined by the integrated shell contribution to the odd-parity master operator. The purpose of the present section is therefore exact: starting from the background shell profile fixed in the previous section, we now isolate the shell-supported part of the axial perturbation equation and write it in the form of an explicit shell kernel $\mathcal{K}_{\mathrm{ax}}(r_*)$.

The crucial point is that the shell kernel is not an external scattering potential. It is the localized strong-field imprint of the FCLET shell background on the gauge-invariant axial master equation.

4.1 Background-dressed axial master equation

In the odd-parity sector, the scalar latency perturbation does not propagate as an independent axial harmonic mode. The shell nevertheless enters the axial branch through the background geometry and the shell-support sector. The gauge-invariant master equation therefore takes the form

$$-\partial_t^2\Phi + \partial_{r_*}^2\Phi - V_{\mathrm{RW}}(r)\,\Phi - \Delta V_{\mathrm{shell}}(r_*)\,\Phi = 0,$$

where:

$V_{\mathrm{RW}}(r)$ is the smooth Schwarzschild-like Regge–Wheeler exterior potential,

$\Delta V_{\mathrm{shell}}(r_*)$ is the shell-localized FCLET correction.

In frequency space, with

$$\Phi(t, r_*) = e^{-i\omega t}\Psi_\omega(r_*),$$

this becomes

$$\frac{d^2\Psi_\omega}{dr_*^2} + [\omega^2 - V_{\mathrm{RW}}(r) - \Delta V_{\mathrm{shell}}(r_*)]\Psi_\omega = 0.$$

This is the precise point at which the background shell profile begins to affect the axial perturbation dynamics.

4.2 Structure of the shell correction

Because the shell correction is generated by the background shell profile, it must be constructed from local shell data. In the present effective strong-field reduction, the shell-supported correction can depend only on:

the shell gradient profile $\partial_{r_*}\bar{\chi}$,

the shell curvature profile $\partial_{r_*}^2\bar{\chi}$,

and the shell-support energy density $\bar{\rho}_{\mathrm{shell}}$.

To leading order in the narrow-shell expansion, the most general local shell correction with the correct scalar structure is therefore

$$\boxed{\Delta V_{\mathrm{shell}}(r_*) = \alpha_\chi\,(\partial_{r_*}\bar{\chi})^2 + \beta_\chi\,\partial_{r_*}^2\bar{\chi} + \gamma_\chi\,\bar{\rho}_{\mathrm{shell}}(r_*).}$$

Here:

α_χ measures the axial sensitivity to shell gradient energy,

β_χ measures the axial sensitivity to shell profile curvature,

γ_χ measures the axial sensitivity to shell-support stress.

These coefficients are the effective output of the axial reduction of the linearized FCLET field equations. In a full first-principles derivation they would be determined uniquely by the explicit action and background solution. In the present benchmark strong-field branch, they define the minimal operator basis consistent with the shell background.

This is the first place where the calculation becomes concrete: once the benchmark shell profile is fixed, $\Delta V_{\mathrm{shell}}$ is explicit.

4.3 Substituting the benchmark shell profile

From the previous section, the benchmark shell profile in tortoise coordinate is

$$\bar{\chi}(r_*) = 1 - \tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).$$

Its derivatives are

$$\partial_{r_*}\bar{\chi} = -\frac{1}{\Delta_*}\,\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right),$$
$$\partial_{r_*}^2\bar{\chi} = \frac{2}{\Delta_*^2}\,\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).$$

The shell-support density was defined as

$$\bar{\rho}_{\mathrm{shell}}(r_*) = \sigma_s(\partial_{r_*}\bar{\chi})^2 = \frac{\sigma_s}{\Delta_*^2}\,\mathrm{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).$$

Substituting these into the shell correction gives

$$\Delta V_{\mathrm{shell}}(r_*) = \frac{\alpha_\chi}{\Delta_*^2}\mathrm{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right) + \frac{2\beta_\chi}{\Delta_*^2}\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right) + \frac{\gamma_\chi\sigma_s}{\Delta_*^2}\mathrm{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).$$

Grouping the even shell-localized terms together, define

$$\boxed{\Xi_s \equiv \alpha_\chi + \gamma_\chi \sigma_s.}$$

Then the shell correction becomes

$$\boxed{\Delta V_{\text{shell}}(r_*) = \frac{\Xi_s}{\Delta_*^2}\,\text{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right) + \frac{2\beta_\chi}{\Delta_*^2}\,\text{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).}$$

This is the explicit benchmark axial shell operator.

4.4 Even and odd shell pieces

The two terms in ΔV_{shell} have different parity around the shell center $r_{*,s}$.

Let

$$u \equiv \frac{r_* - r_{*,s}}{\Delta_*}.$$

Then:

$\text{sech}^4(u)$ is even in u,

$\text{sech}^2(u)\tanh(u)$ is odd in u.

This matters because the integrated shell coupling is obtained by integrating the shell kernel across the shell. Any odd contribution vanishes in the symmetric thin-shell limit. Therefore the β_χ-term does not contribute to the integrated shell coupling at leading order for the symmetric benchmark profile.

This is a highly useful simplification.

The shell kernel therefore separates naturally into:

an **integrated shell-strength term** proportional to Ξ_s,

and a **shape-skew term** proportional to β_χ, which affects detailed finite-thickness structure but not the leading symmetric thin-shell coupling.

This distinction is the key to evaluating Λ_s analytically.

4.5 Definition of the axial shell kernel

We may now define the shell kernel itself:

$$\boxed{\mathcal{K}_{\text{ax}}(r_*) \equiv \Delta V_{\text{shell}}(r_*).}$$

Thus, explicitly,

$$\boxed{\mathcal{K}_{\rm ax}(r_*) = \frac{\Xi_s}{\Delta_*^2}\operatorname{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right) + \frac{2\beta_\chi}{\Delta_*^2}\operatorname{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).}$$

This is the first explicit form of the FCLET axial shell kernel.

Its physical meaning is exact:

the first term is the symmetric shell-response core,

the second term is the profile-curvature asymmetry contribution.

In the strict symmetric thin-shell limit, only the first survives at leading integrated order.

4.6 Thin-shell scaling

The shell kernel scales as

$$\mathcal{K}_{\rm ax} \sim \Delta_*^{-2}$$

inside a shell of width Δ_*. Therefore its integral across the shell scales as

$$\Lambda_s \sim \Delta_*^{-1}.$$

This is exactly what one physically expects: a thinner shell gives a stronger localized coupling in the thin-shell limit.

Thus the shell-response scale is not arbitrary. It is inversely controlled by the tortoise thickness of the shell-support layer.

This is the first quantitative bridge from shell profile to shell scattering strength.

4.7 Benchmark axial operator in compact form

The stationary master equation now takes the explicit form

$$\frac{d^2\Psi_\omega}{dr_*^2} + [\omega^2 - V_{\rm RW}(r) - \mathcal{K}_{\rm ax}(r_*)]\Psi_\omega = 0,$$

with

$$\mathcal{K}_{\rm ax}(r_*) = \frac{\Xi_s}{\Delta_*^2}\operatorname{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right) + \frac{2\beta_\chi}{\Delta_*^2}\operatorname{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).$$

In the symmetric thin-shell reduction, the shell coupling will therefore be controlled primarily by the single effective shell-strength parameter Ξ_s.

This is the simplification that makes the first numerical estimate possible.

4.8 What Section 4 has achieved

The background shell profile has now been converted into an explicit axial shell operator. That is the exact step needed to move from background geometry to shell coupling.

We now have:

a concrete benchmark shell profile,

a concrete shell-support density,

an explicit shell correction $\Delta V_{\mathrm{shell}}$,

and therefore an explicit axial shell kernel $\mathcal{K}_{\mathrm{ax}}(r_*)$.

The next task is now straightforward:
integrate the shell kernel across the shell and derive the thin-shell coupling Λ_s.

5. Construction of the Axial Shell Kernel $\mathcal{K}_{\mathrm{ax}}(r)$

The odd-parity reduction of the previous section showed that the FCLET shell perturbation problem can be written, in gauge-invariant form, as a Regge–Wheeler-type master equation with a shell-supported correction. What remains is to identify that correction explicitly. The purpose of the present section is therefore exact: to construct the axial shell kernel $\mathcal{K}_{\mathrm{ax}}(r)$directly from the shell background data and to isolate the part of the shell operator that survives in the thin-shell limit.

This step is decisive. The shell kernel is the precise object that links the strong-field FCLET background to the perturbative shell-response sector. Without it, the shell coupling $\Lambda_s$remains only schematic. Once it is constructed, the background-to-response bridge becomes explicit.

5.1 Shell-supported correction to the axial operator

In the odd-parity sector, the gauge-invariant master field $\Phi(t,r)$obeys a shell-dressed Regge–Wheeler-type equation of the form

$$-\partial_t^2\Phi + \partial_{r_*}^2\Phi - V_{\mathrm{RW}}(r)\,\Phi - \Delta V_{\mathrm{shell}}(r_*)\,\Phi = 0,$$

where $V_{\mathrm{RW}}(r)$is the smooth exterior axial potential and $\Delta V_{\mathrm{shell}}(r_*)$is the FCLET shell contribution. In frequency space,

$$\Phi(t,r_*) = e^{-i\omega t}\Psi_\omega(r_*),$$

this becomes

$$\frac{d^2\Psi_\omega}{dr_*^2} + [\omega^2 - V_{\mathrm{RW}}(r) - \Delta V_{\mathrm{shell}}(r_*)]\Psi_\omega = 0.$$

The shell correction $\Delta V_{\mathrm{shell}}(r_*)$is not an externally assigned scattering potential. It is the shell-localized imprint of the background FCLET shell profile on the axial perturbation operator. The goal of this section is to make that statement explicit.

5.2 Local shell data entering the kernel

The benchmark shell background fixed in Section 3 is described by the static latency profile

$$\bar{\chi}(r_*) = 1 - \tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right),$$

where $r_{*,s}$is the shell position and $\Delta_*$is the shell tortoise width. Its derivatives are

$$\partial_{r_*}\bar{\chi} = -\frac{1}{\Delta_*}\,\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right),$$
$$\partial_{r_*}^2\bar{\chi} = \frac{2}{\Delta_*^2}\,\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).$$

The shell-support density was likewise fixed as

$$\bar{\rho}_{\mathrm{shell}}(r_*) = \sigma_s(\partial_{r_*}\bar{\chi})^2 = \frac{\sigma_s}{\Delta_*^2}\,\mathrm{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right),$$

with $\sigma_s$the effective shell-support coefficient.

These three quantities are the only shell-localized scalars needed at leading order for the benchmark axial operator:

the shell gradient energy $(\partial_{r_*}\bar{\chi})^2$,

the shell profile curvature $\partial_{r_*}^2\bar{\chi}$,

and the shell-support stress density $\bar{\rho}_{\mathrm{shell}}$.

5.3 Minimal benchmark operator basis

The shell contribution to the axial master operator must be constructed from shell-localized scalar data. To leading order in the narrow-shell expansion, the minimal FCLET operator basis is therefore

$$\boxed{\Delta V_{\mathrm{shell}}(r_*) = \alpha_\chi\,(\partial_{r_*}\bar{\chi})^2 + \beta_\chi\,\partial_{r_*}^2\bar{\chi} + \gamma_\chi\,\bar{\rho}_{\mathrm{shell}}(r_*).}$$

Here:

$\alpha_\chi$is the axial response coefficient of the shell gradient-energy sector,

$\beta_\chi$is the axial response coefficient of the shell-curvature sector,

γ_χ is the axial response coefficient of the shell-support stress sector.

These coefficients encode the effective output of the odd-parity linearized FCLET operator on the shell background. In a more microscopic treatment they would be fixed directly from the full action and background solution. In the present benchmark branch they define the minimal local operator closure consistent with the shell background.

This is the point where the shell kernel ceases to be schematic and becomes algebraically explicit.

5.4 Explicit shell kernel

Substituting the benchmark shell profile into the shell operator gives

$$\Delta V_{\mathrm{shell}}(r_*) = \frac{\alpha_\chi}{\Delta_*^2}\operatorname{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right) + \frac{2\beta_\chi}{\Delta_*^2}\operatorname{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right) + \frac{\gamma_\chi \sigma_s}{\Delta_*^2}\operatorname{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).$$

Grouping the symmetric shell-core contributions together, define

$$\boxed{\Xi_s \equiv \alpha_\chi + \gamma_\chi \sigma_s.}$$

The shell-supported correction then takes the compact form

$$\boxed{\Delta V_{\mathrm{shell}}(r_*) = \frac{\Xi_s}{\Delta_*^2}\operatorname{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right) + \frac{2\beta_\chi}{\Delta_*^2}\operatorname{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).}$$

We now identify this shell-supported correction with the axial shell kernel:

$$\boxed{\mathcal{K}_{\mathrm{ax}}(r_*) \equiv \Delta V_{\mathrm{shell}}(r_*).}$$

Thus the explicit kernel is

$$\boxed{\mathcal{K}_{\mathrm{ax}}(r_*) = \frac{\Xi_s}{\Delta_*^2}\operatorname{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right) + \frac{2\beta_\chi}{\Delta_*^2}\operatorname{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).}$$

This is the first explicit FCLET axial shell kernel.

5.5 Symmetric and antisymmetric shell contributions

The structure of $\mathcal{K}_{\mathrm{ax}}$ is especially transparent if one introduces the dimensionless shell coordinate

$$u \equiv \frac{r_* - r_{*,s}}{\Delta_*}.$$

Then

$$\mathcal{K}_{\mathrm{ax}}(u) = \frac{\Xi_s}{\Delta_*^2}\,\mathrm{sech}^4(u) + \frac{2\beta_\chi}{\Delta_*^2}\,\mathrm{sech}^2(u)\tanh(u).$$

The first term is even under $u \to -u$, while the second term is odd. This distinction matters immediately for the thin-shell reduction.

The even term represents the symmetric shell-response core. It survives shell integration and determines the leading integrated shell strength.

The odd term represents profile-curvature asymmetry across the shell. For the symmetric benchmark shell used here, it integrates to zero at leading order. It therefore affects detailed finite-thickness structure but not the leading thin-shell coupling.

This is an important simplification. It means that the benchmark shell coupling will be controlled by the single effective shell-core parameter Ξ_s, while $\beta_\chi$contributes only beyond leading symmetric thin-shell order.

5.6 Dimensional structure of the kernel

The shell kernel scales as

$$\mathcal{K}_{\mathrm{ax}} \sim \Delta_*^{-2}$$

throughout a shell of width Δ_*. Therefore its integral across the shell necessarily scales as

$$\Lambda_s \sim \Delta_*^{-1}.$$

This is exactly the scaling expected of a thin-shell scattering strength. A narrower shell produces a stronger localized response. The kernel therefore already encodes, before any integration is performed, the correct parametric behavior of the shell coupling.

Because r_*has dimensions of length and inverse frequency, the shell kernel has dimensions

$$[\mathcal{K}_{\mathrm{ax}}] = [r_*^{-2}] = [\omega^2],$$

and the integrated shell coupling will therefore have dimensions

$$[\Lambda_s] = [r_*^{-1}] = [\omega].$$

This is the correct dimensional structure for the reflectivity law derived earlier.

5.7 Benchmark master equation in kernel form

The odd-parity stationary master equation may now be written in final benchmark form as

$$\boxed{\frac{d^2\Psi_\omega}{dr_*^2} + [\omega^2 - V_{\mathrm{RW}}(r) - \mathcal{K}_{\mathrm{ax}}(r_*)]\Psi_\omega = 0,}$$

with

$$\boxed{\mathcal{K}_{\mathrm{ax}}(r_*) = \frac{\Xi_s}{\Delta_*^2}\mathrm{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right) + \frac{2\beta_\chi}{\Delta_*^2}\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).}$$

This is the exact shell-dressed axial operator of the benchmark FCLET branch.

It makes the background-to-response structure completely explicit:

the shell profile determines the shell gradients,

the shell gradients determine the kernel,

the kernel determines the integrated coupling,

and the coupling determines the reflectivity law.

5.8 What Section 5 has achieved

The strong-field shell background has now been converted into an explicit perturbative shell kernel. This is the exact step needed before the shell coupling can be computed.

At this stage we have:

a benchmark shell profile,

explicit shell gradient and shell-support data,

a closed-form axial shell kernel,

and a clean separation between the symmetric shell core and the antisymmetric finite-thickness correction.

The next task is therefore immediate and mathematically well posed:
integrate $\mathcal{K}_{\mathrm{ax}}(r_*)$across the shell-support layer and derive the thin-shell coupling Λ_s.

6. Thin-Shell Limit and the Integrated Coupling Λ_s

The axial shell kernel derived in the previous section now makes the central strong-field quantity of the minimal branch calculable. The shell coupling Λ_s is not an independent parameter. It is the integrated strength of the shell kernel across the shell-support layer. The present section performs that integration explicitly and derives the first closed expression for Λ_s in the benchmark Schwarzschild-like FCLET shell background.

The key simplification is that the benchmark shell profile is symmetric around the shell center. As a result, the leading integrated shell coupling is controlled entirely by the even part

of the shell kernel, while the odd part contributes only to subleading finite-thickness asymmetry effects.

6.1 Definition of the integrated shell coupling

By definition, the thin-shell axial coupling is

$$\boxed{\Lambda_s = \int_{\text{shell}} \mathcal{K}_{\text{ax}}\,(r_*)\,dr_*.}$$

For the benchmark shell kernel derived previously,

$$\mathcal{K}_{\text{ax}}(r_*) = \frac{\Xi_s}{\Delta_*^2}\operatorname{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right) + \frac{2\beta_\chi}{\Delta_*^2}\operatorname{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).$$

Introduce the dimensionless shell coordinate

$$\boxed{u \equiv \frac{r_* - r_{*,s}}{\Delta_*}.}$$

Then

$$dr_* = \Delta_*\,du,$$

and the shell coupling becomes

$$\Lambda_s = \frac{\Xi_s}{\Delta_*}\int \operatorname{sech}^4(u)\,du + \frac{2\beta_\chi}{\Delta_*}\int \operatorname{sech}^2(u)\tanh(u)\,du,$$

with the integrals taken across the shell layer. In the strict thin-shell limit, this means over the full localized support of the shell profile, which may be extended to $(-\infty, +\infty)$ because the profile is exponentially localized.

Thus

$$\boxed{\Lambda_s = \frac{\Xi_s}{\Delta_*}\int_{-\infty}^{+\infty} \operatorname{sech}^4\,(u)\,du + \frac{2\beta_\chi}{\Delta_*}\int_{-\infty}^{+\infty} \operatorname{sech}^2\,(u)\tanh(u)\,du.}$$

6.2 Vanishing of the odd shell contribution

The second integral vanishes identically because its integrand is odd:

$$\operatorname{sech}^2(u)\tanh(u)$$

changes sign under $u \to -u$. Therefore

$$\boxed{\int_{-\infty}^{+\infty} \operatorname{sech}^2(u)\tanh(u)\, du = 0.}$$

This confirms the structural point made in the previous section: the profile-curvature asymmetry term does not contribute to the leading integrated shell coupling of the symmetric benchmark shell.

Thus the thin-shell coupling is determined entirely by the symmetric shell core:

$$\boxed{\Lambda_s = \frac{\Xi_s}{\Delta_*}\int_{-\infty}^{+\infty} \operatorname{sech}^4(u)\, du.}$$

6.3 Exact evaluation of the shell integral

The remaining integral is standard:

$$\int_{-\infty}^{+\infty} \operatorname{sech}^4(u)\, du = \frac{4}{3}.$$

Therefore the axial shell coupling is

$$\boxed{\Lambda_s = \frac{4\Xi_s}{3\Delta_*}.}$$

This is the first exact closed-form expression for the shell coupling in the benchmark FCLET axial thin-shell branch.

The result is structurally decisive. The shell coupling is no longer a schematic shell-strength symbol. It is the inverse tortoise thickness of the shell multiplied by a definite effective shell-strength coefficient.

6.4 Physical meaning of the result

The expression

$$\Lambda_s = \frac{4\Xi_s}{3\Delta_*}$$

has an immediate physical interpretation.

First, it confirms that thinner shells scatter more strongly. As Δ_* decreases, the shell coupling grows. This is exactly the expected thin-shell behavior: compressing the same shell-support structure into a narrower tortoise layer produces a stronger localized interaction.

Second, it shows that the shell coupling is controlled by the composite strength parameter

$$\Xi_s = \alpha_\chi + \gamma_\chi \sigma_s.$$

Thus the shell response is jointly determined by:

the direct axial sensitivity to shell gradient energy,

and the axial imprint of the shell-support stress sector.

This is an important FCLET result. The shell coupling is not controlled by geometry alone. It is controlled by the burden profile and the shell-support sector together.

Third, the dependence on β_χ drops out at leading integrated order for the symmetric benchmark shell. Therefore the dominant shell coupling does not depend on profile skewness but on the symmetric shell core. This makes the benchmark branch cleaner and more robust.

6.5 Shell coupling in terms of proper shell width

The tortoise shell width Δ_* is related to the ordinary radial width Δ by

$$\Delta_* = \sqrt{\frac{\bar{B}}{\bar{A}}}\,\big|_{r_s}\,\Delta.$$

Thus the coupling may also be written as

$$\boxed{\Lambda_s = \frac{4\Xi_s}{3}\sqrt{\frac{\bar{A}}{\bar{B}}}\,\big|_{r_s}\,\frac{1}{\Delta}.}$$

This makes explicit how strong-field redshift affects the shell coupling. Near the shell, the conversion between radial width and tortoise width is highly nontrivial. The shell may be narrow in proper or radial terms while still appearing spectrally soft in tortoise coordinate because of the background redshift structure.

This is precisely why the tortoise-coordinate shell width is the natural quantity controlling the reflectivity law.

6.6 Relation to shell proper distance

Earlier FCLET strong-field work fixed the shell proper distance scale as

$$\rho_s = \frac{\sqrt{2\eta_s}}{\pi}\,\ell_P$$

once the shell-onset threshold is set by $I_{\mathrm{sat}} = 1/2$. The shell width need not be identical to the shell proper distance, but in the absence of a more detailed shell microstructure model it is natural to parameterize them proportionally:

$$\boxed{\Delta_* = \varepsilon_s \, \rho_s,}$$

where ε_s is an order-unity shell-width parameter in tortoise measure.

Then the axial shell coupling becomes

$$\boxed{\Lambda_s = \frac{4\Xi_s}{3\varepsilon_s \rho_s}.}$$

Substituting the FCLET shell distance gives

$$\boxed{\Lambda_s = \frac{4\Xi_s}{3\varepsilon_s} \frac{\pi}{\sqrt{2\eta_s}\,\ell_P}.}$$

This is the first explicit bridge from shell burden parameters to the shell coupling of the perturbation problem.

It shows directly that:

larger species loading η_s produces a thicker shell and therefore smaller Λ_s,

stronger shell-response coefficient Ξ_s produces larger Λ_s,

and the shell-width factor ε_s controls how strongly the background shell profile is compressed into the thin-shell image.

6.7 Relation to the reflectivity law

Because the minimal axial reflectivity law is

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s},$$

the result above immediately yields

$$\boxed{R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\frac{4\Xi_s}{3\Delta_*}}{2i\omega - \frac{4\Xi_s}{3\Delta_*}}.}$$

Equivalently, in terms of the shell proper distance parameterization,

$$\boxed{R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\frac{4\Xi_s}{3\varepsilon_s\rho_s}}{2i\omega - \frac{4\Xi_s}{3\varepsilon_s\rho_s}}.}$$

Thus the shell reflectivity law is no longer structurally derived but numerically empty. Its coupling now has an explicit background-shell form.

The only remaining task is to assign benchmark values to the background coefficients Ξ_s and ε_s in the Schwarzschild-like shell branch.

6.8 Response scale implied by the shell coupling

The minimal branch previously gave the response scale

$$\omega_c^{(\mathrm{ax,thin})} = \frac{\Lambda_s}{2}.$$

Using the integrated shell coupling, this becomes

$$\boxed{\omega_c^{(\mathrm{ax,thin})} = \frac{2\Xi_s}{3\Delta_*} = \frac{2\Xi_s}{3\varepsilon_s\rho_s}.}$$

Thus the shell response bandwidth is now explicitly tied to the shell profile.

This is a major strong-field result. The response scale is no longer only a formal byproduct of the reflectivity law. It is a derived spectral descendant of shell width and shell burden structure.

6.9 What Section 6 has achieved

The thin-shell integration has now closed the missing mathematical step between shell kernel and shell coupling.

We now have the exact result

$$\boxed{\Lambda_s = \frac{4\Xi_s}{3\Delta_*}.}$$

This is the first closed background-derived shell coupling of the FCLET compact-object program.

With this result, the axial strong-field chain is now almost numerically closed:

$$\bar{\chi}(r) \;\longrightarrow\; \mathcal{K}_{\mathrm{ax}}(r_*) \;\longrightarrow\; \Lambda_s \;\longrightarrow\; R_s^{(\mathrm{ax,thin})}(\omega).$$

Only one step remains: assign benchmark numerical values to the shell background parameters and evaluate the corresponding shell coupling explicitly.

That is the task of the next section.

7. Schwarzschild-Like Shell Benchmark Background

To convert the integrated shell coupling into a numerical estimate, the remaining background coefficients must be fixed. The purpose of the present section is therefore to define the canonical Schwarzschild-like benchmark branch of the FCLET shell and assign a minimal but explicit set of strong-field shell parameters.

The axial shell coupling derived above depends on three background quantities:

the shell proper distance ρ_s,

the shell-width parameter ε_s,

and the effective shell-response strength Ξ_s.

The shell proper distance has already been fixed by the earlier FCLET strong-field analysis. The remaining task is therefore to specify benchmark values for ε_s and Ξ_s consistent with the minimal axial thin-shell branch.

7.1 Shell proper distance

With the shell-onset threshold fixed by

$$I_{\mathrm{sat}} = \frac{1}{2},$$

the shell proper distance is

$$\boxed{\rho_s = \frac{\sqrt{2\eta_s}}{\pi}\,\ell_P.}$$

This remains the canonical shell-location law of the strong-field branch.

For the minimal field-content benchmark $\eta_s = 1$,

$$\boxed{\rho_s = \frac{\sqrt{2}}{\pi}\,\ell_P \approx 0.450\,\ell_P.}$$

This is the shell scale used in the canonical benchmark.

7.2 Tortoise-width benchmark

The shell width is not fixed independently by the previous shell-location paper. It must therefore be parameterized. The cleanest benchmark choice is to take the shell tortoise width to be of the same order as the shell proper distance:

$$\boxed{\Delta_* = \varepsilon_s \rho_s, \varepsilon_s \sim \mathcal{O}(1).}$$

The most conservative canonical benchmark is

$$\boxed{\varepsilon_s = 1.}$$

This means the shell's effective tortoise thickness is taken to be equal, at leading order, to its proper shell scale.

This is not an arbitrary scattering ansatz. It is the minimal background closure rule of the benchmark shell branch.

7.3 Effective shell-response strength

The remaining coefficient is

$$\Xi_s = \alpha_\chi + \gamma_\chi \sigma_s.$$

This quantity measures the integrated axial sensitivity of the shell kernel to:

shell gradient energy,

and shell-support stress.

At the present benchmark level, the most natural normalization is the minimal shell-response choice

$$\boxed{\Xi_s = 1.}$$

This means the shell gradient and shell-support sector together define a unit-normalized effective axial scattering core.

Again, this is not a phenomenological reflectivity fit. It is the minimal normalization convention for the background shell kernel. Once a fuller action-level coefficient matching is carried out in later work, this benchmark can be replaced by a first-principles coefficient value.

For the present paper, however, $\Xi_s = 1$ is the correct canonical starting point.

7.4 Canonical Schwarzschild-like shell benchmark

The canonical strong-field benchmark branch of the present paper is therefore defined by

$$\boxed{\eta_s = 1, \varepsilon_s = 1, \Xi_s = 1.}$$

Under these assumptions,

$$\rho_s = \frac{\sqrt{2}}{\pi}\ell_P, \Delta_* = \rho_s,$$

and the shell coupling becomes

$$\Lambda_s = \frac{4}{3\rho_s}.$$

Substituting the shell distance gives

$$\boxed{\Lambda_s = \frac{4}{3}\frac{\pi}{\sqrt{2}\,\ell_P} = \frac{4\pi}{3\sqrt{2}}\,\ell_P^{-1}.}$$

This is the first numerical shell-coupling scale of the FCLET axial branch.

7.5 Magnitude of the benchmark shell coupling

Using the Planck time t_P as the natural frequency unit,

$$\ell_P^{-1} \equiv t_P^{-1},$$

one finds

$$\boxed{\Lambda_s \approx 2.96\, t_P^{-1}.}$$

Thus the benchmark axial shell coupling lies at Planckian frequency scale, as expected for a shell whose support layer is itself Planckian in width.

This immediately has an important implication for observational frequencies: for any astrophysical frequency band far below the Planck scale, including the LIGO band, one generically has

$$\omega \ll \Lambda_s.$$

Therefore the shell reflectivity in the minimal axial branch will lie deep in its low-frequency regime for all currently accessible gravitational-wave observations.

This is the first strong-field numerical consequence of the coupling calculation.

7.6 Response scale of the benchmark branch

Because the minimal axial response scale is

$$\omega_c^{(\mathrm{ax,thin})} = \frac{\Lambda_s}{2},$$

the benchmark shell gives

$$\boxed{\omega_c^{(\mathrm{ax,thin})} = \frac{2\pi}{3\sqrt{2}}\,\ell_P^{-1} \approx 1.48\,t_P^{-1}.}$$

Thus the crossover from shell reflection to shell transparency occurs at Planckian frequency scale in the canonical benchmark branch.

This is fully consistent with the shell's Planckian width and validates the internal logic of the minimal strong-field sector.

7.7 Why the LIGO band lies in the infrared limit

For a representative observational frequency such as

$$f = 150\ \mathrm{Hz}, \omega = 2\pi f \approx 9.42 \times 10^2\ \mathrm{s}^{-1},$$

the ratio to the benchmark shell coupling is

$$\frac{\omega}{\Lambda_s} \sim \omega\, t_P \sim 10^{-41}.$$

Thus the observationally accessible band lies overwhelmingly in the regime

$$\boxed{\omega \ll \Lambda_s.}$$

This means that, in the canonical minimal axial benchmark branch, the shell is effectively probed only in its infrared response sector. The physical shell response observed in such a band is therefore controlled almost entirely by the low-frequency limit R_0, not by the high-frequency transparency turnover.

This is the exact reason the first numerical reflectivity estimate will be very close to the infrared result.

7.8 What Section 7 has fixed

The benchmark strong-field shell background is now numerically specified.

We have fixed:

the shell proper distance,

the shell tortoise width,

the effective shell-response strength,

the shell coupling,

and the shell response scale.

The only remaining step is arithmetic: evaluate the resulting numerical value of Λ_s explicitly and then substitute it into the derived reflectivity law.

That is the task of the next section.

---

8. First Numerical Estimate of Λ_s

The previous section fixed the canonical Schwarzschild-like shell benchmark of the minimal axial branch:

$$\eta_s = 1, \varepsilon_s = 1, \Xi_s = 1.$$

Under these assumptions, the shell proper distance is

$$\rho_s = \frac{\sqrt{2}}{\pi}\,\ell_P,$$

the shell tortoise width is

$$\Delta_* = \rho_s,$$

and the integrated shell coupling is

$$\Lambda_s = \frac{4}{3\rho_s}.$$

The purpose of the present section is simply to evaluate this quantity explicitly and thereby give the first numerical value of the FCLET axial shell-coupling coefficient.

8.1 Canonical benchmark value

Substituting the shell distance,

$$\rho_s = \frac{\sqrt{2}}{\pi}\ell_P,$$

into the coupling formula gives

$$\Lambda_s = \frac{4}{3}\frac{\pi}{\sqrt{2}\,\ell_P}.$$

Therefore

$$\boxed{\Lambda_s = \frac{4\pi}{3\sqrt{2}}\,\ell_P^{-1}.}$$

The numerical prefactor is

$$\frac{4\pi}{3\sqrt{2}} \approx 2.962.$$

Thus the benchmark shell coupling is

$$\boxed{\Lambda_s \approx 2.96\,\ell_P^{-1}.}$$

Equivalently, in Planck time units t_P,

$$\boxed{\Lambda_s \approx 2.96\,t_P^{-1}.}$$

This is the first numerical shell-coupling estimate of the FCLET compact-object program.

8.2 Conversion to SI frequency units

Using

$$t_P \approx 5.391247 \times 10^{-44}\ \text{s},$$

one has

$$t_P^{-1} \approx 1.85487 \times 10^{43}\ \text{s}^{-1}.$$

Therefore the benchmark axial shell coupling is

$$\boxed{\Lambda_s \approx 2.96 \times 1.85487 \times 10^{43}\ \text{s}^{-1} \approx 5.49 \times 10^{43}\ \text{s}^{-1}.}$$

This confirms that the shell response scale of the minimal branch is Planckian, exactly as expected from the Planckian shell width of the strong-field background.

8.3 Benchmark response scale

The minimal axial crossover scale is

$$\omega_c^{(\mathrm{ax,thin})} = \frac{\Lambda_s}{2}.$$

Hence

$$\boxed{\omega_c^{(\mathrm{ax,thin})} \approx 1.48\, t_P^{-1} \approx 2.74 \times 10^{43}\ \mathrm{s}^{-1}.}$$

In ordinary frequency units,

$$f_c^{(\mathrm{ax,thin})} = \frac{\omega_c^{(\mathrm{ax,thin})}}{2\pi} \approx 4.36 \times 10^{42}\ \mathrm{Hz}.$$

Thus the canonical shell-response turnover lies overwhelmingly above any currently accessible gravitational-wave observing band.

8.4 Interpretation of the numerical scale

This benchmark value has an immediate physical meaning.

The shell coupling is not merely "large." It is large precisely because the benchmark shell is Planckian in width. A localized shell-support layer of thickness $\rho_s \sim \ell_P$ necessarily produces a shell coupling of order ℓ_P^{-1}. The result is therefore not an arbitrary huge number. It is the direct perturbative translation of the shell's microscopic support scale.

This also clarifies the status of the minimal branch. Because Λ_s is Planckian, all astrophysical ringdown frequencies satisfy

$$\omega \ll \Lambda_s.$$

Therefore the observationally relevant shell response of the minimal branch lies entirely in its deep infrared regime. This means that the first numerical reflectivity estimate will be almost indistinguishable from the low-frequency limit $R_0 = -1$.

That is not a flaw of the calculation. It is exactly what the benchmark shell width implies.

8.5 Parameter dependence of the numerical result

Although the canonical benchmark gives

$$\Lambda_s \approx 2.96\, \ell_P^{-1},$$

the general expression remains

$$\boxed{\Lambda_s = \frac{4\Xi_s}{3\varepsilon_s\rho_s} = \frac{4\Xi_s}{3\varepsilon_s}\frac{\pi}{\sqrt{2\eta_s}\,\ell_P}.}$$

Thus:

increasing η_s decreases Λ_s,

increasing ε_s decreases Λ_s,

increasing Ξ_s increases Λ_s.

This means the benchmark value is not the only possible branch value, but it is the correct canonical normalization of the minimal axial shell sector.

The present paper therefore does two things at once:

it gives the first numerical shell coupling,

and it shows exactly how that number would shift under different shell-background branches.

8.6 What Section 8 has achieved

The strong-field bottleneck of the minimal axial branch was the absence of a numerical shell-coupling scale. That bottleneck is now removed.

The compact-object branch now possesses the benchmark result

$$\boxed{\Lambda_s \approx 5.49 \times 10^{43}\ \mathrm{s}^{-1}.}$$

The reflectivity law

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}$$

is therefore no longer only formally derived. It now has numerical content.

The next step is immediate: use this value to construct the numerical reflectivity profile itself.

9. Numerical Reflectivity Profile $R_s(\omega)$

With the benchmark shell coupling now fixed, the minimal axial thin-shell reflectivity law becomes numerically explicit. The shell response is

$$\boxed{R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}, \Lambda_s \approx 5.49 \times 10^{43}\ \mathrm{s}^{-1}.}$$

The purpose of the present section is to display the resulting numerical shell-response profile and identify its behavior in the observationally relevant low-frequency regime.

9.1 Exact magnitude and phase

The complex reflectivity may be written as

$$R_s^{(\mathrm{ax,thin})}(\omega) = -\frac{1}{1-\frac{2i\omega}{\Lambda_s}}.$$

Its squared magnitude is

$$\boxed{|\, R_s^{(\mathrm{ax,thin})}(\omega)\,|^2 = \frac{\Lambda_s^2}{4\omega^2+\Lambda_s^2}.}$$

Its phase is determined by

$$\arg R_s^{(\mathrm{ax,thin})}(\omega) = \pi - \arctan\left(\frac{2\omega}{\Lambda_s}\right),$$

up to the usual branch convention for a complex number close to -1.

Thus the numerical response profile is completely fixed once Λ_s is given.

9.2 Infrared branch

Because Λ_s is Planckian, the infrared regime is enormous. For all frequencies satisfying

$$\omega \ll 5.49 \times 10^{43}\ \mathrm{s}^{-1},$$

the shell response is extremely close to

$$R_s^{(\mathrm{ax,thin})}(\omega) \approx -1.$$

In that regime,

$$\boxed{R_s^{(\mathrm{ax,thin})}(\omega) = -1 - \frac{2i\omega}{\Lambda_s} + \mathcal{O}\left(\frac{\omega^2}{\Lambda_s^2}\right).}$$

Thus the shell is nearly perfectly reflective in magnitude and acquires only an extremely small frequency-dependent phase correction.

9.3 Transition region

The shell begins to depart appreciably from full reflectivity only when

$$\omega \sim \omega_c^{(\mathrm{ax,thin})} \approx 2.74 \times 10^{43}\ \mathrm{s}^{-1}.$$

At that point the response enters the crossover from shell reflection to shell transparency. The reflected power is reduced to one half of its zero-frequency value at

$$\omega = \frac{\Lambda_s}{2}.$$

This is the exact half-power scale derived earlier.

9.4 Ultraviolet branch

For

$$\omega \gg \Lambda_s,$$

the shell response becomes

$$R_s^{(\mathrm{ax,thin})}(\omega) \approx -\frac{\Lambda_s}{2i\omega}.$$

Hence

$$|\, R_s^{(\mathrm{ax,thin})}(\omega)\,| \approx \frac{\Lambda_s}{2\omega},$$

and the shell becomes increasingly transparent. This is the high-frequency tail of the minimal branch.

Although this region is far beyond observational relevance, it is conceptually useful because it confirms the internal consistency of the shell-response law: the shell is not a rigid mirror at all frequencies.

9.5 Benchmark profile in words

The numerical reflectivity profile of the canonical minimal axial branch may therefore be summarized very simply:

deep infrared: almost perfect reflection,

Planckian crossover: transition regime,

ultraviolet: increasing transparency.

This is exactly the behavior already inferred structurally, now converted into a numerical frequency profile.

9.6 Numerical shell response as a function of ω/Λ_s

Because the response law depends only on the ratio ω/Λ_s, it is convenient to define

$$x \equiv \frac{\omega}{\Lambda_s}.$$

Then

$$R_s^{(\mathrm{ax,thin})}(x) = \frac{1}{2ix - 1},$$

and

$$|\, R_s^{(\mathrm{ax,thin})}(x)\,|^2 = \frac{1}{1 + 4x^2}.$$

This dimensionless form makes the structure especially transparent:

- $x \ll 1$ gives infrared reflection,
- $x \sim 1$ gives crossover,
- $x \gg 1$ gives transparency.

For the canonical branch, every currently accessible gravitational-wave band lies in the $x \ll 1$ regime.

9.7 Main outcome of the numerical profile

The central outcome of this section is exact:

The benchmark FCLET axial shell is effectively probed only in its infrared response sector by astrophysical frequencies.

This means that the first numerical reflectivity estimate will be almost indistinguishable from the low-frequency limit $R_0 = -1$ in any presently accessible observational band.

The next section makes this explicit for a representative LIGO-band frequency.

10. LIGO-Band Benchmark: $R_s(150\ \mathrm{Hz})$

The minimal axial thin-shell branch is now numerically specified. The most immediate observational question is therefore simple:

$$\boxed{R_s^{(\mathrm{ax,thin})}(150\ \mathrm{Hz}) = ?}$$

The present section answers that question explicitly.

10.1 Frequency conversion

For a representative LIGO-band frequency

$$f = 150\ \text{Hz},$$

the corresponding angular frequency is

$$\boxed{\omega = 2\pi f \approx 9.42 \times 10^{2}\ \text{s}^{-1}.}$$

The ratio to the benchmark shell coupling is therefore

$$\frac{\omega}{\Lambda_s} \approx \frac{9.42 \times 10^{2}}{5.49 \times 10^{43}} \approx 1.72 \times 10^{-41}.$$

Thus

$$\boxed{\frac{2\omega}{\Lambda_s} \approx 3.43 \times 10^{-41}.}$$

This confirms quantitatively that the LIGO band lies deeply inside the infrared shell-response regime of the minimal branch.

10.2 Complex reflectivity at 150 Hz

Substituting into the exact law,

$$R_s^{(\text{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s},$$

gives

$$\boxed{R_s^{(\text{ax,thin})}(150\ \text{Hz}) = \frac{1}{2i(\omega/\Lambda_s) - 1}.}$$

Since $2\omega/\Lambda_s \ll 1$, one obtains the excellent approximation

$$R_s^{(\text{ax,thin})}(150\ \text{Hz}) \approx -1 - i\,3.43 \times 10^{-41}.$$

Therefore

$$\boxed{R_s^{(\mathrm{ax,thin})}(150\ \mathrm{Hz}) \approx -1 - i\,3.43 \times 10^{-41}.}$$

This is the first numerical FCLET shell reflectivity value in an observationally relevant frequency band.

10.3 Magnitude at 150 Hz

The reflected power is

$$|\,R_s^{(\mathrm{ax,thin})}\,|^2 = \frac{\Lambda_s^2}{4\omega^2 + \Lambda_s^2} = \frac{1}{1 + (2\omega/\Lambda_s)^2}.$$

At 150 Hz,

$$(2\omega/\Lambda_s)^2 \approx 1.18 \times 10^{-81},$$

so that

$$\boxed{|\,R_s^{(\mathrm{ax,thin})}(150\ \mathrm{Hz})\,|^2 \approx 1 - 1.18 \times 10^{-81}.}$$

Thus

$$\boxed{|\,R_s^{(\mathrm{ax,thin})}(150\ \mathrm{Hz})\,| \approx 1.}$$

To the precision of any realistic measurement, the shell is perfectly reflective in magnitude in the LIGO band within the canonical minimal axial branch.

10.4 Phase shift at 150 Hz

The shell phase differs from π only by the tiny correction

$$\delta\phi \approx \frac{2\omega}{\Lambda_s} \approx 3.43 \times 10^{-41}.$$

Thus the LIGO-band shell response of the canonical minimal branch is not only unit-reflective in magnitude; it is also essentially in the exact phase-reversal limit.

10.5 Interpretation of the result

This numerical result is extremely strong and must be interpreted carefully.

It does **not** mean that the full FCLET shell must be perfectly reflective in practice at 150 Hz. It means that the **minimal axial thin-shell branch**, when closed by the canonical benchmark shell background, predicts near-perfect LIGO-band reflection. This is a result of:

Planckian shell width,

Planckian shell coupling,

and the conservative one-channel structure of the strict thin-shell axial problem.

In other words, the numerical result confirms, in the strongest possible form, the conclusion already drawn structurally in the previous shell-perturbation paper: the minimal branch is exact but too rigid to represent the full physical shell-response law.

That is a valuable outcome. The theory is now strong enough to reveal its own over-rigid branch limits quantitatively.

10.6 Exact benchmark statement

The benchmark result may therefore be stated compactly as

$$\boxed{R_s^{(\mathrm{ax,thin})}(150\ \mathrm{Hz}) \approx -1 - i\,3.43 \times 10^{-41}, |\ R_s^{(\mathrm{ax,thin})}(150\ \mathrm{Hz})\ | \approx 1.}$$

This is the first numerical strong-field reflectivity estimate of the FCLET compact-object program.

11. Consequences for Echoes and Axial Mode Deformation

The numerical shell coupling derived in this paper gives the minimal axial reflectivity law direct observational content. The consequences are immediate.

11.1 Echo hierarchy

Since the shell is essentially perfectly reflective in the LIGO band within the canonical minimal branch, the echo hierarchy

$$A_n(\omega) \propto \mathcal{A}_0(\omega)\ (R_b(\omega)R_s(\omega))^{n-1} e^{2in\omega L}$$

reduces effectively to

$$A_n(\omega) \propto \mathcal{A}_0(\omega)\ (-R_b(\omega))^{n-1} e^{2in\omega L}$$

throughout the observable low-frequency band.

Thus the shell contributes almost maximal coherent return in the minimal branch. The late-time structure is then controlled mainly by:

barrier leakage,

cavity phase,

and the barrier response itself.

11.2 Axial mode deformation

The shell-induced quasi-normal mode shift becomes

$$\delta\omega_n^{(\mathrm{ax,thin})} \propto \frac{\Lambda_s}{2i\omega_n^{\mathrm{GR}} - \Lambda_s} e^{2i\omega_n^{\mathrm{GR}} L}.$$

For low-frequency axial modes satisfying $| \omega_n^{\mathrm{GR}} | \ll \Lambda_s$, this reduces to

$$\boxed{\delta\omega_n^{(\mathrm{ax,thin})} \propto - e^{2i\omega_n^{\mathrm{GR}} L}.}$$

Thus the shell-return factor is essentially maximal in magnitude in the canonical branch. Any suppression of the physically observable shell response must therefore come from physics absent in the strict minimal branch:

finite-thickness structure,

dissipative shell channels,

and coupled metric-latency response.

11.3 Strong interpretation

This is one of the most important scientific outcomes of the paper. The calculation has not merely produced a number. It has shown, numerically, that the canonical minimal axial branch lies at the "maximally reflective" end of the possible FCLET shell-response spectrum in the astrophysical band.

That conclusion is not a failure of the theory. It is a guide to its next necessary refinement.

The role of the present paper is therefore exact:

it closes the background-to-response bridge,

it gives the first numerical shell coupling,

and it proves that the minimal branch by itself is too stiff to serve as the final physical shell-response law.

This is precisely the kind of result a mature research program should produce.

12. Conclusion

We have evaluated the axial shell-coupling coefficient Λ_s of the finite-capacity latency–erasure theory directly from the strong-field shell background and thereby converted the previously derived minimal axial reflectivity law into a numerically explicit strong-field prediction.

Earlier FCLET work had already established the shell location, the shell-onset threshold, the shell timing scale, and the first action-based shell-response law of the odd-parity thin-shell branch. The missing link was the shell coupling itself. The present paper closed that link.

Starting from the strong-field shell background, we wrote the shell-supported correction to the odd-parity master operator in terms of the shell burden profile, the shell curvature profile, and the shell-support stress sector. This yielded an explicit benchmark axial shell kernel $\mathcal{K}_{\mathrm{ax}}(r_*)$. Integrating that kernel across the shell-support layer, we obtained the thin-shell coupling

$$\Lambda_s = \frac{4\Xi_s}{3\Delta_*}.$$

In the canonical Schwarzschild-like shell benchmark, this becomes

$$\Lambda_s \approx 2.96\,\ell_P^{-1} \approx 5.49 \times 10^{43}\ \mathrm{s}^{-1}.$$

This is the first numerical shell-coupling scale of the FCLET compact-object program.

Substituting this result into the already derived axial shell-response law,

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s},$$

we obtained the first numerical FCLET reflectivity estimate in an observationally relevant band. At 150 Hz, the canonical minimal branch yields

$$R_s^{(\mathrm{ax,thin})}(150\ \mathrm{Hz}) \approx -1 - i\,3.43 \times 10^{-41},$$

with unit magnitude to any practical precision. The shell is therefore effectively fully reflective in the LIGO band within the minimal axial thin-shell branch.

This result is both strong and clarifying. It shows that the strong-field FCLET program has now achieved a genuinely closed derivational chain in its first perturbative branch:

$$\bar{\chi}(r) \;\longrightarrow\; \mathcal{K}_{\mathrm{ax}}(r_*) \;\longrightarrow\; \Lambda_s \;\longrightarrow\; R_s^{(\mathrm{ax,thin})}(\omega).$$

That is a decisive threshold. The shell-response sector is no longer only structurally derived. It is now numerically instantiated.

At the same time, the numerical result reveals the exact limitation of the minimal branch. The shell response is too rigid. A branch that is effectively perfectly reflective throughout the observable low-frequency band cannot yet be the final physical shell-response law of the complete theory. The calculation therefore does exactly what it should do: it identifies, quantitatively, the point at which the minimal thin-shell axial approximation must give way to a more complete shell perturbation theory.

The next task is now sharply defined. The FCLET compact-object program must incorporate:

finite-thickness shell dynamics,

coupled metric-latency perturbations beyond the strict axial branch,

and explicit dissipative internal shell channels.

Only then can the theory move from its first exact numerical branch to its full physical shell spectroscopy.

The present paper has therefore completed one decisive step and isolated the next. The shell coupling is now known. The minimal axial reflectivity law is now numerical. And the path beyond the minimal branch is no longer vague. It is mathematically and physically explicit.

Axial Kernel Coefficients in FCLET Shell Perturbation Theory

Derivation of α_χ, β_χ, and γ_χ from the Linearized Metric–Latency Action

Ali Caner Yücel
Independent Researcher
Gaziantep, Türkiye

Abstract

We derive the axial shell-kernel coefficients of the finite-capacity latency–erasure theory directly from the linearized metric–latency action and thereby remove the last benchmark closure from the minimal strong-field reflectivity sector. Earlier FCLET work established the shell background, fixed the shell-onset threshold $I_{\mathrm{sat}} = 1/2$, derived the shell location and echo-delay scale, and then obtained the first action-based odd-parity thin-shell reflectivity law,

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}.$$

That result closed the shell-response problem at formal level, but its numerical realization still depended on the composite shell-strength parameter

$$\Xi_s = \alpha_\chi + \gamma_\chi \sigma_s,$$

which had not yet been derived from the action itself. The present paper closes that gap.

Starting from the FCLET strong-field action, we expand the coupled metric–latency system to quadratic order around a static spherically symmetric shell background and perform the odd-parity reduction of the perturbation action. Because the background latency field $\bar{\chi}(r)$ is scalar, the odd-parity sector contains no independent propagating axial scalar harmonic. Nevertheless, the shell profile modifies the axial master operator through background dressing, shell-gradient energy, and shell-support stress. We isolate the shell-supported terms of the quadratic action, reduce them to the minimal local operator basis, and derive the coefficients α_χ, β_χ, and γ_χ explicitly.

This yields the first first-principles reconstruction of the axial shell kernel,

$$\mathcal{K}_{\mathrm{ax}}(r_*) = \alpha_\chi(\partial_{r_*}\bar{\chi})^2 + \beta_\chi\ \partial^2_{r_*}\bar{\chi} + \gamma_\chi\,\bar{\rho}_{\mathrm{shell}}(r_*),$$

and therefore the first action-level determination of the shell coupling

$$\Lambda_s = \int_{\mathrm{shell}} \mathcal{K}_{\mathrm{ax}}\,(r_*)\,dr_*.$$

The strong-field significance is immediate. The shell reflectivity sector is no longer controlled by a benchmark normalization convention. It is fixed by the quadratic perturbation structure of the FCLET action itself. The compact-object branch therefore advances from benchmark shell spectroscopy to derived shell spectroscopy.

Keywords

finite-capacity physics; shell perturbation theory; axial kernel coefficients; quadratic action; Regge–Wheeler sector; saturation shell; compact objects; FCLET; strong-field gravity; reflectivity law

1. Introduction

The strong-field branch of the finite-capacity latency–erasure theory has now reached the coefficient-derivation stage. The shell itself has already been established. Its onset threshold is fixed internally by the burden-support crossover,

$$I_{\mathrm{sat}} = \frac{1}{2}, \chi_{\mathrm{sat}} = 1.$$

Its location has already been derived from the shell burden profile. Its cavity geometry has already produced the echo-delay scale. Its odd-parity thin-shell perturbation theory has already yielded the first action-based reflectivity law,

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}.$$

Those achievements transformed the compact-object sector from shell kinematics into shell perturbation dynamics.

But one decisive element remained open.

The form of the axial shell-response law was known. The coefficients feeding the shell kernel were not.

That is the exact problem solved in the present paper.

The previous shell perturbation paper reduced the odd-parity strong-field sector to a shell-supported Regge–Wheeler-type equation and showed that the corresponding thin-shell reflectivity is controlled by the integrated shell coupling Λ_s. That coupling was then written in terms of the shell kernel $\mathcal{K}_{\mathrm{ax}}(r_*)$, and a first benchmark numerical branch was constructed by normalizing the shell-strength combination Ξ_s canonically. That benchmark branch was valuable and revealing. It showed that the minimal axial thin-shell sector is effectively maximally reflective in the observational infrared. It also exposed, with complete clarity, the exact limitation of the branch: the numerical shell response still rested on benchmark coefficient choices rather than on a first-principles coefficient derivation from the FCLET action.

That stage is now over.

The strong-field program no longer needs a benchmark closure for the shell kernel coefficients. It needs the coefficients themselves.

This is not a cosmetic refinement. It is the last remaining structural bottleneck of the minimal axial shell sector. The shell kernel was written in the form

$$\mathcal{K}_{\mathrm{ax}}(r_*) = \alpha_\chi(\partial_{r_*}\bar{\chi})^2 + \beta_\chi\ \partial_{r_*}^2\bar{\chi} + \gamma_\chi\,\bar{\rho}_{\mathrm{shell}}(r_*),$$

and the integrated shell coupling followed from it. But until the coefficients α_χ, β_χ, and γ_χ are derived from the quadratic perturbation action, the numerical shell response of the minimal branch remains only partially closed. The form is derived. The coefficients must now be derived as well.

That is the task of this paper.

The strategy is exact. We begin from the FCLET strong-field action and expand the coupled metric–latency system to quadratic order around the static shell background. We then isolate the odd-parity sector. Because the background latency field is scalar, no independent axial scalar harmonic propagates there. This is not a limitation; it is the axial sector's decisive simplification. The shell enters the odd-parity branch not through a new propagating axial scalar mode, but through background dressing of the axial operator. That dressing is precisely what generates the shell-supported terms of the master action. Once those terms are isolated, their coefficients can be read off directly.

The present paper therefore performs the first full action-level reduction of the axial shell kernel.

Its scientific role is sharp. It does not attempt the final even-parity shell spectroscopy. It does not attempt the full dissipative finite-thickness shell-response problem in all channels. It does not attempt the complete multimode ringdown catalog of the theory. It solves the coefficient problem that stands directly in front of the already derived axial reflectivity law.

That is exactly the right next step, and it is enough to move the minimal axial branch from benchmark shell spectroscopy to derived shell spectroscopy.

The resulting logic is the strongest the compact-object sector has yet achieved:

$$\bar{\chi}(r) \;\longrightarrow\; \mathcal{K}_{\mathrm{ax}}(r_*) \;\longrightarrow\; \Lambda_s \;\longrightarrow\; R_s^{(\mathrm{ax,thin})}(\omega),$$

with every stage now derived from the action-level perturbation structure rather than patched by coefficient convention.

The paper is organized as follows. Section 2 fixes the FCLET strong-field action and the static shell background. Section 3 expands the metric–latency system to quadratic order. Section 4 performs the odd-parity decomposition of the quadratic action. Section 5 isolates the shell-supported terms of the axial operator. Section 6 derives the coefficients α_χ, β_χ, and γ_χ. Section 7 reconstructs the shell kernel from first principles. Section 8 derives the resulting shell coupling Λ_s. Section 9 updates the numerical reflectivity sector. Section 10 concludes.

The compact-object program now advances to the point where coefficient choice is replaced by coefficient derivation. That is the threshold crossed in this paper.

2. FCLET Action and Strong-Field Shell Background

The derivation of the axial kernel coefficients must begin from a definite field theory. The coefficients α_χ, β_χ, and γ_χ are not phenomenological fit parameters. They are the shell-supported coefficients that appear when the coupled metric–latency system is expanded to quadratic order around the strong-field shell background and reduced to the odd-parity sector. The present section therefore fixes the action, the background geometry, the shell profile, and the shell-support conventions that will feed directly into that reduction.

The guiding principle is exact. The strong-field shell is not an inserted membrane. It is a background solution of the FCLET action in which the latency field χ forms a narrow, burden-supported transition layer outside the classical horizon scale. The odd-parity kernel coefficients are descendants of that shell background.

2.1 Effective strong-field FCLET action

We work with the minimal strong-field FCLET action

$$S[g,\chi]=\int d^4x\sqrt{-g}\left[\frac{1}{16\pi G}R-\frac{1}{2}Z_\chi(\chi)\,g^{\mu\nu}\nabla_\mu\chi\nabla_\nu\chi-U(\chi)-\mathcal{W}(\chi,\nabla\chi)\right].$$

The terms have distinct roles.

The Einstein–Hilbert term fixes the gravitational sector.

The kinetic factor $Z_\chi(\chi)$ controls the shell-state-dependent normalization of the latency field.

The potential $U(\chi)$ controls the background shell-support configuration.

The shell functional $\mathcal{W}(\chi,\nabla\chi)$ represents the effective burden-support sector that localizes stress in the shell layer.

This action is the correct starting point for the axial coefficient problem. It is broad enough to support a nontrivial shell background and narrow enough to admit an explicit odd-parity reduction.

For the present paper, the shell-support functional is taken in the minimal gradient-supported form

$$\mathcal{W}(\chi,\nabla\chi)=\frac{\sigma_s}{2}\,(g^{\mu\nu}\nabla_\mu\chi\nabla_\nu\chi)^2,$$

with σ_s the shell-support coefficient. This term does not introduce a new propagating field. It strengthens the shell-support stress wherever the latency gradient is concentrated. That is exactly the structure needed for the FCLET shell layer.

Thus the action becomes

$$S[g,\chi]=\int d^4x\sqrt{-g}\left[\frac{1}{16\pi G}R-\frac{1}{2}Z_\chi(\chi)\,(\nabla\chi)^2-U(\chi)-\frac{\sigma_s}{2}((\nabla\chi)^2)^2\right].$$

This is the strong-field benchmark action of the present paper.

2.2 Field equations

Varying the action with respect to the metric gives

$$G_{\mu\nu} = 8\pi G\, T^{(\chi)}_{\mu\nu},$$

with effective latency stress tensor

$$T^{(\chi)}_{\mu\nu} = Z_\chi(\chi)\,\nabla_\mu\chi\nabla_\nu\chi - g_{\mu\nu}\left[\frac{1}{2}Z_\chi(\chi)(\nabla\chi)^2 + U(\chi)\right] + T^{(W)}_{\mu\nu}.$$

The shell-support contribution is

$$T^{(W)}_{\mu\nu} = 2\sigma_s\,(\nabla\chi)^2\,\nabla_\mu\chi\nabla_\nu\chi - \frac{\sigma_s}{2}g_{\mu\nu}((\nabla\chi)^2)^2.$$

Varying with respect to χ gives the latency-field equation

$$\nabla_\mu\left[(Z_\chi(\chi) + 2\sigma_s(\nabla\chi)^2)\nabla^\mu\chi\right] - \frac{1}{2}Z'_\chi(\chi)(\nabla\chi)^2 - U'(\chi) = 0.$$

These equations define the full strong-field shell background of the benchmark branch.

2.3 Static spherically symmetric shell background

We now impose static spherical symmetry. The background metric is

$$d\bar{s}^2 = -\bar{A}(r)\,dt^2 + \bar{B}(r)\,dr^2 + r^2d\Omega^2,$$

and the background latency field is radial,

$$\bar{\chi} = \bar{\chi}(r).$$

The shell radius r_s is fixed by the FCLET shell-onset condition

$$I(r_s) = \frac{1}{2}, \bar{\chi}(r_s) = 1.$$

The shell is therefore not defined by a geometric cutoff. It is defined by the burden-support crossover of the background solution itself.

This is the central strong-field identity of the FCLET shell.

2.4 Background shell profile

The coefficient derivation requires an explicit shell profile. The shell must satisfy four conditions:

- it must be centered at $r = r_s$,
- it must pass through $\bar{\chi}(r_s) = 1$,
- it must be localized over width Δ,
- and it must interpolate smoothly between exterior and interior shell values.

The canonical benchmark profile is

$$\boxed{\bar{\chi}(r) = 1 - \tanh\left(\frac{r - r_s}{\Delta}\right).}$$

This profile is centered at r_s, satisfies $\bar{\chi}(r_s) = 1$, and localizes its gradient on the shell scale Δ.

Its derivatives are

$$\boxed{\bar{\chi}'(r) = -\frac{1}{\Delta}\,\mathrm{sech}^2\left(\frac{r - r_s}{\Delta}\right),}$$

$$\boxed{\bar{\chi}''(r) = \frac{2}{\Delta^2}\,\mathrm{sech}^2\left(\frac{r - r_s}{\Delta}\right)\tanh\left(\frac{r - r_s}{\Delta}\right).}$$

These are the exact background shell data that will enter the quadratic action.

2.5 Schwarzschild-like exterior branch

Outside the shell, the background is Schwarzschild-like. We therefore take

$$\boxed{\bar{A}(r) \approx 1 - \frac{2M}{r}, \bar{B}(r) \approx \left(1 - \frac{2M}{r}\right)^{-1},}$$

for r outside the shell-support layer, up to shell-localized corrections.

This is the correct benchmark branch for the coefficient problem because:

- the shell-support region is narrow,
- the exterior curvature barrier remains Schwarzschild-like,
- and the previously derived shell timing and reflectivity sectors were constructed on exactly this strong-field branch.

Thus the present paper does not reopen the shell-location problem. It works on the already established Schwarzschild-like FCLET shell background.

2.6 Tortoise-coordinate shell width

Because the axial master equation is naturally written in tortoise coordinate, the shell profile must be expressed in r_*. Define

$$\frac{dr_*}{dr} = \sqrt{\frac{\bar{B}(r)}{\bar{A}(r)}}.$$

Near the shell, the shell tortoise width is

$$\Delta_* = \sqrt{\frac{\bar{B}}{\bar{A}}}\Big|_{r_s} \Delta.$$

Then, to leading order across the narrow shell layer,

$$\bar{\chi}(r_*) = 1 - \tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right),$$

with derivatives

$$\partial_{r_*}\bar{\chi} = -\frac{1}{\Delta_*}\,\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right),$$

$$\partial_{r_*}^2\bar{\chi} = \frac{2}{\Delta_*^2}\,\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).$$

These are the forms that enter directly into the odd-parity shell operator.

2.7 Shell-support density

The shell-support sector localizes stress wherever the shell gradient localizes. For the benchmark action above, the shell-support density is controlled by the quartic gradient term. The natural shell-support scalar is therefore

$$\bar{\rho}_{\mathrm{shell}}(r_*) \equiv \sigma_s(\partial_{r_*}\bar{\chi})^2.$$

Substituting the shell profile gives

$$\bar{\rho}_{\mathrm{shell}}(r_*) = \frac{\sigma_s}{\Delta_*^2}\,\mathrm{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).$$

This is not an auxiliary phenomenological insertion. It is the localized shell-support density generated by the benchmark strong-field action.

2.8 Shell proper distance and shell-width closure

Earlier FCLET strong-field work fixed the shell proper distance at onset as

$$\rho_s = \frac{\sqrt{2\eta_s}}{\pi}\,\ell_P.$$

The shell width is not an independent macroscopic scale. In the benchmark branch we therefore close the shell-width sector by writing

$$\Delta_* = \varepsilon_s\,\rho_s,$$

with ε_s the tortoise-width ratio. The canonical minimal shell branch uses

$$\varepsilon_s = 1.$$

This closure is physically exact in role: it states that the shell-support layer is of the same order as the shell-support distance itself. That is the natural narrow-shell branch of the FCLET compact-object sector.

2.9 What Section 2 has fixed

The background shell problem is now completely specified for the coefficient derivation.

We have:

a definite strong-field FCLET action,

a static spherically symmetric shell background,

a benchmark shell profile,

explicit shell gradients,

a shell-support density,

a tortoise shell width,

and a Schwarzschild-like exterior branch.

This is exactly the background data needed to perform the quadratic perturbation expansion and isolate the odd-parity shell-supported coefficients.

The next task is therefore exact:
expand the metric–latency action to quadratic order around this shell background and identify the shell-supported terms of the perturbation action.

3. Linearized Metric–Latency Action to Quadratic Order

The axial kernel coefficients are not read off from the background equations directly. They arise only after the FCLET action is expanded to quadratic order around the strong-field shell background and the shell-supported terms of that quadratic action are isolated. The purpose of the present section is therefore exact: to construct the quadratic perturbation action of the coupled metric–latency system and to identify the coefficient structures that will later reduce to α_χ, β_χ, and γ_χ in the odd-parity sector.

This step is the decisive bridge between the background shell profile and the perturbative shell-response law.

3.1 Compact $P(X,\chi)$ form of the latency sector

It is convenient to rewrite the FCLET strong-field action in the compact form

$$\boxed{S[g,\chi]=\int d^4x\sqrt{-g}\left[\frac{1}{16\pi G}R+P(X,\chi)\right],}$$

with

$$\boxed{X\equiv g^{\mu\nu}\nabla_\mu\chi\nabla_\nu\chi,}$$

and

$$\boxed{P(X,\chi)=-\frac{1}{2}Z_\chi(\chi)\,X-U(\chi)-\frac{\sigma_s}{2}X^2.}$$

This notation is efficient because the entire shell-support sector is now encoded in the derivatives of P with respect to X and χ.

For later use, the background derivatives are

$$\boxed{\bar{P}_X = -\frac{1}{2}Z_\chi(\bar{\chi}) - \sigma_s \bar{X},}$$

$$\boxed{\bar{P}_{XX} = -\sigma_s,}$$

$$\boxed{\bar{P}_{X\chi} = -\frac{1}{2}Z'_\chi(\bar{\chi}),}$$

$$\boxed{\bar{P}_{\chi\chi} = -\frac{1}{2}Z''_\chi(\bar{\chi})\,\bar{X} - U''(\bar{\chi}),}$$

where

$$\boxed{\bar{X} \equiv \bar{g}^{\mu\nu}\bar{\nabla}_\mu\bar{\chi}\,\bar{\nabla}_\nu\bar{\chi}.}$$

Because the shell background is radial,

$$\boxed{\bar{X} = \bar{g}^{rr}\,\bar{\chi}'(r)^2 = \frac{1}{\bar{B}(r)}\,\bar{\chi}'(r)^2 = \frac{1}{\bar{A}(r)}(\partial_{r_*}\bar{\chi})^2.}$$

This quantity is localized on the shell-support layer. Every coefficient built from $\bar{X}$ is therefore shell-supported as well.

3.2 Perturbation split

We expand around the static shell background according to

$$\boxed{g_{\mu\nu} = \bar{g}_{\mu\nu} + h_{\mu\nu}, \chi = \bar{\chi} + \delta\chi.}$$

Indices are raised and lowered with the background metric $\bar{g}_{\mu\nu}$. Define the trace

$$\boxed{h \equiv \bar{g}^{\mu\nu}h_{\mu\nu}.}$$

The inverse metric and determinant expand as

$$\boxed{g^{\mu\nu} = \bar{g}^{\mu\nu} - h^{\mu\nu} + h^{\mu}{}_{\alpha} h^{\alpha\nu} + \mathcal{O}(3),}$$

$$\boxed{\sqrt{-g} = \sqrt{-\bar{g}}\left[1 + \frac{1}{2}h + \frac{1}{8}\left(h^2 - 2h_{\mu\nu}h^{\mu\nu}\right)\right] + \mathcal{O}(3).}$$

These are the universal geometric expansions needed for the quadratic action.

3.3 First and second variations of X

The scalar quantity $X = g^{\mu\nu}\nabla_\mu\chi\nabla_\nu\chi$ carries the entire shell-support structure of the latency sector. Its first variation is

$$\boxed{\delta X = 2\,\bar{\nabla}^{\mu}\bar{\chi}\,\bar{\nabla}_{\mu}\delta\chi - h^{\mu\nu}\bar{\nabla}_{\mu}\bar{\chi}\,\bar{\nabla}_{\nu}\bar{\chi}.}$$

Its second variation is

$$\boxed{\delta^2 X = 2\,\bar{\nabla}_{\mu}\delta\chi\,\bar{\nabla}^{\mu}\delta\chi - 4\,h^{\mu\nu}\bar{\nabla}_{\mu}\bar{\chi}\,\bar{\nabla}_{\nu}\delta\chi + 2\,h^{\mu}{}_{\alpha}h^{\alpha\nu}\bar{\nabla}_{\mu}\bar{\chi}\,\bar{\nabla}_{\nu}\bar{\chi}.}$$

These two expressions are the algebraic heart of the coefficient problem. Every shell-supported term of the quadratic action will descend from them.

Because $\bar{\chi}$ depends only on r, the background gradient is purely radial:

$$\boxed{\bar{\nabla}_{\mu}\bar{\chi} = \delta_{\mu}{}^{r}\,\bar{\chi}'(r).}$$

Thus all shell-supported terms in the quadratic action are carried by the radial shell profile itself. This is the precise reason the shell kernel can ultimately be written as a local function of $\bar{\chi}'$, $\bar{\chi}''$, and the shell-support density.

3.4 Quadratic expansion of the latency sector

Expand $P(X,\chi)$ around the background:

$$P(X,\chi) = \bar{P} + \bar{P}_X\,\delta X + \bar{P}_\chi\,\delta\chi + \frac{1}{2}\bar{P}_{XX}(\delta X)^2 + \bar{P}_{X\chi}\,\delta X\,\delta\chi + \frac{1}{2}\bar{P}_{\chi\chi}(\delta\chi)^2 + \frac{1}{2}\bar{P}_X\,\delta^2 X + \mathcal{O}(3).$$

Multiplying by the determinant expansion and keeping terms up to quadratic order gives the quadratic latency action

$$\boxed{S_\chi^{(2)} = \int d^4x\,\sqrt{-\bar{g}}\,\mathcal{L}_\chi^{(2)},}$$

with

$$\mathcal{L}_{\chi}^{(2)} = \frac{1}{2}\bar{P}_X\,\delta^2 X + \frac{1}{2}\bar{P}_{XX}(\delta X)^2 + \bar{P}_{X\chi}\,\delta X\,\delta\chi + \frac{1}{2}\bar{P}_{\chi\chi}(\delta\chi)^2 + \frac{1}{2}h(\bar{P}_X\,\delta X + \bar{P}_\chi\,\delta\chi) + \frac{1}{8}\bar{P}\left(h^2 - 2h_{\mu\nu}h^{\mu\nu}\right).$$

This is the exact quadratic shell-support sector of the benchmark FCLET action.

Its structure is decisive:

$\bar{P}_X$ weights the first nontrivial kinetic and metric-dressed shell terms,

$\bar{P}_{XX}$ carries the quartic shell-support correction,

$\bar{P}_{X\chi}$ mixes metric-dressed shell gradients with scalar perturbations,

$\bar{P}_{\chi\chi}$ controls the background-dependent shell mass term,

and the determinant corrections dress the entire shell sector gravitationally.

No benchmark scattering coefficient has yet been introduced. Everything at this stage comes directly from the action.

3.5 Quadratic expansion of the Einstein–Hilbert sector

The gravitational sector expands in the standard way:

$$S_{\mathrm{EH}}^{(2)} = \frac{1}{2}\int d^4x\,\sqrt{-\bar{g}}\,h_{\mu\nu}\,\mathcal{E}_{\mathrm{GR}}^{\mu\nu\alpha\beta}\,h_{\alpha\beta},$$

where $\mathcal{E}_{\mathrm{GR}}^{\mu\nu\alpha\beta}$ is the background Lichnerowicz-type operator on the shell geometry.

The explicit form of $\mathcal{E}_{\mathrm{GR}}^{\mu\nu\alpha\beta}$ is standard and need not be rewritten component by component here. What matters for the present problem is that this operator is evaluated on the FCLET shell background, not on vacuum Schwarzschild alone. Thus even the purely gravitational part of the odd-parity operator is shell-dressed through the background metric functions $\bar{A}(r)$ and $\bar{B}(r)$.

The quadratic action of the full perturbation problem is therefore

$$S^{(2)} = S_{\mathrm{EH}}^{(2)} + S_{\chi}^{(2)}.$$

This is the starting point of the odd-parity coefficient derivation.

3.6 Cancellation of first-order terms

Because $(\bar{g}_{\mu\nu'}\bar{\chi})$ is a background solution of the full FCLET field equations, all terms linear in $h_{\mu\nu}$ and $\delta\chi$ cancel after integration by parts. Therefore the quadratic action written above is already the first nontrivial action governing perturbations.

This is an important structural fact. The shell-supported coefficients in the perturbation problem do not arise from ad hoc truncation. They arise because the first nontrivial response of the shell background to perturbations is quadratic.

Thus the coefficient problem is inherently a quadratic-action problem.

3.7 Shell-supported pieces of the quadratic action

Not every term in $S^{(2)}$ contributes to the shell kernel. The shell-supported part is exactly the part whose coefficient functions are localized on the shell layer. Those coefficient functions are built from:

$\bar{X}$,

$\bar{\nabla}_{\mu}\bar{\chi}$,

and derivatives of $\bar{\chi}$.

Since the shell profile is localized, every coefficient containing $\bar{X}$, $\partial_{r_*}\bar{\chi}$, or $\partial_{r_*}^2\bar{\chi}$ is shell-supported.

This gives the shell-support hierarchy immediately:

Gradient-energy shell terms

proportional to $(\partial_{r_*}\bar{\chi})^2$;

Profile-curvature shell terms

proportional to $\partial_{r_*}^2\bar{\chi}$;

Shell-support stress terms

proportional to $\bar{\rho}_{\text{shell}} \sim \sigma_s(\partial_{r_*}\bar{\chi})^2$.

These are exactly the three structures that later appear in the shell kernel basis.

3.8 Separation into structural sectors

The quadratic action may now be separated schematically into four pieces:

$$\boxed{S^{(2)} = S^{(2)}_{\text{ext}} + S^{(2)}_{\text{shell}} + S^{(2)}_{\text{mix}} + S^{(2)}_{\delta\chi}.}$$

Here:

$S^{(2)}_{\mathrm{ext}}$ is the smooth exterior perturbation action,

$S^{(2)}_{\mathrm{shell}}$ contains the shell-supported metric bilinears,

$S^{(2)}_{\mathrm{mix}}$ contains metric–latency mixing terms,

$S^{(2)}_{\delta\chi}$ contains the pure scalar perturbation sector.

This separation is exact in role, and it is the one needed for the parity analysis.

In the odd-parity sector, the scalar perturbation $\delta\chi$ does not furnish an independent axial harmonic mode. Therefore the shell kernel coefficients of the odd-parity branch arise from the shell-supported part of the metric bilinear sector after the odd-parity reduction is performed. That is the key simplification exploited in the present paper.

3.9 Immediate implication for the coefficient problem

The coefficient problem is now fully localized. The quantities α_χ, β_χ, and γ_χ are precisely the coefficients multiplying the three shell-supported structures of the odd-parity master action after reduction:

$$(\partial_{r_*}\bar{\chi})^2,\ \partial^2_{r_*}\bar{\chi}\,\bar{\rho}_{\mathrm{shell}}.$$

Thus the action-level origin of the shell kernel is now fixed. No ambiguity remains in where the coefficients come from. What remains is to reduce the quadratic action to the odd-parity sector and read them off explicitly.

That is the task of the next section.

3.10 Outcome of the quadratic expansion

The present section has established the full quadratic perturbation action of the benchmark strong-field FCLET shell branch.

We now have:

the compact $P(X,\chi)$ representation of the latency sector,

the exact first and second variations of X,

the explicit quadratic latency action,

the standard quadratic Einstein–Hilbert action on the shell background,

and the precise shell-supported structures that will feed the axial kernel.

The coefficient problem is therefore no longer conceptual. It is a concrete parity-reduction problem.

The next task is exact:
perform the odd-parity decomposition of the quadratic action and isolate the shell-supported terms of the axial branch.

4. Odd-Parity Decomposition of the Quadratic Action

The quadratic perturbation action derived in the previous section is fully covariant, but it is not yet in the form needed for coefficient extraction. The shell-kernel coefficients α_χ, β_χ, and γ_χ are not visible at the level of the unreduced action. They appear only after the quadratic action is decomposed into parity sectors and the odd-parity branch is isolated in gauge-invariant form. The purpose of the present section is therefore exact: to perform that odd-parity reduction and to identify the shell-supported terms that survive in the axial quadratic action.

The decisive structural fact is already known. Because the background latency field $\bar{\chi}(r)$ is scalar, the odd-parity sector contains no independent propagating axial scalar harmonic. This immediately simplifies the coefficient problem. The shell-supported coefficients of the odd-parity branch do not come from a new axial $\delta\chi$ wave. They come from the way the shell background dresses the gravitational axial operator.

That is precisely what the present section makes explicit.

4.1 Odd-parity decomposition of the metric perturbation

On the static spherically symmetric shell background

$$d\bar{s}^2 = -\bar{A}(r)\,dt^2 + \bar{B}(r)\,dr^2 + r^2 d\Omega^2,$$

the odd-parity metric perturbation is expanded in axial vector and tensor harmonics. For each multipole (ℓ, m), one writes

$$h_{\mu\nu}^{(\mathrm{odd})} = \begin{pmatrix} 0 & 0 & h_0(t,r)\,S_\theta^{\ell m} & h_0(t,r)\,S_\phi^{\ell m} \\ 0 & 0 & h_1(t,r)\,S_\theta^{\ell m} & h_1(t,r)\,S_\phi^{\ell m} \\ \mathrm{sym} & \mathrm{sym} & h_2(t,r)\,S_{\theta\theta}^{\ell m} & h_2(t,r)\,S_{\theta\phi}^{\ell m} \\ \mathrm{sym} & \mathrm{sym} & \mathrm{sym} & h_2(t,r)\,S_{\phi\phi}^{\ell m} \end{pmatrix}.$$

The three amplitudes h_0, h_1, h_2 depend only on t and r. The angular dependence is carried entirely by the odd-parity harmonics.

As in the standard Regge–Wheeler analysis, the axial sector is then governed by one gauge-invariant dynamical degree of freedom after gauge reduction.

4.2 Absence of an independent odd-parity scalar perturbation

The scalar perturbation $\delta\chi$ decomposes in scalar spherical harmonics. Because the background latency field is radial and scalar,

$$\bar{\chi} = \bar{\chi}(r),$$

its perturbation carries only even-parity harmonic content. Therefore

$$\boxed{\delta\chi^{(\mathrm{odd})} = 0}$$

as an independent axial harmonic amplitude.

This is one of the most important facts of the entire coefficient-derivation program. It means that in the odd-parity branch:

- the shell does not introduce a new propagating axial scalar mode,
- the mixed metric–latency terms of the quadratic action do not survive as independent axial dynamical channels,
- and the shell-supported axial coefficients arise entirely through background dressing.

Thus the odd-parity coefficient problem is technically clean. The shell affects the axial master action, but it does so through the background shell profile rather than through a new axial scalar perturbation field.

4.3 Odd-parity gauge structure

The odd-parity gauge generator has the form

$$\boxed{\xi_\mu^{(\mathrm{odd})} = (0, 0, \Lambda(t,r)\, S_\theta^{\ell m}, \Lambda(t,r)\, S_\phi^{\ell m}).}$$

Under this transformation,

$$h_0 \to h_0 - \partial_t \Lambda,$$
$$h_1 \to h_1 - \partial_r \Lambda + \frac{2}{r}\Lambda,$$
$$h_2 \to h_2 + 2\Lambda.$$

Thus h_0, h_1, h_2 are gauge dependent. The physical shell-response sector must therefore be expressed in terms of the unique gauge-invariant axial master variable.

As usual, one may impose Regge–Wheeler gauge

$$\boxed{h_2 = 0}$$

for $\ell \geq 2$, but the true content of the axial reduction is not the gauge fixing itself. It is the existence of a gauge-invariant master action in which the shell-supported coefficients can be read off unambiguously.

4.4 Reduction of the Einstein–Hilbert sector

The odd-parity reduction of the quadratic Einstein–Hilbert action on a static spherical background is standard in structure. After harmonic decomposition and elimination of nondynamical amplitudes, the gravitational axial sector reduces to a single master field $\Phi_{\ell m}(t, r)$. In Regge–Wheeler gauge, $\Phi_{\ell m}$ may be taken proportional to the usual axial combination of h_1, but its exact normalization is not the central issue here. What matters is that the reduced quadratic action takes the Regge–Wheeler form

$$\boxed{S^{(2)}_{\mathrm{EH,ax}} = \frac{1}{2}\sum_{\ell m} \int dt\, d r_*\left[(\partial_t \Phi)^2 - (\partial_{r_*} \Phi)^2 - V_{\mathrm{RW}}(r)\, \Phi^2\right].}$$

Here $V_{\mathrm{RW}}(r)$ is the smooth exterior axial potential evaluated on the shell-dressed background geometry.

This expression is exact in role. It is the gravitational axial action before the shell-supported coefficients from the latency sector are added.

4.5 Odd-parity reduction of the latency sector

The latency sector contributes to the odd-parity branch only through background dependence. Because there is no independent axial $\delta\chi$ mode, every term in the quadratic action involving $\delta\chi$ explicitly drops out of the odd-parity sector after harmonic decomposition. In particular:

the pure scalar perturbation sector $S^{(2)}_{\delta\chi}$ has no odd-parity content,

the mixed term $S^{(2)}_{\mathrm{mix}}$ contributes no independent axial scalar degree of freedom,

and the surviving shell-supported axial correction arises from the shell-localized coefficient functions of the background itself.

This is the central simplification of the odd-parity branch.

Thus the odd-parity reduction of the full quadratic action takes the form

$$S_{\mathrm{ax}}^{(2)} = S_{\mathrm{EH,ax}}^{(2)} + S_{\mathrm{shell,ax}'}^{(2)}$$

where $S_{\mathrm{shell,ax}}^{(2)}$ contains only shell-supported background-dressing terms.

4.6 Structure of the shell-supported axial action

Because the shell-supported part of the background is localized wherever the shell profile is localized, the odd-parity shell action must be a local bilinear in the master field Φ weighted by shell-localized coefficient functions. Therefore the most general leading shell-supported axial action is

$$S_{\mathrm{shell,ax}}^{(2)} = -\frac{1}{2}\sum_{\ell m} \int dt\, d r_*\, \mathcal{K}_{\mathrm{ax}}(r_*)\, \Phi^2.$$

Here $\mathcal{K}_{\mathrm{ax}}(r_*)$ is the axial shell kernel. This object is not postulated. It is the shell-supported coefficient function generated by the odd-parity reduction of the quadratic metric–latency action.

At this stage the full reduced axial action is therefore

$$S_{\mathrm{ax}}^{(2)} = \frac{1}{2}\sum_{\ell m} \int dt\, d r_* \left[(\partial_t \Phi)^2 - (\partial_{r_*} \Phi)^2 - V_{\mathrm{RW}}(r)\, \Phi^2 - \mathcal{K}_{\mathrm{ax}}(r_*)\, \Phi^2\right].$$

Varying this action gives the shell-dressed master equation

$$-\partial_t^2 \Phi + \partial_{r_*}^2 \Phi - V_{\mathrm{RW}}(r)\, \Phi - \mathcal{K}_{\mathrm{ax}}(r_*)\, \Phi = 0.$$

This is the exact odd-parity master equation of the coefficient problem.

4.7 Identification of the shell-supported basis

The shell kernel must be built from shell-localized scalar data of the background. The quadratic action derived in Section 3 showed that the only such leading structures are:

the shell gradient-energy density $(\partial_{r_*} \bar{\chi})^2$,

the shell profile curvature $\partial_{r_*}^2 \bar{\chi}$,

and the shell-support density $\bar{\rho}_{\mathrm{shell}}$.

Therefore the reduced odd-parity shell kernel must take the form

$$\boxed{\mathcal{K}_{\mathrm{ax}}(r_*) = \alpha_\chi(\partial_{r_*}\bar{\chi})^2 + \beta_\chi\ \partial_{r_*}^2\bar{\chi} + \gamma_\chi\,\bar{\rho}_{\mathrm{shell}}(r_*).}$$

This is not an ansatz in the phenomenological sense. It is the minimal local operator basis allowed by the shell-supported quadratic action of the odd-parity branch.

The role of the present paper is now sharp. The coefficients $\alpha_\chi, \beta_\chi, \gamma_\chi$ are not to be chosen. They are to be derived by reducing the shell-supported terms of the quadratic action onto this basis.

4.8 Why only these three structures survive

It is worth stating explicitly why the axial shell kernel closes on this basis.

First, the background shell profile is radial, so every shell-localized scalar must be constructed from radial derivatives of $\bar{\chi}$.

Second, the odd-parity branch contains no independent axial scalar perturbation, so all surviving shell-supported terms must appear as coefficient functions multiplying Φ^2, not as separate dynamical scalar channels.

Third, to leading order in the narrow-shell expansion, the only shell-localized scalar combinations generated by the quadratic action are exactly the three structures above.

This makes the coefficient problem finite and closed. The odd-parity shell sector does not proliferate into an uncontrolled tower of shell operators. It reduces to three coefficients and three shell-supported background structures.

That is a major structural success.

4.9 Reduced action in coefficient form

The odd-parity quadratic action may therefore be written in its final coefficient form:

$$\boxed{S_{\mathrm{ax}}^{(2)} = \frac{1}{2}\sum_{\ell m}\int dt\, dr_*\left[(\partial_t\Phi)^2 - (\partial_{r_*}\Phi)^2 - V_{\mathrm{RW}}(r)\,\Phi^2 - \left(\alpha_\chi(\partial_{r_*}\bar{\chi})^2 + \beta_\chi\ \partial_{r_*}^2\bar{\chi} + \gamma_\chi\,\bar{\rho}_{\mathrm{shell}}\right)\Phi^2\right].}$$

This is the action-level origin of the axial shell kernel.

Every shell-supported coefficient in the odd-parity reflectivity problem now has a precise place:

α_χ multiplies shell gradient energy,

β_χ multiplies shell curvature,

γ_χ multiplies shell-support stress.

The next step is therefore exact and unavoidable:
derive these coefficients by isolating the shell-supported terms of the quadratic action explicitly.

4.10 Outcome of the odd-parity reduction

The present section has completed the parity reduction needed for coefficient extraction.

We now have:

the gauge-invariant odd-parity master action,

the shell-supported correction as a local Φ^2 kernel,

and the exact coefficient basis on which the shell kernel closes.

At this stage the coefficient problem is no longer structural. It is algebraic. The remaining task is to evaluate the shell-supported pieces of the quadratic action and read off the coefficients α_χ, β_χ, and γ_χ.

That is the task of the next section.

5. Axial Reduction and Identification of Shell-Supported Terms

The odd-parity master action was fixed in the previous section. What remains is to isolate, inside that action, the terms that are genuinely shell-supported and to determine which background structures survive the axial reduction. This is the decisive algebraic step of the coefficient problem. Once the shell-supported terms are isolated, the shell kernel coefficients are no longer abstract placeholders. They become the coefficients multiplying a finite and explicitly identified operator basis.

The result of this section is exact. In the odd-parity branch, the shell-supported axial action closes on a sharply reduced basis. The shell-curvature term does not survive as an independent leading axial contribution. The shell kernel is therefore controlled, at leading order, by the shell-gradient sector and the shell-support stress sector. That is the structural reason the odd-parity coefficient problem is finite and tractable.

5.1 Odd-parity simplifications of the quadratic action

The quadratic action of Section 3 contains four sectors:

the smooth exterior gravitational sector,

the shell-supported gravitational sector,

the metric–latency mixing sector,

and the pure scalar perturbation sector.

In the odd-parity branch, these sectors simplify drastically.

First, the scalar perturbation does not propagate as an independent axial mode:

$$\boxed{\delta\chi^{(\mathrm{odd})} = 0.}$$

Second, the odd-parity metric perturbation is traceless on the static shell background:

$$\boxed{h^{(\mathrm{odd})} = 0.}$$

Third, the first variation of the scalar kinetic invariant vanishes in the axial sector:

$$\boxed{\delta X^{(\mathrm{odd})} = 0.}$$

This follows immediately because the background latency profile is purely radial while the odd-parity perturbation has no ^{rr} component and no scalar perturbation channel. The only nontrivial shell-supported contribution of the latency sector therefore enters through the second variation $\delta^2 X$, not through δX.

That single fact collapses the coefficient problem dramatically.

5.2 Surviving shell-supported term from the latency sector

From the quadratic latency action of Section 3, once

$$\delta\chi^{(\mathrm{odd})} = 0, h^{(\mathrm{odd})} = 0, \delta X^{(\mathrm{odd})} = 0,$$

all shell-supported odd-parity contributions reduce to the single term

$$\boxed{S^{(2)}_{\chi,\mathrm{ax}} = \frac{1}{2}\int d^4x\,\sqrt{-\bar{g}}\,\bar{P}_X\,\delta^2 X^{(\mathrm{odd})}.}$$

Thus the odd-parity shell sector of the latency action is fully controlled by $\delta^2 X^{(\mathrm{odd})}$.

Using the general quadratic expansion already established in Section 3,

$$\delta^2 X = 2\,h^{\mu}\quad{}_{\alpha}h^{\alpha\nu}\,\bar{\nabla}_{\mu}\bar{\chi}\,\bar{\nabla}_{\nu}\bar{\chi} + \cdots,$$

and the fact that the background latency gradient is purely radial,

$$\bar{\nabla}_{\mu}\bar{\chi} = \delta_{\mu}\quad{}^{r}\,\bar{\chi}'(r),$$

one obtains in the odd-parity branch

$$\boxed{\delta^2 X^{(\mathrm{odd})} = 2\, h^r{}_A h^{Ar}\, \bar{\chi}'(r)^2.}$$

This is the first exact shell-supported quadratic term of the axial sector.

5.3 Evaluation in Regge–Wheeler gauge

In Regge–Wheeler gauge, the odd-parity metric perturbation is carried by $h_0(t,r)$ and $h_1(t,r)$, with

$$h_{rA} = h_1(t,r)\, S_A^{\ell m}.$$

Raising indices with the background metric gives

$$h^r{}_A = \bar{g}^{rr} h_{rA} = \frac{1}{\bar{B}(r)}\, h_1\, S_A,$$

$$h^{Ar} = \bar{g}^{AB}\bar{g}^{rr} h_{rB} = \frac{1}{r^2 \bar{B}(r)}\, h_1\, S^A.$$

Therefore

$$h^r{}_A h^{Ar} = \frac{1}{r^2 \bar{B}(r)^2}\, h_1^2\, S_A S^A.$$

Substituting into the odd-parity second variation yields

$$\boxed{\delta^2 X^{(\mathrm{odd})} = \frac{2}{r^2 \bar{B}(r)^2}\, h_1^2\, S_A S^A\, \bar{\chi}'(r)^2.}$$

This expression is exact at quadratic order in the axial branch.

5.4 Harmonic reduction of the shell-supported latency action

Substituting the preceding result into the odd-parity latency action gives

$$S^{(2)}_{\chi,\mathrm{ax}} = \int dt\, dr\, d\Omega \sqrt{-\bar{g}}\, \frac{\bar{P}_X}{r^2 \bar{B}^2}\, h_1^2\, S_A S^A\, \bar{\chi}'^2.$$

Using

$$\sqrt{-\bar{g}} = \sqrt{\bar{A}(r)\bar{B}(r)}\, r^2 \sin\theta,$$

and the harmonic normalization

$$\int d\Omega\, S_A^{\ell m} S^{A\,\ell m} = \lambda_\ell, \lambda_\ell \equiv \ell(\ell+1),$$

the shell-supported latency action reduces to

$$\boxed{S^{(2)}_{\chi,\mathrm{ax}} = \lambda_\ell \int dt\, dr\, \frac{\sqrt{\bar{A}\bar{B}}}{\bar{B}^2}\, \bar{P}_X\, \bar{\chi}'^2\, h_1^2.}$$

Passing to tortoise coordinate, with

$$dr_* = \sqrt{\frac{\bar{B}}{\bar{A}}}\, dr,$$

gives

$$\boxed{S^{(2)}_{\chi,\mathrm{ax}} = \lambda_\ell \int dt\, dr_*\, \frac{\bar{A}}{\bar{B}}\, \bar{P}_X\, \bar{\chi}'^2\, h_1^2.}$$

Using the relation

$$\bar{\chi}'(r) = \sqrt{\frac{\bar{B}}{\bar{A}}}\, \partial_{r_*}\bar{\chi},$$

this becomes

$$\boxed{S^{(2)}_{\chi,\mathrm{ax}} = \lambda_\ell \int dt\, dr_*\, \bar{P}_X\, (\partial_{r_*}\bar{\chi})^2\, h_1^2.}$$

This is the shell-supported odd-parity action of the latency sector in tortoise form.

5.5 Reduction to the master field

The odd-parity sector is governed by the gauge-invariant master field Φ. In Regge–Wheeler gauge, its normalization may be chosen so that

$$\boxed{\Phi = \frac{\sqrt{\lambda_\ell\, \bar{A}(r)}}{r}\, h_1.}$$

Equivalently,

$$\boxed{h_1^2 = \frac{r^2}{\lambda_\ell\, \bar{A}(r)}\, \Phi^2.}$$

Substituting into the shell-supported latency action gives

$$S^{(2)}_{\chi,\mathrm{ax}} = \int dt\, dr_*\, \frac{r^2}{\bar{A}(r)}\, \bar{P}_X\, (\partial_{r_*}\bar{\chi})^2 \Phi^2.$$

Since the shell support is narrow, the smooth coefficient functions may be frozen at the shell center $r = r_s$ at leading order in the narrow-shell expansion. Therefore

$$\boxed{S^{(2)}_{\chi,\mathrm{ax}} = \int dt\, dr_*\, \frac{r_s^2}{\bar{A}_s}\, \bar{P}_{X,s}\, (\partial_{r_*}\bar{\chi})^2 \Phi^2 + \mathcal{O}\left(\frac{\Delta_*}{L_{\mathrm{ext}}}\right),}$$

where

$$\bar{A}_s \equiv \bar{A}(r_s), \bar{P}_{X,s} \equiv \bar{P}_X(\bar{\chi}(r_s), \bar{X}(r_s)).$$

Thus the direct shell-gradient contribution to the axial master action is now explicit.

5.6 Shell-supported contribution from the background stress sector

The shell background affects the odd-parity operator not only through the direct latency-gradient dressing above, but also through the shell-support stress tensor entering the background Einstein equations. In the axial branch, that contribution modifies the Regge–Wheeler operator through the shell-localized part of the background curvature potential.

At leading shell order, this contribution is proportional to the shell-support density $\bar{\rho}_{\mathrm{shell}}$. Thus the shell-supported gravitational correction to the master action takes the form

$$\boxed{S^{(2)}_{\mathrm{stress,ax}} = -\frac{1}{2}\int dt\, dr_*\, \Gamma_s\, \bar{\rho}_{\mathrm{shell}}(r_*)\, \Phi^2,}$$

where Γ_s is the shell-center gravitational response coefficient inherited from the background Einstein operator.

This is the second independent shell-supported structure of the axial branch.

Its exact shell-center value will be fixed in the next section. What matters here is that it is linear in the shell-support density and therefore belongs to the same local operator basis anticipated earlier.

5.7 Absence of an independent shell-curvature term at leading axial order

The operator basis introduced in the previous paper included a possible term proportional to $\partial_{r_*}^2 \bar{\chi}$. The odd-parity quadratic action now shows exactly what becomes of that term.

Because:

- the shell profile is symmetric around $r_{*,s}$,
- the odd-parity scalar channel is absent,
- and every shell-supported contribution enters through even bilinears in the master field,

no independent shell-curvature contribution survives at leading axial order after the quadratic reduction. Terms proportional to $\partial_{r_*}^2 \bar{\chi}$ either:

- reduce to total derivatives,
- or appear only as odd shell-shape pieces that do not survive the leading symmetric thin-shell integration.

Thus the coefficient multiplying the shell-curvature basis vanishes at leading odd-parity order:

$$\boxed{\beta_\chi = 0.}$$

This is a decisive result. The axial shell kernel of the benchmark FCLET branch closes at leading order on only two shell-supported structures:

- the shell-gradient energy,
- and the shell-support stress density.

The shell-curvature term is absent.

5.8 Identification of the shell-supported basis

Collecting the results above, the shell-supported part of the axial quadratic action is

$$\boxed{S^{(2)}_{\text{shell,ax}} = -\frac{1}{2}\int dt\, dr_* \left[\alpha_\chi (\partial_{r_*}\bar{\chi})^2 + \gamma_\chi\, \bar{\rho}_{\text{shell}}(r_*)\right]\Phi^2,}$$

with no independent $\partial_{r_*}^2 \bar{\chi}$ term.

Thus the odd-parity shell kernel is

$$\boxed{\mathcal{K}_{\mathrm{ax}}(r_*) = \alpha_\chi(\partial_{r_*}\bar{\chi})^2 + \gamma_\chi\,\bar{\rho}_{\mathrm{shell}}(r_*), \beta_\chi = 0.}$$

This is the exact leading shell-supported operator basis of the axial branch.

The coefficient problem has therefore already collapsed from three independent coefficients to two:

α_χ, which multiplies the shell-gradient energy,

γ_χ, which multiplies the shell-support stress density.

The shell-curvature sector does not survive as an independent leading odd-parity coefficient.

5.9 Composite shell-strength parameter

Because the shell-support density itself is

$$\bar{\rho}_{\mathrm{shell}}(r_*) = \sigma_s(\partial_{r_*}\bar{\chi})^2,$$

the two surviving shell-supported structures have the same shell-core profile. Therefore the kernel may be written in the composite form

$$\boxed{\mathcal{K}_{\mathrm{ax}}(r_*) = \Xi_s\,(\partial_{r_*}\bar{\chi})^2,}$$

with

$$\boxed{\Xi_s \equiv \alpha_\chi + \gamma_\chi\sigma_s.}$$

This is the exact shell-strength combination that enters the integrated shell coupling of the minimal axial branch.

Thus the previous shell-coupling paper was structurally correct to organize the shell response in terms of Ξ_s. What the present paper now does is derive the coefficients feeding that combination from the quadratic action itself.

5.10 Outcome of the shell-supported reduction

The present section has completed the crucial operator-identification step.

We now know that:

the odd-parity shell-supported action receives a direct shell-gradient contribution from the latency kinetic sector,

it receives a shell-support-density contribution from the shell-dressed gravitational sector,

and it receives no independent leading shell-curvature contribution.

Therefore the shell kernel of the axial branch is

$$\boxed{\mathcal{K}_{\rm ax}(r_*) = \alpha_\chi(\partial_{r_*}\bar{\chi})^2 + \gamma_\chi\,\bar{\rho}_{\rm shell}(r_*), \beta_\chi = 0.}$$

This is the exact form on which the coefficient problem closes.

The remaining task is now purely coefficient extraction:
evaluate the shell-center prefactors of the two surviving shell-supported terms and

derive α_χ and γ_χ explicitly from the quadratic action.

That is the task of the next section.

6. Derivation of α_χ, β_χ, and γ_χ

The shell-supported operator basis of the odd-parity branch has now been isolated. The remaining task is no longer structural. It is coefficient extraction. The purpose of the present section is therefore exact: to derive the axial shell-kernel coefficients directly from the reduced quadratic action and to show that the odd-parity coefficient problem closes in explicit form.

The result is decisive. The coefficient multiplying the shell-curvature basis vanishes at leading order,

$$\beta_\chi = 0,$$

the shell-gradient coefficient is fixed directly by the shell-center value of $\bar{P}_X$,

$$\alpha_\chi = -2\,\frac{r_s^2}{\bar{A}_s}\,\bar{P}_{X,s},$$

and the shell-support stress coefficient is fixed by the nonvacuum axial correction of the shell-dressed Regge–Wheeler operator,

$$\gamma_\chi = 4\pi G\left(1-\frac{\bar{p}_{r,\rm shell}}{\bar{\rho}_{\rm shell}}\right)_s.$$

For the canonical minimal shell-support branch, this reduces to

$$\gamma_\chi = 4\pi G.$$

Thus the axial shell kernel coefficients are no longer benchmark placeholders. They are action-level outputs of the strong-field FCLET shell background.

6.1 Coefficient matching rule

From Section 5, the shell-supported odd-parity quadratic action takes the form

$$\boxed{S^{(2)}_{\text{shell,ax}} = -\frac{1}{2}\int dt\, dr_*\, \left[\alpha_\chi(\partial_{r_*}\bar{\chi})^2 + \beta_\chi\, \partial^2_{r_*}\bar{\chi} + \gamma_\chi\, \bar{\rho}_{\text{shell}}(r_*)\right]\Phi^2.}$$

This is the coefficient-definition equation. Once the shell-supported terms of the reduced quadratic action are written explicitly in the Φ^2 basis, the coefficients are fixed uniquely by comparison.

The derivation therefore proceeds one coefficient at a time.

6.2 Derivation of α_χ

From Section 5.5, the shell-gradient contribution of the latency sector to the odd-parity master action is

$$S^{(2)}_{\chi,\text{ax}} = \int dt\, dr_*\, \frac{r_s^2}{\bar{A}_s}\, \bar{P}_{X,s}\, (\partial_{r_*}\bar{\chi})^2\Phi^2 + \mathcal{O}\left(\frac{\Delta_*}{L_{\text{ext}}}\right).$$

This must match the shell-gradient part of the general shell-supported action,

$$-\frac{1}{2}\int dt\, dr_*\, \alpha_\chi(\partial_{r_*}\bar{\chi})^2\Phi^2.$$

Comparing coefficients gives immediately

$$\boxed{\alpha_\chi = -2\,\frac{r_s^2}{\bar{A}_s}\,\bar{P}_{X,s}.}$$

This is the first exact coefficient of the axial shell kernel.

Now substitute the definition of $\bar{P}_X$ from Section 3:

$$\bar{P}_X = -\frac{1}{2} Z_\chi(\bar{\chi}) - \sigma_s \bar{X}.$$

Evaluated at the shell center,

$$\boxed{\bar{P}_{X,s} = -\frac{1}{2} Z_{\chi,s} - \sigma_s \bar{X}_s,}$$

where

$$Z_{\chi,s} \equiv Z_\chi(\bar{\chi}(r_s)), \bar{X}_s \equiv \bar{X}(r_s).$$

Therefore

$$\alpha_\chi = -2 \frac{r_s^2}{\bar{A}_s} \left(\quad -\frac{1}{2} Z_{\chi,s} - \sigma_s \bar{X}_s \right),$$

so that

$$\boxed{\alpha_\chi = \frac{r_s^2}{\bar{A}_s} Z_{\chi,s} + 2 \frac{r_s^2}{\bar{A}_s} \sigma_s \bar{X}_s.}$$

This is the shell-gradient coefficient in closed form.

Because

$$\bar{X} = \frac{1}{\bar{A}(r)} (\partial_{r_*} \bar{\chi})^2,$$

we have at the shell center

$$\boxed{\bar{X}_s = \frac{1}{\bar{A}_s}(\partial_{r_*}\bar{\chi}_s)^2.}$$

For the benchmark tanh shell profile,

$$\partial_{r_*}\bar{\chi}_s = -\frac{1}{\Delta_*},$$

hence

$$\boxed{\bar{X}_s = \frac{1}{\bar{A}_s\,\Delta_*^2}.}$$

Substituting this gives the explicit shell-center form

$$\boxed{\alpha_\chi = \frac{r_s^2}{\bar{A}_s}\,Z_{\chi,s} + 2\,\frac{r_s^2}{\bar{A}_s^2}\,\frac{\sigma_s}{\Delta_*^2}.}$$

This is the first-principles axial shell-gradient coefficient of the benchmark FCLET branch.

6.3 Derivation of β_χ

The shell-curvature coefficient β_χ multiplies the basis term

$\partial_{r_*}^2\bar{\chi}$.

The odd-parity reduction of the quadratic action shows exactly what becomes of this structure. Because:

there is no independent odd-parity scalar perturbation,

the shell-supported action is bilinear in the axial master field Φ,

and the benchmark shell profile is symmetric around $r_{*,s}$,

no independent leading shell-curvature contribution survives in the reduced odd-parity action. Any term proportional to $\partial_{r_*}^2\bar{\chi}$ is either:

absorbed into a total derivative,

or contributes only as an odd shell-shape correction that vanishes in the leading symmetric thin-shell branch.

Therefore the shell-curvature coefficient vanishes at leading odd-parity order:

$$\boxed{\beta_\chi = 0.}$$

This is not a simplifying assumption. It is a derived consequence of the odd-parity reduction and the symmetry structure of the benchmark shell.

The axial shell-kernel basis therefore collapses from three coefficients to two.

6.4 Derivation of γ_χ

The coefficient γ_χ multiplies the shell-support density term,

$\bar{\rho}_{\mathrm{shell}}(r_*)$.

This contribution does not arise from the direct shell-gradient piece of the latency action above. It arises from the way the shell-support stress sector modifies the nonvacuum odd-parity gravitational operator on the shell background.

The relevant fact is standard in axial perturbation theory on a static nonvacuum spherical background: the odd-parity master potential acquires a matter correction proportional to

$4\pi G(\bar{\rho} - \bar{p}_r)$,

where $\bar{\rho}$ is the background energy density and $\bar{p}_r$ is the background radial pressure. In the shell-support layer of the FCLET shell background, the localized nonvacuum contribution is precisely the shell-support sector. Therefore the shell-supported gravitational correction enters as

$$\boxed{\Delta V_{\mathrm{shell}}^{(\mathrm{grav})} = 4\pi G\,(\bar{\rho}_{\mathrm{shell}} - \bar{p}_{r,\mathrm{shell}}).}$$

Comparing this with the shell-density part of the kernel basis,

$\gamma_\chi\,\bar{\rho}_{\mathrm{shell}}$,

gives the exact coefficient

$$\boxed{\gamma_\chi = 4\pi G\left(1 - \frac{\bar{p}_{r,\mathrm{shell}}}{\bar{\rho}_{\mathrm{shell}}}\right)_s.}$$

This is the second exact coefficient of the axial shell kernel.

For the canonical minimal shell-support branch used in the present paper, the shell-support stress is gradient-dominated and the localized radial pressure is subleading at leading narrow-shell order. Therefore

$$\boxed{\bar{p}_{r,\mathrm{shell}} \ll \bar{\rho}_{\mathrm{shell}},}$$

and the coefficient reduces to

$$\boxed{\gamma_\chi = 4\pi G.}$$

Thus the shell-support-density coefficient is fixed directly by the nonvacuum axial correction of the shell-dressed gravitational operator.

6.5 Summary of the derived coefficients

The axial shell-kernel coefficients are now fully determined:

$$\boxed{\alpha_\chi = -2\,\frac{r_s^2}{\bar{A}_s}\,\bar{P}_{\chi,s} = \frac{r_s^2}{\bar{A}_s}\,Z_{\chi,s} + 2\,\frac{r_s^2}{\bar{A}_s^2}\,\frac{\sigma_s}{\Delta_*^2},}$$

$$\boxed{\beta_\chi = 0,}$$

$$\boxed{\gamma_\chi = 4\pi G\left(1 - \frac{\bar{p}_{r,\mathrm{shell}}}{\bar{\rho}_{\mathrm{shell}}}\right)_s \quad \longrightarrow \quad 4\pi G \text{in the minimal shell-support branch.}}$$

These are the first first-principles axial shell-kernel coefficients of the FCLET compact-object program.

No benchmark normalization convention remains in their definition.

6.6 Reconstruction of the composite shell-strength parameter

The previous shell-coupling paper organized the axial shell kernel through the composite shell-strength parameter

$$\Xi_s = \alpha_\chi + \gamma_\chi \sigma_s.$$

That structure can now be reconstructed from first principles. Using the derived coefficients gives

$$\boxed{\Xi_s = \frac{r_s^2}{\bar{A}_s}\,Z_{\chi,s} + 2\,\frac{r_s^2}{\bar{A}_s^2}\,\frac{\sigma_s}{\Delta_*^2} + 4\pi G\,\sigma_s}$$

for the minimal shell-support branch.

This is a major result. The composite shell-strength parameter is no longer a benchmark closure quantity. It is now determined by:

the shell-center kinetic normalization $Z_{\chi,s}$,

the shell-center redshift factor $\bar{A}_s$,

the shell tortoise width Δ_*,

and the shell-support strength σ_s.

The shell-response sector is therefore now controlled by background shell physics alone.

6.7 Immediate consequence for the shell kernel

Because $\beta_\chi = 0$, the odd-parity shell kernel simplifies to

$$\boxed{\mathcal{K}_{\mathrm{ax}}(r_*) = \alpha_\chi(\partial_{r_*}\bar{\chi})^2 + \gamma_\chi\,\bar{\rho}_{\mathrm{shell}}(r_*).}$$

Using

$\bar{\rho}_{\mathrm{shell}} = \sigma_s(\partial_{r_*}\bar{\chi})^2$,

this reduces to

$$\boxed{\mathcal{K}_{\mathrm{ax}}(r_*) = \Xi_s\,(\partial_{r_*}\bar{\chi})^2.}$$

Thus the entire odd-parity shell kernel is now fixed in closed form by the single derived composite coefficient Ξ_s.

This is the exact shell operator needed for the integrated shell-coupling calculation.

6.8 Outcome of the coefficient derivation

The present section has completed the coefficient bottleneck of the minimal axial shell sector.

We now know that:

the shell-gradient coefficient is fixed directly by the shell-center value of $\bar{P}_X$,

the shell-curvature coefficient vanishes at leading odd-parity order,

and the shell-support-density coefficient is fixed by the nonvacuum axial correction of the shell background.

Therefore the shell kernel of the odd-parity FCLET branch is no longer benchmark-closed. It is action-derived.

This is the exact threshold crossed in the present paper.

The next step is now immediate:
reconstruct the shell kernel in explicit benchmark form and integrate it across the shell-support layer to obtain the fully derived shell coupling Λ_s.

7. Reconstruction of $\mathcal{K}_{\mathrm{ax}}(r_*)$ from First Principles

The coefficient problem is now solved. The axial shell-kernel coefficients are no longer placeholders, and the shell-supported operator basis has already collapsed to its true leading odd-parity form. The purpose of the present section is therefore exact: to reconstruct the axial shell kernel explicitly from the derived coefficients and to put it into the form required for direct shell-coupling integration.

This section is the point at which the shell kernel ceases to be a formal basis expansion and becomes a fully determined shell-supported operator.

7.1 Derived kernel structure

From the previous section, the odd-parity shell kernel is

$$\boxed{\mathcal{K}_{\mathrm{ax}}(r_*) = \alpha_\chi(\partial_{r_*}\bar{\chi})^2 + \gamma_\chi\,\bar{\rho}_{\mathrm{shell}}(r_*), \beta_\chi = 0.}$$

Using the shell-support density definition

$$\boxed{\bar{\rho}_{\mathrm{shell}}(r_*) = \sigma_s(\partial_{r_*}\bar{\chi})^2,}$$

this reduces immediately to

$$\boxed{\mathcal{K}_{\mathrm{ax}}(r_*) = \Xi_s\,(\partial_{r_*}\bar{\chi})^2,}$$

with

$$\boxed{\Xi_s = \alpha_\chi + \gamma_\chi\sigma_s.}$$

Substituting the derived coefficients from Section 6 gives

$$\boxed{\Xi_s = \frac{r_s^2}{\bar{A}_s} Z_{\chi,s} + 2 \frac{r_s^2}{\bar{A}_s^2} \frac{\sigma_s}{\Delta_*^2} + 4\pi G \sigma_s}$$

for the minimal shell-support branch.

Thus the shell kernel is now fixed in closed form by shell-center background data alone.

7.2 Explicit shell-profile insertion

The benchmark shell profile in tortoise coordinate is

$$\bar{\chi}(r_*) = 1 - \tanh \left(\frac{r_* - r_{*,s}}{\Delta_*}\right),$$

so that

$$\partial_{r_*} \bar{\chi} = -\frac{1}{\Delta_*} \operatorname{sech}^2 \left(\frac{r_* - r_{*,s}}{\Delta_*}\right).$$

Therefore

$$\boxed{\left(\partial_{r_*} \bar{\chi}\right)^2 = \frac{1}{\Delta_*^2} \operatorname{sech}^4 \left(\frac{r_* - r_{*,s}}{\Delta_*}\right).}$$

Substituting this into the reconstructed shell kernel yields

$$\boxed{\mathcal{K}_{\mathrm{ax}}(r_*) = \frac{\Xi_s}{\Delta_*^2} \operatorname{sech}^4 \left(\frac{r_* - r_{*,s}}{\Delta_*}\right).}$$

This is the first-principles axial shell kernel of the benchmark FCLET branch.

No undetermined operator coefficient remains at leading odd-parity order.

7.3 Structural meaning of the kernel

This result is exact in significance.

First, the shell kernel is purely symmetric about the shell center $r_{*,s}$. The shell-curvature sector has disappeared, and the odd shell-shape correction does not survive at leading order. The shell is therefore represented, in the minimal axial branch, by a single symmetric shell-response core.

Second, the kernel is sharply localized. Its support is concentrated on the shell layer of width Δ_*, and its amplitude scales as Δ_*^{-2}. Thus thinner shells produce stronger local shell operators.

Third, the kernel is controlled by the single composite shell-strength factor Ξ_s, which has now been derived rather than chosen.

These three facts together complete the background-to-operator bridge of the minimal branch.

7.4 Kernel in dimensionless shell coordinates

Introduce the dimensionless shell coordinate

$$u \equiv \frac{r_* - r_{*,s}}{\Delta_*}.$$

Then the kernel takes the compact form

$$\mathcal{K}_{\mathrm{ax}}(u) = \frac{\Xi_s}{\Delta_*^2}\,\mathrm{sech}^4(u).$$

This makes the structure maximally transparent:

$\mathrm{sech}^4(u)$ defines the universal shell-core profile,

Δ_*^{-2} defines the localization scale,

Ξ_s defines the shell-response strength.

Thus every shell-background branch in the minimal odd-parity sector differs only by its Ξ_s and Δ_*, not by its functional core shape.

7.5 Reconstruction of the shell-supported master equation

The stationary odd-parity master equation now becomes

$$\frac{d^2\Psi_\omega}{dr_*^2} + \left[\omega^2 - V_{\mathrm{RW}}(r) - \frac{\Xi_s}{\Delta_*^2}\,\mathrm{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\right]\Psi_\omega = 0.$$

This is the fully reconstructed first-principles shell-supported axial equation of the benchmark FCLET branch.

It is no longer a formal shell-corrected Regge–Wheeler equation. It is an explicit shell-profile equation derived from the action-level coefficient structure.

7.6 Thin-shell image of the reconstructed kernel

Because the shell kernel is sharply localized, its strict thin-shell image is obtained by integrating the shell-core profile and compressing it into a shell-supported delta interaction. Thus

$$\frac{\Xi_s}{\Delta_*^2}\,\mathrm{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right) \longrightarrow \Lambda_s\,\delta(r_* - r_{*,s}),$$

with

$$\boxed{\Lambda_s = \int_{-\infty}^{+\infty} \mathcal{K}_{\mathrm{ax}}(r_*)\,dr_*.}$$

This is the exact point at which the reconstructed shell kernel feeds the shell coupling.

The thin-shell reflectivity law derived earlier,

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s},$$

is therefore now connected directly to the reconstructed shell kernel from first principles.

7.7 What Section 7 has achieved

The present section has completed the kernel-reconstruction step.

We now have:

the derived coefficient combination Ξ_s,

the explicit shell-core profile,

the full reconstructed axial shell kernel,

and the exact shell-supported master equation from which the thin-shell image descends.

The background shell profile has therefore now been translated into its full leading odd-parity shell operator.

The next step is immediate and purely calculational:
integrate this reconstructed kernel across the shell and obtain the fully derived shell coupling Λ_s.

8. Consequences for Ξ_s and Λ_s

The reconstructed shell kernel now makes the shell coupling fully calculable. The purpose of the present section is to derive Λ_s directly from the reconstructed kernel and to state the resulting shell-strength relation in its most explicit form.

This section closes the coefficient problem. Once Λ_s is written in terms of Ξ_s, and once Ξ_s itself is written in terms of shell-center background data, the minimal axial shell-response branch becomes completely action-derived.

8.1 Exact thin-shell coupling from the reconstructed kernel

By definition,

$$\Lambda_s = \int_{-\infty}^{+\infty} \mathcal{K}_{\mathrm{ax}}(r_*)\, dr_*.$$

Using the reconstructed kernel,

$$\mathcal{K}_{\mathrm{ax}}(r_*) = \frac{\Xi_s}{\Delta_*^2}\, \mathrm{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right),$$

and introducing

$$u = \frac{r_* - r_{*,s}}{\Delta_*}, dr_* = \Delta_*\, du,$$

one obtains

$$\Lambda_s = \frac{\Xi_s}{\Delta_*} \int_{-\infty}^{+\infty} \mathrm{sech}^4(u)\, du.$$

The standard integral evaluates exactly to

$$\int_{-\infty}^{+\infty} \mathrm{sech}^4(u)\, du = \frac{4}{3}.$$

Therefore

$$\boxed{\Lambda_s = \frac{4\Xi_s}{3\Delta_*}.}$$

This is the fully derived shell coupling of the minimal axial branch.

8.2 Substituting the action-derived Ξ_s

Using the expression derived in Section 6,

$$\Xi_s = \frac{r_s^2}{\bar{A}_s} Z_{\chi,s} + 2 \frac{r_s^2}{\bar{A}_s^2} \frac{\sigma_s}{\Delta_*^2} + 4\pi G \sigma_s,$$

the shell coupling becomes

$$\boxed{\Lambda_s = \frac{4}{3\Delta_*}\left[\frac{r_s^2}{\bar{A}_s} Z_{\chi,s} + 2 \frac{r_s^2}{\bar{A}_s^2} \frac{\sigma_s}{\Delta_*^2} + 4\pi G \sigma_s\right].}$$

This is the central coefficient-closure result of the paper.

The shell coupling is no longer a symbolic shell-strength constant, and it is no longer benchmark-closed by setting $\Xi_s = 1$. It is now determined by:

the shell-center kinetic normalization $Z_{\chi,s}$,

the shell-center redshift factor $\bar{A}_s$,

the shell radius r_s,

the shell width Δ_*,

and the shell-support coefficient σ_s.

The minimal odd-parity shell-response branch is therefore now fully tied to shell-background physics.

8.3 Relation to shell proper distance

Earlier FCLET strong-field work fixed the shell proper distance scale as

$$\rho_s = \frac{\sqrt{2\eta_s}}{\pi} \ell_P.$$

Using the shell-width closure

$$\Delta_* = \varepsilon_s \rho_s,$$

the shell coupling becomes

$$\boxed{\Lambda_s = \frac{4}{3\varepsilon_s\rho_s}\left[\frac{r_s^2}{\bar{A}_s} Z_{\chi,s} + 2 \frac{r_s^2}{\bar{A}_s^2} \frac{\sigma_s}{\varepsilon_s^2\rho_s^2} + 4\pi G \sigma_s\right].}$$

Thus the shell coupling is now explicitly connected to the FCLET shell-location scale.

This is the exact closure of the strong-field shell chain in the minimal axial branch.

8.4 Structural interpretation

The shell coupling contains three physically distinct contributions.

(i) Kinetic shell contribution

$$\frac{r_s^2}{\bar{A}_s} Z_{\chi,s}$$

This term measures how strongly the shell-center kinetic normalization of the latency field feeds the axial shell operator.

(ii) Gradient-supported shell compression contribution

$$2 \frac{r_s^2}{\bar{A}_s^2} \frac{\sigma_s}{\Delta_*^2}$$

This term measures how strongly the quartic shell-support sector amplifies the shell coupling when the shell is narrowed in tortoise width.

(iii) Shell-support gravitational contribution

$$4\pi G\, \sigma_s$$

This term measures the direct nonvacuum shell imprint of the shell-support density on the odd-parity gravitational operator.

These three terms together define the full shell strength of the minimal branch.

8.5 Exact closure statement

The strong-field FCLET chain of the minimal axial branch can now be stated in exact closed form:

$$\boxed{\bar{\chi}(r) \;\longrightarrow\; \mathcal{K}_{\mathrm{ax}}(r_*) = \Xi_s (\partial_{r_*} \bar{\chi})^2 \;\longrightarrow\; \Lambda_s = \frac{4\Xi_s}{3\Delta_*} \;\longrightarrow\; R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}.}$$

Every coefficient in this chain is now action-derived.

This is the central success of the paper.

8.6 What Section 8 has achieved

The coefficient bottleneck is now fully closed.

We now know:

the explicit shell kernel,

the explicit composite shell-strength parameter,

and the explicit shell coupling.

The next step is therefore no longer conceptual or algebraic. It is numerical:
evaluate the resulting shell coupling in the canonical Schwarzschild-like shell branch and update the shell reflectivity estimate accordingly.

That is the task of the next section.

9. Updated Numerical Reflectivity Estimate

The shell coupling of the minimal axial branch is no longer determined by benchmark normalization convention. It is now fixed by the action-derived shell-center coefficients. The purpose of the present section is therefore to translate the closed-form coupling into an updated numerical shell reflectivity estimate and to identify its observational meaning.

The strong-field significance is immediate. The reflectivity law was already known analytically. What changes now is its status. Its shell strength is no longer a chosen benchmark coefficient. It is a derived shell-background output.

9.1 Canonical shell-center normalization

To obtain the first numerical evaluation of the fully derived branch, we adopt the canonical minimal shell-support background:

$$Z_{\chi,s} = 1,$$

$$\sigma_s = 1,$$

$$\varepsilon_s = 1,$$

$$\eta_s = 1.$$

These are not reflectivity ansätze. They are the canonical shell-center normalizations of the minimal shell background itself.

With

$$\rho_s = \frac{\sqrt{2}}{\pi}\,\ell_P, \Delta_* = \rho_s,$$

the coupling becomes

$$\Lambda_s = \frac{4}{3\rho_s}\left[\frac{r_s^2}{\bar{A}_s} + 2\,\frac{r_s^2}{\bar{A}_s^2}\frac{1}{\rho_s^2} + 4\pi G\right].$$

In the narrow-shell strong-field regime, the second term dominates because it carries the strongest shell-compression dependence. Therefore the leading canonical shell coupling scales as

$$\boxed{\Lambda_s \sim \frac{8}{3}\,\frac{r_s^2}{\bar{A}_s^2\,\rho_s^3}.}$$

This is the first fully coefficient-derived shell-coupling estimate of the minimal branch.

9.2 Physical reading of the result

This result sharpens the interpretation of the earlier benchmark branch.

The shell coupling is not merely large because the shell is Planckian. It is large because:

the shell is Planckian in width,

the shell-support sector is gradient-amplified,

and the shell-center redshift factor enhances the shell-supported operator.

Thus the extremely strong infrared reflectivity of the minimal branch is not accidental. It is the natural perturbative consequence of a Planck-thin, strongly dressed shell-support layer.

9.3 Updated reflectivity law

The reflectivity law remains

$$\boxed{R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}.}$$

But Λ_s now carries derived shell-center content rather than benchmark shell-strength closure. Therefore the updated reflectivity profile is no longer “benchmark-normalized reflectivity.” It is the first action-derived numerical reflectivity estimate of the minimal axial shell sector.

9.4 Observational implication

Because the fully derived Λ_s remains overwhelmingly above astrophysical frequency scales, the minimal axial branch remains deep in its infrared response regime in the observational band. Therefore the updated numerical estimate preserves the central physical conclusion already seen structurally:

$$\boxed{R_s^{(\mathrm{ax,thin})}(\omega) \approx -1 \text{throughout the observational infrared.}}$$

The significance of the present paper is that this conclusion is no longer imposed by benchmark shell-strength convention. It is now implied by the action-derived shell coefficients themselves.

9.5 What Section 9 has achieved

The numerical shell-response estimate of the minimal axial branch has now been upgraded from benchmark-normalized to coefficient-derived.

This is the final closure step of the minimal odd-parity shell program.

The next and final task is therefore simply to state the resulting strong-field conclusion of the paper.

10. Conclusion

We have derived the axial shell-kernel coefficients of the finite-capacity latency–erasure theory directly from the linearized metric–latency action and thereby removed the last benchmark coefficient closure from the minimal strong-field reflectivity sector.

Earlier FCLET work had already established the shell background, the shell-onset threshold, the shell location, the echo-delay scale, and the first odd-parity thin-shell reflectivity law,

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}.$$

What remained open was the coefficient problem: the shell kernel coefficients entering the shell coupling had not yet been derived from the action itself. The present paper closed that gap.

Starting from the strong-field FCLET action, we expanded the coupled metric–latency system to quadratic order around the static shell background and reduced the perturbation problem to the odd-parity sector. Because the background latency field is scalar, the axial branch contains no independent propagating odd-parity scalar mode. This simplification made the coefficient problem tractable and sharp. The shell-supported odd-parity action reduced to a local master-field bilinear with a shell kernel built from the shell gradient energy and the shell-support density. No independent leading shell-curvature contribution survived. Accordingly,

$$\beta_\chi = 0.$$

The remaining coefficients were then derived explicitly. The shell-gradient coefficient is

$$\alpha_\chi = \frac{r_s^2}{\bar{A}_s} Z_{\chi,s} + 2 \frac{r_s^2}{\bar{A}_s^2} \frac{\sigma_s}{\Delta_*^2},$$

and the shell-support-density coefficient is

$$\gamma_\chi = 4\pi G \left(1 - \frac{\bar{p}_{r,\mathrm{shell}}}{\bar{\rho}_{\mathrm{shell}}}\right)_s,$$

reducing to $\gamma_\chi = 4\pi G$ in the canonical minimal shell-support branch. The shell kernel therefore closes exactly as

$$\mathcal{K}_{\mathrm{ax}}(r_*) = \Xi_s \, (\partial_{r_*} \bar{\chi})^2, \Xi_s = \alpha_\chi + \gamma_\chi \sigma_s.$$

Integrating this kernel across the shell-support layer gives the fully derived shell coupling

$$\Lambda_s = \frac{4\Xi_s}{3\Delta_*}.$$

This is the decisive closure result of the paper.

The strong-field significance is exact. The axial shell-response sector of FCLET is no longer controlled by a benchmark normalization convention. It is now controlled by action-derived shell coefficients. The chain

$$\bar{\chi}(r) \longrightarrow \mathcal{K}_{\mathrm{ax}}(r_*) \longrightarrow \Lambda_s \longrightarrow R_s^{(\mathrm{ax,thin})}(\omega)$$

is now fully closed at the level of the minimal odd-parity branch.

That is a major threshold in the compact-object program. The shell reflectivity sector is no longer merely structurally derived. Its coefficients are derived. Its shell coupling is derived. Its minimal branch is fully action-based.

The physical conclusion is equally sharp. The minimal axial branch remains extremely rigid. Once the shell coefficients are derived from the action, the strong shell-support layer still drives the observationally relevant response deep into the infrared reflection regime. Thus the central lesson of the previous shell-response papers survives in strengthened form: the minimal odd-parity thin-shell branch is exact, calculable, and too stiff to represent the full physical shell-response law of the theory.

That is not a weakness. It is the correct scientific outcome. The theory has now advanced far enough to expose, by derivation rather than conjecture, the limit of its minimal branch.

The next strong-field task is therefore exact and unavoidable: finite-thickness shell perturbation theory with coupled metric–latency dynamics beyond the strict axial thin-shell approximation. Only that broader sector can soften the shell response away from the maximal infrared rigidity of the minimal branch and produce the full physical shell spectroscopy of FCLET compact objects.

The present paper has completed everything that can be completed within the minimal odd-parity shell branch. The coefficient problem is closed. The kernel problem is closed. The shell-coupling problem is closed. The remaining problem is now the next one, and it is fully visible.

Appendix A. Shell-Center Evaluation of $\bar{P}_X$, $\bar{X}$, and α_χ

This appendix records the shell-center quantities entering the coefficient derivation and makes explicit the shell-center evaluation of the gradient-sector coefficient α_χ.

A.1 Strong-field latency sector in $P(X,\chi)$ form

The benchmark strong-field FCLET action uses

$$P(X,\chi) = -\frac{1}{2}Z_\chi(\chi)\,X - U(\chi) - \frac{\sigma_s}{2}X^2,$$

with

$$X = g^{\mu\nu}\nabla_\mu\chi\nabla_\nu\chi.$$

The derivative of P with respect to X is

$$\boxed{P_X = -\frac{1}{2}Z_\chi(\chi) - \sigma_s X.}$$

Therefore, on the shell background,

$$\boxed{\bar{P}_X = -\frac{1}{2}Z_\chi(\bar{\chi}) - \sigma_s \bar{X}.}$$

A.2 Shell-center value of $\bar{X}$

On the static spherically symmetric shell background,

$$d\bar{s}^2 = -\bar{A}(r)\,dt^2 + \bar{B}(r)\,dr^2 + r^2 d\Omega^2, \bar{\chi} = \bar{\chi}(r),$$

the shell profile is radial. Hence

$$\bar{X} = \bar{g}^{rr}\bar{\chi}'(r)^2 = \frac{1}{\bar{B}(r)}\,\bar{\chi}'(r)^2.$$

Passing to tortoise coordinate,

$$\frac{dr_*}{dr} = \sqrt{\frac{\bar{B}}{\bar{A}}},$$

gives

$$\boxed{\bar{X} = \frac{1}{\bar{A}(r)}\,(\partial_{r_*}\bar{\chi})^2.}$$

At the shell center $r = r_s$, the benchmark shell profile is

$$\bar{\chi}(r_*) = 1 - \tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right),$$

so that

$$\partial_{r_*}\bar{\chi} = -\frac{1}{\Delta_*}\,\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).$$

Therefore at the shell center,

$$\boxed{\partial_{r_*}\bar{\chi}_s = -\frac{1}{\Delta_*},}$$

and hence

$$\boxed{\bar{X}_s = \frac{1}{\bar{A}_s\,\Delta_*^2},}$$

where $\bar{A}_s \equiv \bar{A}(r_s)$.

A.3 Shell-center value of $\bar{P}_{X,s}$

Evaluating $\bar{P}_X$ at the shell center gives

$$\boxed{\bar{P}_{X,s} = -\frac{1}{2}Z_{\chi,s} - \sigma_s \bar{X}_s,}$$

with

$Z_{\chi,s} \equiv Z_\chi(\bar{\chi}(r_s))$.

Using the shell-center expression for $\bar{X}_s$, this becomes

$$\boxed{\bar{P}_{X,s} = -\frac{1}{2}Z_{\chi,s} - \frac{\sigma_s}{\bar{A}_s\,\Delta_*^2}.}$$

A.4 Derivation of α_χ

The odd-parity shell-gradient contribution to the quadratic master action is

$$S^{(2)}_{\chi,\mathrm{ax}} = \int dt\, dr_*\, \frac{r_s^2}{\bar{A}_s}\, \bar{P}_{X,s}\, (\partial_{r_*}\bar{\chi})^2 \Phi^2.$$

Matching this against the shell-gradient part of the shell-supported master action,

$$-\frac{1}{2}\int dt\, dr_*\, \alpha_\chi (\partial_{r_*}\bar{\chi})^2 \Phi^2,$$

gives

$$\boxed{\alpha_\chi = -2\,\frac{r_s^2}{\bar{A}_s}\,\bar{P}_{X,s}.}$$

Substituting the shell-center expression for $\bar{P}_{X,s}$ yields

$$\boxed{\alpha_\chi = \frac{r_s^2}{\bar{A}_s}\,Z_{\chi,s} + 2\,\frac{r_s^2}{\bar{A}_s^2}\,\frac{\sigma_s}{\Delta_*^2}.}$$

This is the exact shell-gradient coefficient of the minimal odd-parity branch.

Appendix B. Odd-Parity Vanishing of $\delta\chi$, δX, and the Curvature Coefficient β_χ

This appendix records the structural reason the odd-parity shell kernel closes on the gradient-energy and shell-support-density sectors alone.

B.1 No independent odd-parity scalar perturbation

The background latency field is scalar and radial:

$$\bar{\chi} = \bar{\chi}(r).$$

Its perturbation decomposes in scalar spherical harmonics and therefore carries even-parity harmonic content. Thus the odd-parity sector contains no independent scalar harmonic amplitude:

$$\boxed{\delta\chi^{(\mathrm{odd})} = 0.}$$

This is the central simplification of the axial branch.

B.2 Vanishing of the first variation δX

The first variation of

$$X = g^{\mu\nu}\nabla_\mu\chi\nabla_\nu\chi$$

is

$$\delta X = 2\,\bar{\nabla}^{\mu}\bar{\chi}\,\bar{\nabla}_{\mu}\delta\chi - h^{\mu\nu}\bar{\nabla}_{\mu}\bar{\chi}\,\bar{\nabla}_{\nu}\bar{\chi}.$$

In the odd-parity sector:

$$\delta\chi^{(\mathrm{odd})} = 0,$$

the background latency gradient is purely radial,

and the odd-parity metric perturbation has no ^{rr} component.

Therefore

$$\boxed{\delta X^{(\mathrm{odd})} = 0.}$$

This is why the odd-parity shell-supported latency action is controlled by $^{\delta^2 X}$, not by $^{\delta X}$.

B.3 Why $\partial^2_{r_*}\bar{\chi}$ does not survive as an independent leading coefficient

The benchmark shell profile in tortoise coordinate is

$$\bar{\chi}(r_*) = 1 - \tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).$$

Its second derivative is

$$\boxed{\partial^2_{r_*}\bar{\chi} = \frac{2}{\Delta_*^2}\,\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).}$$

Define the dimensionless shell coordinate

$$u = \frac{r_* - r_{*,s}}{\Delta_*}.$$

Then $\partial^2_{r_*}\bar{\chi} \propto \mathrm{sech}^2(u)\tanh(u)$, which is odd under $u \to -u$.

The leading thin-shell coupling is obtained by integrating the shell-supported kernel across a symmetric shell-support layer. Therefore any term proportional to $\partial_{r_*}^2 \bar{\chi}$ vanishes at leading integrated order.

Equivalently, at action level, such terms reduce either to:

total derivatives,

or odd shell-shape corrections that do not survive the leading symmetric thin-shell reduction.

Thus the shell-curvature coefficient vanishes at leading odd-parity order:

$$\boxed{\beta_\chi = 0.}$$

This is a derived result of the odd-parity branch, not a simplifying convention.

Appendix C. Exact Shell Integral, Derived Λ_s, and Canonical Numerical Normalization

This appendix records the thin-shell integration and the canonical numerical evaluation of the shell coupling.

C.1 Reconstructed shell kernel

The first-principles axial shell kernel is

$$\boxed{\mathcal{K}_{\mathrm{ax}}(r_*) = \Xi_s\,(\partial_{r_*}\bar{\chi})^2,}$$

with

$$\Xi_s = \alpha_\chi + \gamma_\chi \sigma_s,$$

and

$$\partial_{r_*}\bar{\chi} = -\frac{1}{\Delta_*}\,\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).$$

Therefore

$$\boxed{\mathcal{K}_{\rm ax}(r_*) = \frac{\Xi_s}{\Delta_*^2}\,\mathrm{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).}$$

C.2 Exact thin-shell integral

By definition,

$$\Lambda_s = \int_{-\infty}^{+\infty} \mathcal{K}_{\rm ax}\,(r_*)\,dr_*.$$

Introduce

$$u = \frac{r_* - r_{*,s}}{\Delta_*}, dr_* = \Delta_*\,du.$$

Then

$$\Lambda_s = \frac{\Xi_s}{\Delta_*}\int_{-\infty}^{+\infty} \mathrm{sech}^4\,(u)\,du.$$

Using the standard integral

$$\boxed{\int_{-\infty}^{+\infty} \mathrm{sech}^4\,(u)\,du = \frac{4}{3},}$$

one obtains

$$\boxed{\Lambda_s = \frac{4\Xi_s}{3\Delta_*}.}$$

This is the exact shell coupling of the minimal odd-parity branch.

C.3 Shell-width closure

The shell width is written in terms of the shell proper distance ρ_s as

$$\boxed{\Delta_* = \varepsilon_s \rho_s.}$$

Earlier FCLET strong-field work fixed

$$\boxed{\rho_s = \frac{\sqrt{2\eta_s}}{\pi}\,\ell_P.}$$

Thus the shell coupling becomes

$$\boxed{\Lambda_s = \frac{4\Xi_s}{3\varepsilon_s\rho_s} = \frac{4\Xi_s}{3\varepsilon_s}\frac{\pi}{\sqrt{2\eta_s}\,\ell_P}.}$$

C.4 Canonical minimal normalization

The canonical minimal shell branch is defined by

$$\boxed{\eta_s = 1, \varepsilon_s = 1, Z_{\chi,s} = 1, \sigma_s = 1.}$$

In the earlier benchmark shell-coupling paper, this normalization was supplemented by the benchmark convention $\Xi_s = 1$. In the present coefficient-derived branch, Ξ_s is instead determined by the shell-center coefficients themselves. The shell coupling is therefore not benchmark-normalized by hand; it is reconstructed from the coefficient sector and then inserted into

$$\Lambda_s = \frac{4\Xi_s}{3\Delta_*}.$$

C.5 Reflectivity law

Once Λ_s is known, the minimal odd-parity thin-shell reflectivity law is

$$\boxed{R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}.}$$

Its low-frequency limit is

$$R_0^{(\mathrm{ax,thin})} = \lim_{\omega\to 0} R_s^{(\mathrm{ax,thin})}(\omega) = -1.$$

Its reflected power is

$$|\, R_s^{(\mathrm{ax,thin})}(\omega)\,|^2 = \frac{\Lambda_s^2}{4\omega^2 + \Lambda_s^2}.$$

Its response scale is

$$\omega_c^{(\mathrm{ax,thin})} = \frac{\Lambda_s}{2}.$$

These formulas define the full minimal axial shell-response sector once the shell coupling has been evaluated.

Linearized Latency Dynamics in the Saturated Core of FCLET Compact Objects

Quenching, Core Regularity, and the Derivation of the Inner Latency Boundary Condition

Ali Caner Yücel
Independent Researcher
Gaziantep, Türkiye

Abstract

We derive the inner latency boundary condition of the finite-capacity latency–erasure theory directly from the linearized saturated-core dynamics and thereby remove the last non-derived closure standing between the minimal shell branch and the full finite-thickness shell program. Earlier FCLET work established the shell background, fixed the shell-onset threshold, derived the shell location and echo-delay scale, constructed the odd-parity shell perturbation sector, and then derived the axial shell-kernel coefficients from the quadratic metric–latency action. What remained open was the core-side closure problem: once the shell is treated as a finite-thickness layer and the latency perturbation becomes dynamical in the coupled sector, what inner condition does the saturated core impose on $\delta\chi$?

This paper answers that question from the action itself. We linearize the latency equation in the saturated-core regime around

$$\chi = \chi_{\mathrm{sat}} + \delta\chi,$$

and derive the effective core perturbation operator in terms of the shell-center kinetic normalization $Z_\chi(\chi)$ and the local potential curvature $U''(\chi)$. We show that the inner latency behavior is controlled by two distinct FCLET quenching channels. In the first, the kinetic sector degenerates at saturation, $Z_\chi(\chi_{\mathrm{sat}}) \to 0$, and the perturbation loses propagating support. In the second, the core remains kinetically regular but the potential curvature $U''(\chi_{\mathrm{sat}})$ is large and positive, forcing the latency perturbation into a massive quenching regime. In both cases the dynamically admissible core solution is a decaying, non-growing branch rather than a freely oscillatory inner latency cavity.

The result is decisive. The inner latency condition is no longer introduced as a physically motivated anchoring ansatz. It is derived as the regular quenching branch of the saturated-core perturbation equation. This closes the methodological gap identified at the end of the axial shell-kernel program and prepares the next strong-field step: finite-thickness shell matching with fully coupled metric–latency perturbations.

1. Introduction

The strong-field compact-object program of the finite-capacity latency–erasure theory has now reached the interior boundary problem. That problem was not visible at the beginning of the shell program, because the first exact perturbative branch was the odd-parity thin-shell sector. In that branch, the scalar latency perturbation does not propagate as an independent axial harmonic mode, and the shell-response law can be derived without specifying how $\delta\chi$ behaves inside a finite-thickness shell-support layer. That branch is now complete. The shell onset was derived. The shell location was derived. The shell timing law was derived. The shell reflectivity law was derived. The axial shell-kernel coefficients were derived. The minimal odd-parity shell sector now forms a closed derivational chain.

That closure exposed the next problem with complete clarity.

Once the shell is treated as a finite-thickness layer and the latency perturbation becomes dynamically active in the coupled sector, one must specify what happens on the core side of the shell. In earlier discussion, the most natural physical closure was to say that the saturated core should quench latency perturbations rather than support them as a second freely oscillatory cavity. That physical intuition is strong. But physical motivation is not enough. In the FCLET program, every condition that can be derived must be derived. The inner latency condition is no exception.

This paper derives it.

The question is exact. Let the saturated core be described by a background near

$$\chi = \chi_{\mathrm{sat}},$$

and consider a linear perturbation

$$\chi = \chi_{\mathrm{sat}} + \delta\chi.$$

What does the linearized latency equation demand inside the core? Does it admit free oscillatory propagation? Does it force decay? Does it produce a pinned or quenched branch? The answer depends on the way the FCLET action behaves in the saturation limit, and in particular on two quantities:

the kinetic normalization $Z_\chi(\chi)$,

the potential curvature $U''(\chi)$.

That is the real core problem.

There are two physically decisive scenarios.

In the first, the kinetic sector itself degenerates at saturation:

$$Z_\chi(\chi_{\mathrm{sat}}) \to 0.$$

In that case the saturated core ceases to support ordinary latency propagation. The perturbation is dynamically frozen or strongly quenched because the field loses propagating support at the kinetic level.

In the second, the kinetic factor remains finite at saturation, but the local potential curvature becomes large and positive:

$$U''(\chi_{\mathrm{sat}}) \gg 0.$$

In that case the perturbation remains formally dynamical, but it becomes strongly massive in the core and therefore decays rather than propagates as a free interior mode.

These are distinct quenching channels, and the present paper treats them as such.

That distinction matters because it determines the status of the future finite-thickness shell paper. If the inner core condition is not derived, then the finite-thickness matching problem remains partially closed by choice. That would lower the methodological standard precisely at the point where the program has become strongest. We do not permit that regression. The inner core condition must be obtained from the linearized saturated-core dynamics itself.

That is why this paper comes before the full finite-thickness coupled shell paper.

Its role is sharp. It does not attempt the complete shell-matching problem. It does not attempt the full polar spectroscopic sector. It isolates the interior side of the future shell problem and solves it first. Once the regular quenching branch of $\delta\chi$ is derived inside the saturated core, the finite-thickness shell paper can proceed without any non-derived interior closure.

The paper is organized as follows. Section 2 fixes the saturated-core limit of the FCLET action and identifies the two quenching channels. Section 3 derives the linearized latency equation in the core. Section 4 analyzes the kinetically degenerate saturation regime. Section 5 analyzes the large-curvature potential-locking regime. Section 6 identifies the regular decaying core branch and derives the inner latency boundary condition. Section 7 states the consequences for future finite-thickness shell matching. Section 8 concludes.

The compact-object program therefore takes its next decisive methodological step here. The inner core condition will not be assumed. It will be derived.

2. Saturated-Core Limit of the FCLET Action

The derivation of the inner latency condition begins from the strong-field FCLET action in the neighborhood of saturation. The decisive issue is not the shell as a whole, but the local form of the latency sector as the background approaches

$$\chi = \chi_{\mathrm{sat}}.$$

The saturated core is defined by the fact that the system is no longer in the weak-load or merely transitional regime. It has crossed into the burden-dominated interior. The correct question is therefore not whether χ continues to behave like a generic scalar field there. The correct question is how the action deforms the scalar dynamics as the saturation point is approached.

We take the latency sector in the effective form

$$\mathcal{L}_\chi = -\frac{1}{2} Z_\chi(\chi)\, g^{\mu\nu}\nabla_\mu\chi\nabla_\nu\chi - U(\chi),$$

with the understanding that the full shell-support sector has already been absorbed into the strong-field background and that the present paper isolates the interior latency dynamics itself.

Expand around the saturated-core background,

$$\chi = \chi_{\mathrm{sat}} + \delta\chi.$$

The decisive quantities are the shell-center limits

$$Z_{\chi,\mathrm{sat}} \equiv Z_\chi(\chi_{\mathrm{sat}}), U''_{\mathrm{sat}} \equiv U''(\chi_{\mathrm{sat}}).$$

These two numbers divide the core dynamics into the two fundamental FCLET quenching channels.

2.1 Kinetic-degeneracy channel

If

$$\boxed{Z_\chi(\chi_{\mathrm{sat}}) = 0,}$$

then the core lies at a kinetic degeneracy point. In this regime the latency field loses ordinary propagating support at saturation itself. The perturbation equation is no longer that of a standard wave-carrying scalar. The core becomes dynamically resistant to latency excitation at the level of the kinetic operator.

This is the first FCLET quenching mechanism.

2.2 Potential-locking channel

If instead

$$\boxed{Z_\chi(\chi_{\mathrm{sat}}) > 0, U''(\chi_{\mathrm{sat}}) \gg 0,}$$

then the core remains kinetically regular but becomes strongly confining in the potential sector. The perturbation behaves like a heavy massive mode in the core. In that regime the

field does not lose support because the kinetic term vanishes; it loses practical mobility because the restoring force is overwhelmingly strong.

This is the second FCLET quenching mechanism.

2.3 The exact task

The program now has a single exact question:

Which of these two mechanisms is realized by the saturated FCLET core, and what inner perturbative branch does it enforce?

That answer determines whether the future finite-thickness shell problem closes with:

an exact decaying core branch,

an exact pinned core branch,

or some more structured regular interior mode.

That answer will not be chosen. It will be read off from the linearized core equation.

3. Linearized Latency Equation in the Saturated Core

The inner core condition must be obtained from the linearized latency equation itself. The purpose of the present section is therefore exact: to expand the FCLET latency sector around the saturated-core background, derive the linearized equation obeyed by $\delta\chi$, and put that equation into the form needed to classify the admissible inner branches.

The decisive point is immediate. The core-side closure is not a separate physical postulate. It is the regular solution class of the linearized saturated-core operator.

3.1 Saturated-core background expansion

We begin from the latency sector

$$\mathcal{L}_\chi = -\frac{1}{2} Z_\chi(\chi)\, g^{\mu\nu}\nabla_\mu\chi\nabla_\nu\chi - U(\chi),$$

and expand around the saturated-core background

$$\boxed{\chi = \chi_{\mathrm{sat}} + \delta\chi.}$$

In the core, the background is taken to be saturated and stationary, so at leading order

$$\boxed{\bar{\chi} = \chi_{\mathrm{sat}}, \nabla_\mu\bar{\chi} = 0.}$$

This is the correct interior limit of a saturated core: the background no longer carries an active shell gradient. The shell gradient belongs to the transition layer. The core itself is the region in which the latency field has already settled into the saturation configuration.

The background metric in the core is written as

$$\boxed{d\bar{s}^2 = -\bar{A}_c(r)\,dt^2 + \bar{B}_c(r)\,dr^2 + r^2 d\Omega^2.}$$

No assumption of exact Schwarzschild form is made inside the core. What matters here is only that the core geometry is static and regular enough to support a linear perturbation analysis.

3.2 Background saturation condition

For χ_{sat} to define a stationary saturated core, it must satisfy the background core field equation. Since $\nabla_\mu \bar{\chi} = 0$, the kinetic part of the background field equation vanishes identically, and the core background condition reduces to

$$\boxed{U'(\chi_{\mathrm{sat}}) = 0.}$$

This is the first exact statement of the core problem. The saturated value χ_{sat} is not just a shell-onset marker; in the core it is also a stationary point of the effective latency potential.

This condition is essential because it guarantees that the perturbation equation begins at linear order rather than inheriting a residual source term.

3.3 Linearized core equation

Varying the latency equation around the saturated background yields the first-order equation for $\delta\chi$. Because the background field is constant in the core, all terms involving background gradients vanish, and the linearization simplifies drastically. The result is

$$\boxed{Z_{\chi,\mathrm{sat}}\,\bar{\Box}\,\delta\chi - U''_{\mathrm{sat}}\,\delta\chi = 0,}$$

where

$$\boxed{Z_{\chi,\mathrm{sat}} \equiv Z_\chi(\chi_{\mathrm{sat}}), U''_{\mathrm{sat}} \equiv U''(\chi_{\mathrm{sat}}),}$$

and $\bar{\Box}$ is the d'Alembertian of the saturated-core background metric.

This is the central interior perturbation equation of the paper.

It already exhibits the two FCLET quenching channels clearly:

if $Z_{\chi,\mathrm{sat}} \to 0$, the kinetic support of the perturbation collapses;

if $Z_{\chi,\mathrm{sat}}$ remains finite but U''_{sat} is large and positive, the perturbation becomes strongly massive.

The entire core boundary problem is contained in this one equation.

3.4 Explicit coordinate form

On the static spherical core background,

$$d\bar{s}^2 = -\bar{A}_c(r)\,dt^2 + \bar{B}_c(r)\,dr^2 + r^2 d\Omega^2,$$

the core d'Alembertian acting on $\delta\chi$ is

$$\bar{\Box}\,\delta\chi = -\frac{1}{\bar{A}_c}\partial_t^2\delta\chi + \frac{1}{r^2\sqrt{\bar{A}_c\bar{B}_c}}\partial_r\left(r^2\sqrt{\frac{\bar{A}_c}{\bar{B}_c}}\;\partial_r\delta\chi\right) + \frac{1}{r^2}\Delta_{S^2}\delta\chi.$$

Therefore the linearized core equation becomes

$$\boxed{-\frac{Z_{\chi,\mathrm{sat}}}{\bar{A}_c}\partial_t^2\delta\chi + \frac{Z_{\chi,\mathrm{sat}}}{r^2\sqrt{\bar{A}_c\bar{B}_c}}\partial_r\left(r^2\sqrt{\frac{\bar{A}_c}{\bar{B}_c}}\;\partial_r\delta\chi\right) + \frac{Z_{\chi,\mathrm{sat}}}{r^2}\Delta_{S^2}\delta\chi - U''_{\mathrm{sat}}\,\delta\chi = 0.}$$

This is the full linearized latency equation in the saturated core.

3.5 Harmonic decomposition

To analyze the interior mode structure, decompose $\delta\chi$ into spherical harmonics:

$$\boxed{\delta\chi(t,r,\theta,\phi) = \sum_{\ell m}\frac{\psi_{\ell m}(t,r)}{r}\,Y_{\ell m}(\theta,\phi).}$$

Then

$$\Delta_{S^2}Y_{\ell m} = -\ell(\ell+1)Y_{\ell m},$$

and the linearized core equation reduces mode by mode to

$$-\frac{Z_{\chi,\mathrm{sat}}}{\bar{A}_c}\;\partial_t^2\psi_{\ell m} + Z_{\chi,\mathrm{sat}}\,\mathcal{D}_r\psi_{\ell m} - \left[U''_{\mathrm{sat}} + Z_{\chi,\mathrm{sat}}\;\frac{\ell(\ell+1)}{r^2}\right]\psi_{\ell m} = 0,$$

where $\mathcal{D}_r$ is the radial second-order operator induced by the static core geometry after the standard $1/r$ extraction.

At this stage the exact form of $\mathcal{D}_r$ is less important than the structural fact that the perturbation equation is governed by the competition between:

the kinetic prefactor $Z_{\chi,\mathrm{sat}}$,

and the restoring curvature U''_{sat}.

That is the entire quenching problem.

3.6 Core tortoise-coordinate form

Introduce the core tortoise coordinate $r_{*,c}$ by

$$\boxed{\frac{dr_{*,c}}{dr} = \sqrt{\frac{\bar{B}_c(r)}{\bar{A}_c(r)}}.}$$

Then, after the standard radial reduction, the mode equation takes the Regge–Wheeler-type form

$$\boxed{-Z_{\chi,\mathrm{sat}}\ \partial_t^2\psi_{\ell m} + Z_{\chi,\mathrm{sat}}\ \partial_{r_{*,c}}^2\psi_{\ell m} - V^{(\ell)}_{\chi,\mathrm{core}}(r)\,\psi_{\ell m} = 0,}$$

with the effective core potential

$$\boxed{V^{(\ell)}_{\chi,\mathrm{core}}(r) = Z_{\chi,\mathrm{sat}}\,V^{(\ell)}_{\mathrm{geom}}(r) + \bar{A}_c(r)\,U''_{\mathrm{sat}}.}$$

Here $V^{(\ell)}_{\mathrm{geom}}(r)$ collects the angular barrier and curvature terms induced by the static core geometry.

This form is decisive. It shows that the core perturbation problem is governed by an effective mass-like contribution

$$\bar{A}_c(r)\,U''_{\mathrm{sat}}$$

and an overall kinetic prefactor

$$Z_{\chi,\mathrm{sat}}.$$

Every admissible inner branch must now be classified from this operator.

3.7 Two quenching channels in equation form

The two FCLET quenching channels now appear in mathematically exact form.

Kinetic-degeneracy channel

If

$$\boxed{Z_{\chi,\mathrm{sat}} \to 0,}$$

then the time-derivative and radial-propagation terms collapse, while the restoring term proportional to U''_{sat} remains. The perturbation equation ceases to describe an ordinary propagating core scalar mode. The core no longer supports latency propagation in the standard sense.

Potential-locking channel

If

$$\boxed{Z_{\chi,\mathrm{sat}} > 0, U''_{\mathrm{sat}} \gg 0,}$$

then the perturbation remains formally propagating, but the effective core potential becomes strongly positive:

$$V^{(\ell)}_{\chi,\mathrm{core}}(r) \approx \bar{A}_c(r)\, U''_{\mathrm{sat}}.$$

In that case the core supports only exponentially suppressed or strongly attenuated perturbations rather than a freely oscillatory inner latency cavity.

Thus the core quenching problem is not a matter of interpretive taste. It is the direct classification problem of the linearized operator.

3.8 Stationary mode form

For the boundary-condition problem, the most useful representation is the stationary one. Write

$$\boxed{\psi_{\ell m}(t,r) = e^{-i\omega t}\, \varphi_{\ell m}(r).}$$

Then the core equation becomes

$$\boxed{Z_{\chi,\mathrm{sat}} \frac{d^2\varphi_{\ell m}}{dr^2_{*,c}} + Z_{\chi,\mathrm{sat}}\, \omega^2\, \varphi_{\ell m} - V^{(\ell)}_{\chi,\mathrm{core}}(r)\, \varphi_{\ell m} = 0.}$$

Equivalently,

$$\boxed{\frac{d^2\varphi_{\ell m}}{dr^2_{*,c}} + \omega^2\, \varphi_{\ell m} - \left[V^{(\ell)}_{\mathrm{geom}}(r) + \bar{A}_c(r)\, \frac{U''_{\mathrm{sat}}}{Z_{\chi,\mathrm{sat}}}\right] \varphi_{\ell m} = 0,}$$

provided $Z_{\chi,\mathrm{sat}} \neq 0$.

This form isolates the decisive quantity:

$$\boxed{m_{\chi,\mathrm{eff}}^2 \equiv \frac{U_{\mathrm{sat}}''}{Z_{\chi,\mathrm{sat}}}.}$$

The core-side behavior of $\delta\chi$ is therefore determined by whether $m_{\chi,\mathrm{eff}}^2$ is finite, large, or effectively divergent.

3.9 Exact meaning of the core problem

The inner latency boundary condition is now reduced to a precise spectral question.

The admissible core-side branch is determined by the solutions of

$$\frac{d^2\varphi_{\ell m}}{dr_{*,c}^2} + \omega^2\,\varphi_{\ell m} - \left[V_{\mathrm{geom}}^{(\ell)}(r) + \bar{A}_c(r)\, m_{\chi,\mathrm{eff}}^2\right]\varphi_{\ell m} = 0.$$

If the effective mass term is large and positive, only decaying or non-growing branches survive.
If the kinetic factor collapses, propagation itself degenerates and the interior mode is dynamically pinned.
If neither happens, then the core would act as a genuine propagation cavity — and that would have to be accepted. Nothing is pre-decided.

That is exactly the methodological standard the program now enforces.

3.10 Outcome of the linearized core derivation

The present section has completed the derivation of the inner-core perturbation operator.

We now have:

the exact linearized latency equation in the saturated core,

the harmonic decomposition of the perturbation,

the tortoise-coordinate core operator,

and the exact effective mass parameter

$$m_{\chi,\mathrm{eff}}^2 = \frac{U_{\mathrm{sat}}''}{Z_{\chi,\mathrm{sat}}}.$$

This is the full mathematical structure needed to determine whether the saturated core dynamically quenches $\delta\chi$.

The next task is therefore exact:
analyze first the kinetically degenerate saturation channel and then the large-curvature potential-locking channel.

4. Kinetically Degenerate Saturation Regime

The first quenching channel of the saturated core arises when the kinetic normalization of the latency field collapses at saturation itself. This is the most direct route to dynamical anchoring, because it eliminates ordinary propagating support at the level of the action rather than only through a large restoring curvature. The purpose of the present section is to analyze that regime explicitly and determine the admissible inner branch of the core perturbation equation.

The core result is exact. If the saturation point is a kinetic degeneracy point of the FCLET latency sector, then the core does not support a freely propagating latency perturbation. The dynamically admissible inner branch is a non-growing anchored mode rather than an oscillatory cavity solution.

4.1 Saturation as a kinetic degeneracy point

We begin from the core perturbation equation derived in the previous section,

$$Z_{\chi,\mathrm{sat}}\,\bar{\Box}\,\delta\chi - U''_{\mathrm{sat}}\,\delta\chi = 0.$$

The kinetically degenerate saturation regime is defined by

$$\boxed{Z_{\chi,\mathrm{sat}} = 0.}$$

At this point the naive wave operator disappears from the linearized equation. This does not mean the perturbation problem becomes ill-defined. It means that the saturated core ceases to support ordinary latency propagation at leading order. The perturbation is no longer governed by a standard second-order hyperbolic operator with finite kinetic weight.

This is the first FCLET quenching mechanism in its exact action-level form.

4.2 Leading core equation at the degeneracy point

Setting $Z_{\chi,\mathrm{sat}} = 0$ in the linearized equation gives immediately

$$\boxed{U''_{\mathrm{sat}}\,\delta\chi = 0.}$$

If the saturated core is stable, then

$$\boxed{U''_{\mathrm{sat}} > 0.}$$

Under that condition, the only admissible solution at leading order is

$$\boxed{\delta\chi = 0.}$$

This is not an imposed boundary condition. It is the linearized field equation itself in the exact kinetic-degeneracy limit.

This is the strongest possible form of core quenching. The interior latency perturbation is not merely damped. It is annihilated at leading order by the collapse of kinetic support.

4.3 Near-degeneracy expansion

To understand the interior branch more precisely, it is useful to expand near the degeneracy point rather than only exactly at it. Let

$$\boxed{Z_{\chi,\mathrm{sat}} = \varepsilon_Z, 0 < \varepsilon_Z \ll 1.}$$

Then the stationary core equation becomes

$$\varepsilon_Z \frac{d^2\varphi_{\ell m}}{dr_{*,c}^2} + \varepsilon_Z\, \omega^2\, \varphi_{\ell m} - V_{\chi,\mathrm{core}}^{(\ell)}(r)\, \varphi_{\ell m} = 0,$$

with

$$V_{\chi,\mathrm{core}}^{(\ell)}(r) = \varepsilon_Z\, V_{\mathrm{geom}}^{(\ell)}(r) + \bar{A}_c(r)\, U_{\mathrm{sat}}''.$$

Dividing by ε_Z gives

$$\frac{d^2\varphi_{\ell m}}{dr_{*,c}^2} + \omega^2\, \varphi_{\ell m} - \left[V_{\mathrm{geom}}^{(\ell)}(r) + \bar{A}_c(r)\, \frac{U_{\mathrm{sat}}''}{\varepsilon_Z}\right]\varphi_{\ell m} = 0.$$

Thus the effective core mass is

$$\boxed{m_{\chi,\mathrm{eff}}^2 = \frac{U_{\mathrm{sat}}''}{\varepsilon_Z} \to \infty(\varepsilon_Z \to 0^+).}$$

Therefore the kinetic degeneracy limit is equivalent, from the point of view of the stationary core equation, to an infinitely large positive core mass barrier. The core branch cannot remain oscillatory in that limit.

4.4 Local asymptotic core solution

Deep in the saturated core, where $\bar{A}_c(r)$ and the geometric coefficients vary slowly on the scale of the rapidly growing effective mass, the local equation reduces to

$$\frac{d^2\varphi}{dr_{*,c}^2} - \kappa_c^2\,\varphi \approx 0,$$

with

$$\boxed{\kappa_c^2 = \bar{A}_c\,\frac{U''_{\mathrm{sat}}}{\varepsilon_Z} - \omega^2 - V_{\mathrm{geom}}^{(\ell)}.}$$

In the near-degenerate regime, the first term dominates, so

$$\boxed{\kappa_c^2 > 0.}$$

The local core solutions are therefore

$$\boxed{\varphi(r_{*,c}) = C_+\,e^{+\kappa_c r_{*,c}} + C_-\,e^{-\kappa_c r_{*,c}}.}$$

The growing branch is inadmissible in the saturated interior. The only regular branch is the decaying one.

Thus the interior latency mode satisfies

$$\boxed{\varphi(r_{*,c}) \propto e^{-\kappa_c |r_{*,c}|}}$$

toward the interior of the saturated core.

This is the first exact derivation of a quenching branch.

4.5 Derived interior condition in the degenerate channel

Because the regular inner branch decays exponentially into the saturated core, the interior condition is not a chosen pinning rule. It is the regular decaying solution of the linearized core operator. In exact form,

$$\boxed{\delta\chi \to 0 \text{toward the saturated-core interior}}$$

in the kinetic-degeneracy channel.

Equivalently, at any finite inner anchoring surface Σ_{in} placed sufficiently inside the quenching region, one obtains the effective boundary condition

$$\boxed{\delta\chi\,|_{\Sigma_{\mathrm{in}}} \approx 0.}$$

This is the first case in which the previously discussed anchoring behavior is not an ansatz but a derived interior asymptotic law.

4.6 Core regularity versus cavity behavior

It is useful to state explicitly what has been ruled out.

In the kinetically degenerate regime, the saturated core does **not** support:

a freely oscillatory latency cavity,

a reflective scalar standing-wave interior,

or a second resonance chamber independent of the shell.

Those possibilities are eliminated by the collapse of kinetic support. The core is an anchoring medium, not a propagation cavity.

This is precisely the type of result needed before the finite-thickness shell paper can be written cleanly.

4.7 Strong-field significance of the degeneracy channel

The kinetic-degeneracy channel is especially powerful because it yields the inner-core closure in the strongest possible way. The decay of $\delta\chi$ is not merely due to a large but finite restoring force. It is enforced by the disappearance of ordinary propagation itself.

If this channel is realized by the FCLET action at saturation, then the future finite-thickness shell paper acquires an exact inner latency closure with no phenomenological residue at all.

That is the strongest possible methodological outcome.

4.8 Outcome of the kinetic-degeneracy analysis

The conclusion of the present section is exact:

If $Z_{\chi,\mathrm{sat}} \to 0$ and $U''_{\mathrm{sat}} > 0$, then the saturated core supports only the regular decaying latency branch.

In that regime, the effective inner-core condition is

$$\delta\chi \to 0 \text{toward the saturated interior.}$$

This is a derived result, not a chosen closure.

The next task is to analyze the second quenching channel, in which the core remains kinetically regular but becomes strongly confining through a large positive potential curvature.

5. Potential-Locking Saturation Regime

The second quenching channel of the FCLET saturated core arises when the kinetic factor remains finite at saturation but the potential curvature becomes large and positive. In this regime the core does not lose propagating support by kinetic collapse. It loses practical mobility because the perturbation becomes strongly massive. The purpose of the present section is to analyze this regime explicitly and determine whether it also yields a derived decaying inner branch.

The result is again exact. If the saturated core is kinetically regular but strongly curved in the potential sector, then the admissible inner latency solution is still a decaying, non-growing branch rather than a freely oscillatory cavity mode.

5.1 Regular kinetic support at saturation

The potential-locking regime is defined by

$$\boxed{Z_{\chi,\mathrm{sat}} > 0, U''_{\mathrm{sat}} \gg 0.}$$

In this case the linearized core equation remains

$$Z_{\chi,\mathrm{sat}} \, \square \, \delta\chi - U''_{\mathrm{sat}} \, \delta\chi = 0,$$

but the kinetic operator remains nondegenerate. The field is therefore still formally dynamical. The issue is not whether the core supports a second-order perturbation equation. It does. The issue is whether the corresponding inner modes are oscillatory or exponentially quenched.

That question is answered by the effective mass scale

$$\boxed{m^2_{\chi,\mathrm{eff}} = \frac{U''_{\mathrm{sat}}}{Z_{\chi,\mathrm{sat}}}.}$$

If this quantity is large and positive, the core behaves as a massive locking region for the latency perturbation.

5.2 Stationary core equation

Using the stationary mode decomposition

$$\delta\chi = e^{-i\omega t} \sum_{\ell m} \frac{\varphi_{\ell m}(r)}{r} Y_{\ell m},$$

the core equation becomes

$$\frac{d^2\varphi_{\ell m}}{dr_{*,c}^2} + \omega^2\,\varphi_{\ell m} - \left[V_{\rm geom}^{(\ell)}(r) + \bar{A}_c(r)\,m_{\chi,\rm eff}^2\right]\varphi_{\ell m} = 0.$$

This is an ordinary Schrödinger-type radial equation with a positive core potential dominated by the mass-like term

$$\bar{A}_c(r)\,m_{\chi,\rm eff}^2.$$

The quenching problem is therefore a standard spectral classification problem.

5.3 Deep-core asymptotics

Inside the saturated core, the background metric varies slowly compared with the locking scale if

$$m_{\chi,\rm eff}^2 \gg \omega^2, m_{\chi,\rm eff}^2 \gg V_{\rm geom}^{(\ell)}.$$

In that regime the local equation reduces to

$$\frac{d^2\varphi}{dr_{*,c}^2} - \kappa_{\rm lock}^2\,\varphi \approx 0,$$

with

$$\boxed{\kappa_{\rm lock}^2 = \bar{A}_c\,m_{\chi,\rm eff}^2 - \omega^2 - V_{\rm geom}^{(\ell)}.}$$

Since $m_{\chi,\rm eff}^2$ is large and positive, one has

$$\boxed{\kappa_{\rm lock}^2 > 0}$$

throughout the locking regime.

The local solutions are therefore

$$\boxed{\varphi(r_{*,c}) = D_+\,e^{+\kappa_{\rm lock} r_{*,c}} + D_-\,e^{-\kappa_{\rm lock} r_{*,c}}.}$$

Again, the growing branch is inadmissible. The regular inner solution is the decaying one.

Thus the potential-locking regime also yields

$$\boxed{\varphi(r_{*,c}) \propto e^{-\kappa_{\rm lock}|r_{*,c}|}}$$

toward the core interior.

5.4 Derived quenching branch

The implication is exact. In the potential-locking regime, the inner core still does not behave as a freely oscillatory latency cavity. The large positive potential curvature forces the perturbation into an evanescent branch.

Thus the physically admissible inner solution satisfies

$$\boxed{\delta\chi \to 0 \text{toward the saturated-core interior}}$$

also in the potential-locking channel.

This is a second independent derivation of the same qualitative inner behavior reached in the previous section.

The importance of this result is substantial. It shows that the quenching of the latency perturbation is not a fragile consequence of one special degeneracy limit. It arises in both of the structurally natural FCLET saturation regimes.

5.5 Exact difference from the degeneracy channel

Although both channels yield quenching, their physical meanings differ.

In the kinetic-degeneracy channel:

propagation is suppressed because kinetic support collapses.

In the potential-locking channel:

propagation is suppressed because the core becomes an overwhelmingly massive barrier.

This distinction matters for later finite-thickness shell dynamics, because the detailed penetration depth and effective inner decay scale are different:

$$\kappa_c^2 \sim \bar{A}_c \, \frac{U''_{\mathrm{sat}}}{Z_{\chi,\mathrm{sat}}} \text{with } Z_{\chi,\mathrm{sat}} \to 0$$

in the first case, and

$$\kappa_{\mathrm{lock}}^2 \sim \bar{A}_c \, m_{\chi,\mathrm{eff}}^2$$

with finite $Z_{\chi,\mathrm{sat}}$ in the second.

But for the purpose of the core boundary problem, both channels select the same branch class: the decaying non-growing inner mode.

5.6 Effective inner boundary condition

As in the previous section, once the core-side solution decays exponentially toward the saturated interior, the future finite-thickness shell paper does not need an arbitrary interior pinning rule. It needs the regular interior branch.

Operationally, at an inner anchoring surface Σ_{in} chosen sufficiently inside the quenching region, that branch yields the effective condition

$$\boxed{\delta\chi\,|_{\Sigma_{\mathrm{in}}} \approx 0.}$$

This is not imposed by preference. It is the finite-location image of the decaying inner solution.

Thus the physical intuition of saturation anchoring survives, but it survives now as a derived asymptotic consequence of the core operator rather than as a guessed closure.

5.7 Outcome of the potential-locking analysis

The conclusion of the present section is exact:

If $Z_{\chi,\mathrm{sat}} > 0$ and $U''_{\mathrm{sat}} \gg 0$, then the saturated core again supports only the regular decaying latency branch.

Thus the inner latency perturbation is quenched not only when kinetic support collapses, but also when the saturated core becomes sufficiently stiff in the potential sector.

The next task is therefore clear:
combine the two channels and state the derived inner-core latency condition in its final form.

6. Regular Quenching Branch and the Derived Inner Core Condition

The previous two sections established the decisive result of the saturated-core analysis. The inner latency perturbation does not require an imposed anchoring rule. In both structurally natural FCLET saturation channels, the linearized core equation selects the same physical branch: the non-growing decaying solution. The purpose of the present section is therefore exact: to combine those two channels into a single core classification statement and extract the derived inner latency condition in the form required by the future finite-thickness shell-matching problem.

This is the central closure result of the paper.

6.1 Two distinct mechanisms, one admissible branch

The kinetic-degeneracy channel gave

$$Z_{\chi,\mathrm{sat}} \to 0, U''_{\mathrm{sat}} > 0,$$

and forced the interior perturbation into the decaying branch because ordinary propagation lost kinetic support.

The potential-locking channel gave

$$Z_{\chi,\mathrm{sat}} > 0, U''_{\mathrm{sat}} \gg 0,$$

and forced the interior perturbation into the decaying branch because the core became a strongly positive massive barrier.

These are physically distinct mechanisms, but they select the same inner branch class. In both cases the regular interior solution satisfies

$$\boxed{\delta\chi \to 0 \text{toward the saturated-core interior.}}$$

This is the first exact statement of the core quenching law of FCLET compact objects.

6.2 Exclusion of a freely oscillatory inner latency cavity

The linearized core analysis now allows a precise negative statement. A saturated FCLET core does **not** generically act as a second free latency cavity.

That conclusion is not interpretive. It follows directly from the operator analysis:

if $Z_{\chi,\mathrm{sat}} \to 0$, the core is kinetically non-propagating;

if $U''_{\mathrm{sat}}/Z_{\chi,\mathrm{sat}}$ is large and positive, the core is evanescent rather than oscillatory.

Therefore the physically admissible inner branch is not of the form

$$\delta\chi \sim e^{\pm ikr_{*,c}},$$

but of the form

$$\delta\chi \sim e^{-\kappa|r_{*,c}|}.$$

This is the exact reason a free oscillatory interior latency mode is excluded in the saturated-core regime.

6.3 Derived asymptotic inner condition

The core result is most naturally stated as an asymptotic interior condition. Let the saturated-core interior correspond to decreasing $r_{*,c}$ or, more invariantly, to motion deeper into the burden-dominated region. Then the admissible branch is

$$\boxed{\delta\chi_{\mathrm{reg}}(r_{*,c}) \propto e^{-\kappa_{\mathrm{core}}|r_{*,c}|},}$$

with

$$\kappa_{\mathrm{core}} > 0,$$

where κ_{core} is determined by the appropriate quenching channel:

$\kappa_{\mathrm{core}} = \kappa_c$ in the kinetic-degeneracy regime,

$\kappa_{\mathrm{core}} = \kappa_{\mathrm{lock}}$ in the potential-locking regime.

Thus the exact asymptotic inner condition is

$$\boxed{\delta\chi_{\mathrm{reg}} \to 0 \text{monotonically toward the saturated interior.}}$$

This is not a guessed boundary rule. It is the interior regular branch of the linearized core equation.

6.4 Effective finite-location condition

For the future finite-thickness shell problem, one does not match at asymptotic interior infinity. One matches at a finite inner shell surface Σ_{in} lying sufficiently inside the quenching region. The asymptotic decay law then induces an effective finite-location condition.

If Σ_{in} is placed deep enough that

$$\kappa_{\mathrm{core}}\, L_{\mathrm{in}} \gg 1,$$

with L_{in} the remaining interior distance to the quenching region, then the regular branch gives

$$\boxed{\delta\chi\,|_{\Sigma_{\mathrm{in}}} \approx 0.}$$

This is the finite-location image of the asymptotic quenching law.

It is important to state this precisely. The future shell paper is not allowed to say "we choose $\delta\chi = 0$." It must say:

$$\boxed{\delta\chi\,|_{\Sigma_{\mathrm{in}}} \approx 0 \text{because the inner branch derived from the saturated-core operator is exponentially quenched.}}$$

That is the correct methodological status of the condition.

6.5 Derived Robin form of the inner condition

The decaying branch also yields a more refined local statement than the approximate Dirichlet form above. Since

$$\delta\chi_{\mathrm{reg}}(r_{*,c}) \propto e^{-\kappa_{\mathrm{core}}|r_{*,c}|},$$

its radial derivative satisfies

$$\partial_{r_{*,c}} \delta\chi_{\mathrm{reg}} = -\kappa_{\mathrm{core}}\, \delta\chi_{\mathrm{reg}}$$

up to the sign determined by the chosen inward orientation.

Thus the exact local regularity law of the quenched branch is the derived Robin condition

$$\boxed{\partial_{r_{*,c}} \delta\chi + \kappa_{\mathrm{core}}\, \delta\chi = 0 \text{on the regular inner branch.}}$$

This is stronger than the approximate Dirichlet reduction. It shows that the true derived inner condition is not "pinning by fiat," but exponential quenching with definite decay scale.

The Dirichlet form

$$\delta\chi\,|_{\Sigma_{\mathrm{in}}} \approx 0$$

is therefore the deep-quenching approximation to the more exact derived Robin condition.

This is the most precise form of the inner latency closure obtained in the present paper.

6.6 Final derived inner-core condition

The previous observations can now be summarized in the exact form needed for future work.

Asymptotic quenching law

$$\boxed{\delta\chi \to 0 \text{toward the saturated-core interior.}}$$

Local regular-branch law

$$\boxed{\partial_{r_{*,c}} \delta\chi + \kappa_{\mathrm{core}}\, \delta\chi = 0.}$$

Deep-quenching approximation

$$\boxed{\delta\chi\,|_{\Sigma_{\mathrm{in}}} \approx 0.}$$

These three statements are not alternatives in logical status. They are the same derived core closure written at three different levels of approximation:

asymptotic,

local,

and practical matching form.

This is the exact closure structure required by the future finite-thickness shell program.

6.7 Methodological significance

This result has a methodological weight beyond its algebraic form. The compact-object program now preserves its strongest internal rule: every condition that can be derived is derived.

That standard was first enforced sharply when

$$\beta_\chi = 0$$

ceased to be a benchmark omission and became a derived odd-parity result. The present paper extends the same standard to the core-side latency condition. The future finite-thickness shell paper will not rest on a physically motivated anchoring ansatz. It will rest on a derived regular quenching branch.

That is a major strengthening of the program.

6.8 Outcome of the quenching-branch analysis

The exact conclusion of the present section is

The saturated FCLET core selects a regular decaying latency branch, and the inner core condition is therefore derived rather than assumed.

This is the central result of the paper.

The next task is now immediate:
state how this derived inner condition enters the future finite-thickness shell matching problem and what it changes in the next strong-field stage of the program.

7. Consequences for Future Finite-Thickness Shell Matching

The inner latency condition derived in the previous section does not merely close an abstract core problem. It changes the status of the next major strong-field paper. The future finite-thickness shell program is no longer forced to choose an interior closure by physical taste. Its core-side latency branch is now fixed by the regular quenching dynamics of the saturated core. The purpose of the present section is to state that consequence explicitly and to show how the future shell-matching problem is now mathematically organized.

This is the practical payoff of the entire paper.

7.1 What is already derived before shell matching begins

Once the shell is treated as a finite-thickness layer, the coupled metric–latency problem has three radial regions:

the exterior region,

the shell-support layer,

and the saturated core.

The present paper has now fixed the core-side latency behavior. Thus the finite-thickness shell program will begin with the following already-derived ingredients:

Exterior side

The exterior perturbation sector is solved on the shell-dressed strong-field background and supplies the incoming and outgoing asymptotic wave content.

Shell-support layer

The shell itself carries the finite-thickness coupled metric–latency dynamics that must be solved directly.

Core side

The latency perturbation is constrained to lie on the regular decaying branch derived from the saturated-core operator.

This means the core is no longer an undetermined closure region. It is a mathematically classified region of the perturbation problem.

7.2 Matching laws at the shell interfaces

The shell-support layer has two faces:

an outer face Σ_{out},

and an inner face Σ_{in}.

At these faces, the correct matching conditions for the latency perturbation are not guessed. They are derived from the quadratic action. In the absence of an explicit delta-supported source on the interface, they are

$$\boxed{[\delta\chi] = 0, [\Pi_\chi] = 0,}$$

where

$$\Pi_\chi \equiv \frac{\partial \mathcal{L}^{(2)}}{\partial(\partial_{r_*}\delta\chi)}$$

is the canonical radial momentum of the linearized latency sector.

These matching laws remain exact.

What the present paper adds is the core-side branch condition that must be imposed on the inner solution before matching is attempted.

7.3 Derived core-side closure for the future shell paper

The future finite-thickness shell problem must therefore be organized as follows.

In the shell layer

Solve the fully coupled metric–latency perturbation equations.

At the shell faces

Impose continuity of the field and canonical momentum:

$$[\delta\chi]_{\Sigma_{\rm out}} = 0, [\Pi_\chi]_{\Sigma_{\rm out}} = 0,$$
$$[\delta\chi]_{\Sigma_{\rm in}} = 0, [\Pi_\chi]_{\Sigma_{\rm in}} = 0.$$

Inside the saturated core

Select the regular quenching branch:

$$\boxed{\partial_{r_{*,c}}\delta\chi + \kappa_{\rm core}\,\delta\chi = 0,}$$

or, in the deep-quenching approximation,

$$\boxed{\delta\chi\,|_{\Sigma_{\rm in}} \approx 0.}$$

This is the exact structure of the future latency matching problem.

7.4 Why this matters for the full shell reflectivity problem

Without a derived core-side closure, the future finite-thickness shell paper would contain a non-derived interior choice. That would weaken the program precisely where it has become strongest. The present paper eliminates that weakness.

Now the full shell reflectivity sector can be built from:

an exterior asymptotic wave problem,

a finite-thickness shell-support layer,

and a derived core-side regular branch.

Thus the future reflectivity law of the full coupled shell sector will not be the output of a partially chosen problem. It will be the output of a fully derived matching structure.

That is the exact methodological significance of the present result.

7.5 Immediate strong-field implication

The current paper also sharpens the physical expectation for the full shell-response law.

The minimal odd-parity thin-shell branch gave a maximally rigid infrared response,

$$R_s(\omega) \approx -1$$

throughout the observational band.

The present paper shows that once the full finite-thickness shell problem is solved, the latency sector will not be allowed to open an arbitrary second oscillatory cavity on the core side. The core is dynamically quenched. Therefore any softening of the full shell response must come from:

finite shell thickness,

coupled metric–latency dynamics within the shell layer itself,

and channel mixing,
not from an unconstrained propagating latency reservoir in the core.

This is a very strong restriction on the structure of the future finite-thickness solution.

7.6 Outcome of the finite-thickness consequence analysis

The exact conclusion of the present section is

The future finite-thickness shell-matching problem now has a derived core-side latency closure.

The next strong-field paper can therefore proceed without any non-derived interior latency ansatz.

That is precisely the closure needed before the full coupled shell program begins.

8. Conclusion

We have derived the inner latency boundary structure of the finite-capacity latency–erasure theory directly from the linearized saturated-core dynamics and thereby removed the last non-derived closure that stood between the minimal shell branch and the full finite-thickness shell program.

Earlier FCLET work had already established the shell background, the shell-onset threshold, the shell location, the echo-delay scale, the odd-parity shell perturbation law, the axial shell coupling, and the action-derived kernel coefficients of the minimal branch. What remained open was the core-side latency condition. Once the shell is treated as a finite-thickness layer and the latency perturbation becomes dynamically active in the coupled sector, the theory must specify what the saturated core does to $\delta\chi$. The present paper solved that problem at the level required by the program's own methodological standard.

Starting from the FCLET latency action, we expanded around the saturated-core background

$$\chi = \chi_{\mathrm{sat}} + \delta\chi, \nabla_\mu \bar{\chi} = 0, U'(\chi_{\mathrm{sat}}) = 0,$$

and derived the exact linearized core equation

$$Z_{\chi,\mathrm{sat}}\,\bar{\Box}\,\delta\chi - U''_{\mathrm{sat}}\,\delta\chi = 0.$$

This equation revealed two distinct but equally natural FCLET quenching channels.

In the first, the saturation point is a kinetic degeneracy point,

$$Z_{\chi,\mathrm{sat}} \to 0.$$

In that regime the core loses ordinary propagating latency support, and the only admissible inner branch is the non-growing quenched solution.

In the second, the kinetic factor remains finite but the potential curvature becomes strongly positive,

$$Z_{\chi,\mathrm{sat}} > 0, U''_{\mathrm{sat}} \gg 0.$$

In that regime the core remains formally dynamical, but the perturbation becomes strongly massive and again reduces to a decaying non-growing branch.

Thus both structurally natural FCLET saturation regimes lead to the same conclusion:

$$\boxed{\delta\chi \to 0\text{toward the saturated-core interior.}}$$

More precisely, the derived local regularity law is the Robin-type condition

$$\boxed{\partial_{r_{*,c}}\delta\chi + \kappa_{\mathrm{core}}\,\delta\chi = 0,}$$

with the approximate Dirichlet form

$$\delta\chi\,|_{\Sigma_{\mathrm{in}}} \approx 0$$

emerging only as the deep-quenching limit of that derived branch.

This distinction is crucial. The present paper has not justified a physically motivated anchoring ansatz. It has replaced that ansatz with a derived regular quenching branch of the interior operator.

That is the strongest possible methodological outcome. The compact-object program no longer needs to choose the core-side latency behavior when moving to the finite-thickness shell problem. It now knows it.

The consequence for future work is exact. The next strong-field paper — the finite-thickness coupled metric–latency shell program — will now begin from:

action-derived shell-face matching laws,

and a derived core-side regular latency branch.

That means the full shell-matching problem can now be written without non-derived interior closure.

The present paper therefore closes a decisive gap in the FCLET compact-object program. The shell background is derived. The shell perturbation law is derived. The shell kernel coefficients are derived. The shell coupling is derived. And now the inner latency condition is derived as well.

The finite-thickness shell program is therefore no longer waiting on a missing interior assumption. It is ready.

Appendix A. Linearization of the Latency Equation Around χ_{sat}

This appendix records the linearization of the latency equation in the saturated-core regime and fixes the notation used in the main text.

A.1 Latency sector

The effective latency action is

$$S_\chi = \int d^4x \sqrt{-g}\left[-\frac{1}{2}Z_\chi(\chi)\, g^{\mu\nu}\nabla_\mu\chi\nabla_\nu\chi - U(\chi)\right].$$

Varying with respect to χ gives the exact field equation

$$\nabla_\mu\big(Z_\chi(\chi)\nabla^\mu\chi\big) - \frac{1}{2}Z'_\chi(\chi)\,(\nabla\chi)^2 - U'(\chi) = 0.$$

A.2 Saturated-core background

In the saturated core, the background is expanded as

$$\chi = \bar{\chi} + \delta\chi, \bar{\chi} = \chi_{\mathrm{sat}}, \nabla_\mu\bar{\chi} = 0.$$

Since the background is stationary and saturated, the background equation reduces to

$$\boxed{U'(\chi_{\mathrm{sat}}) = 0.}$$

Thus χ_{sat} is a stationary point of the effective latency potential.

A.3 Linearized equation

Expand the field equation to first order in $\delta\chi$. Because the background gradient vanishes, all terms involving $(\nabla\bar{\chi})^2$ and $\nabla_\mu\bar{\chi}$ drop out. The only surviving first-order terms are

$$Z_{\chi,\mathrm{sat}}\,\bar{\Box}\,\delta\chi - U''_{\mathrm{sat}}\,\delta\chi = 0,$$

where

$$Z_{\chi,\mathrm{sat}} \equiv Z_\chi(\chi_{\mathrm{sat}}), U''_{\mathrm{sat}} \equiv U''(\chi_{\mathrm{sat}}).$$

Thus the linearized saturated-core operator is

$$\boxed{\mathcal{L}^{(1)}_{\mathrm{core}} = Z_{\chi,\mathrm{sat}}\,\bar{\Box} - U''_{\mathrm{sat}}.}$$

This is the exact first-order core operator used throughout the paper.

A.4 Core effective mass

Provided $Z_{\chi,\mathrm{sat}} \neq 0$, the core equation may be written as

$$\bar{\Box}\,\delta\chi - m^2_{\chi,\mathrm{eff}}\,\delta\chi = 0,$$

with

$$\boxed{m^2_{\chi,\mathrm{eff}} = \frac{U''_{\mathrm{sat}}}{Z_{\chi,\mathrm{sat}}}.}$$

This is the effective latency mass in the saturated core.

Appendix B. Asymptotic Core Solutions in the Two Quenching Channels

This appendix records the local asymptotic solutions of the linearized core equation in the two FCLET quenching regimes.

B.1 Stationary mode decomposition

Write the perturbation as

$$\delta\chi(t,r,\theta,\phi) = e^{-i\omega t}\sum_{\ell m}\frac{\varphi_{\ell m}(r)}{r}Y_{\ell m}(\theta,\phi).$$

Then the radial core equation takes the form

$$\frac{d^2\varphi_{\ell m}}{dr_{*,c}^2} + \omega^2\varphi_{\ell m} - \left[V_{\mathrm{geom}}^{(\ell)}(r) + \bar{A}_c(r)\, m_{\chi,\mathrm{eff}}^2\right]\varphi_{\ell m} = 0,$$

whenever $Z_{\chi,\mathrm{sat}} \neq 0$.

B.2 Kinetic-degeneracy channel

Let

$$Z_{\chi,\mathrm{sat}} = \varepsilon_Z, 0 < \varepsilon_Z \ll 1.$$

Then

$$m_{\chi,\mathrm{eff}}^2 = \frac{U_{\mathrm{sat}}''}{\varepsilon_Z} \to \infty(\varepsilon_Z \to 0^+).$$

Deep in the core, the mode equation reduces to

$$\frac{d^2\varphi}{dr_{*,c}^2} - \kappa_c^2\varphi \approx 0,$$

with

$$\kappa_c^2 = \bar{A}_c\, \frac{U_{\mathrm{sat}}''}{\varepsilon_Z} - \omega^2 - V_{\mathrm{geom}}^{(\ell)}.$$

The local solutions are

$$\varphi = C_+ e^{+\kappa_c r_{*,c}} + C_- e^{-\kappa_c r_{*,c}}.$$

The growing branch is inadmissible. Therefore the regular core solution is

$$\boxed{\varphi_{\mathrm{reg}} \propto e^{-\kappa_c |r_{*,c}|}.}$$

B.3 Potential-locking channel

Let

$$Z_{\chi,\mathrm{sat}} > 0, U_{\mathrm{sat}}'' \gg 0.$$

Then

$$m_{\chi,\mathrm{eff}}^2 = \frac{U_{\mathrm{sat}}''}{Z_{\chi,\mathrm{sat}}} \gg 0.$$

The local deep-core equation becomes

$$\frac{d^2\varphi}{dr_{*,c}^2} - \kappa_{\mathrm{lock}}^2 \varphi \approx 0,$$

with

$$\kappa_{\mathrm{lock}}^2 = \bar{A}_c \, m_{\chi,\mathrm{eff}}^2 - \omega^2 - V_{\mathrm{geom}}^{(\ell)}.$$

Again the solutions are

$$\varphi = D_+ e^{+\kappa_{\mathrm{lock}} r_{*,c}} + D_- e^{-\kappa_{\mathrm{lock}} r_{*,c}},$$

and regularity selects

$$\boxed{\varphi_{\mathrm{reg}} \propto e^{-\kappa_{\mathrm{lock}} |r_{*,c}|}.}$$

B.4 Unified quenching form

Both channels therefore reduce to the same regular asymptotic structure:

$$\boxed{\varphi_{\mathrm{reg}} \propto e^{-\kappa_{\mathrm{core}} |r_{*,c}|}, \kappa_{\mathrm{core}} > 0.}$$

Hence

$$\boxed{\delta\chi_{\mathrm{reg}} \to 0 \text{toward the saturated-core interior.}}$$

This is the asymptotic origin of the derived inner-core condition.

Appendix C. Derived Robin Condition and Deep-Quenching Approximation

This appendix records the local form of the regular core branch and its reduction to the practical condition used in future finite-thickness matching.

C.1 Local regular branch

For the regular decaying core solution,

$$\delta\chi_{\mathrm{reg}}(r_{*,c}) \propto e^{-\kappa_{\mathrm{core}} |r_{*,c}|},$$

one immediately has

$$\partial_{r_{*,c}} \delta\chi_{\mathrm{reg}} = -\kappa_{\mathrm{core}}\, \delta\chi_{\mathrm{reg}},$$

up to the orientation sign of the inward radial coordinate.

Thus the exact local regularity law is the Robin condition

$$\boxed{\partial_{r_{*,c}} \delta\chi + \kappa_{\mathrm{core}}\, \delta\chi = 0.}$$

This is the derived inner latency condition of the paper.

C.2 Deep-quenching reduction

Suppose the inner shell interface Σ_{in} is placed sufficiently deep in the quenching region that

$$\kappa_{\mathrm{core}} L_{\mathrm{in}} \gg 1,$$

where L_{in} is the remaining interior distance to the strongly saturated region. Then the regular solution is exponentially suppressed already at Σ_{in}. In that regime the Robin condition reduces effectively to

$$\boxed{\delta\chi\,|_{\Sigma_{\mathrm{in}}} \approx 0.}$$

This is not the fundamental boundary condition. It is the deep-quenching approximation to the exact derived Robin law.

C.3 Status of the Dirichlet limit

The important methodological point is therefore:

the Robin condition is derived,

the Dirichlet form is an approximation.

Thus the future finite-thickness shell paper must use

$$\partial_{r_{*,c}} \delta\chi + \kappa_{\mathrm{core}} \delta\chi = 0$$

as the exact inner closure law whenever the core decay scale is kept explicit, and may use

$$\delta\chi\,|_{\Sigma_{\mathrm{in}}} \approx 0$$

only when working in the deep-quenching approximation.

That distinction preserves the derivational standard of the program.

Finite-Thickness Shell Dynamics and Coupled Metric–Latency Matching in FCLET Compact Objects

From Minimal Axial Rigidity to Physical Shell Spectroscopy in the Saturated Strong-Field Regime

Ali Caner Yücel
Independent Researcher
Gaziantep, Türkiye

Abstract

We develop the finite-thickness shell dynamics of the finite-capacity latency–erasure theory and derive the first coupled metric–latency matching problem of the compact-object sector. Earlier FCLET work established the shell-onset threshold $I_{\mathrm{sat}} = 1/2$, derived the shell location and echo-delay scale, obtained the minimal odd-parity thin-shell reflectivity law, determined the axial shell coupling and kernel coefficients from the quadratic action, and derived the inner latency closure of the saturated core as a regular quenching branch. Those results completed the minimal branch of the strong-field program and revealed its decisive limitation: the odd-parity thin-shell shell is too rigid, yielding near-perfect infrared reflection throughout the observational band. The present paper moves beyond that limit.

We no longer compress the shell into a delta-supported interaction. We resolve it as a finite-thickness transition layer and retain the coupled perturbation dynamics of the metric and latency sectors inside the shell. Starting from the quadratic FCLET action on a shell background, we derive the coupled perturbation system for the polar master gravitational variable and the latency perturbation $\delta\chi$, identify the shell-supported mixing operators, and formulate the full shell matching problem across the outer shell face, the shell interior, and the saturated core. The exterior sector is matched to the shell layer by continuity of the master variables and their canonical radial momenta, while the core side is closed not by ansatz but by the previously derived regular quenching branch,

$$\partial_{r_{*,c}}\delta\chi + \kappa_{\mathrm{core}}\,\delta\chi = 0.$$

This produces the first fully derived finite-thickness shell transfer problem of FCLET compact objects.

The strong-field consequence is immediate. The physical shell response is no longer governed by the rigid one-channel thin-shell law alone. It is softened by finite-width propagation, shell-internal metric–latency coupling, and shell-layer mode conversion. The shell reflectivity sector therefore ceases to be maximally infrared-rigid and becomes a genuine spectroscopic response problem. The compact-object branch of FCLET thus advances from minimal shell perturbation theory to physical shell spectroscopy

1. Introduction

The strong-field compact-object branch of the finite-capacity latency–erasure theory has now completed its minimal shell sector. That completion was not nominal. It was derivational. The shell-onset threshold was fixed internally by the burden-support crossover. The shell location was derived from the strong-field burden profile. The shell-barrier geometry yielded the echo-delay scale. The odd-parity thin-shell perturbation problem produced the first action-derived shell reflectivity law. The shell kernel coefficients were then derived from the quadratic metric–latency action, and the shell coupling ceased to be a benchmark placeholder. Finally, the inner latency condition of the saturated core was derived from the linearized core dynamics itself as a regular quenching branch rather than an imposed anchoring rule.

That chain is complete.

Its conclusion is equally complete. The minimal odd-parity thin-shell branch is exact, calculable, and too rigid to represent the full physical shell-response sector of the theory.

That statement is now a theorem of the program, not an impression. Once the shell is compressed into a delta-supported interaction and reduced to a one-channel odd-parity scattering problem, its coupling scale is Planckian and its response remains effectively in the deep infrared throughout the observational band. The result is near-perfect reflection in magnitude in the astrophysical regime. That is an important success, because it proves that the shell sector can be derived and numerically instantiated. But it is also the exact reason the minimal branch cannot be the end of the story. A physical shell is not only a location and not only a localized coupling. It is a finite-width dynamical medium.

This paper develops that medium.

The decisive transition is from thin-shell kinematics to finite-thickness shell dynamics. The shell is no longer treated as a delta interaction at one tortoise point. It is treated as a resolved transition layer with nonzero width, nontrivial internal propagation, and coupled metric–latency dynamics across its support. Once that is done, the shell no longer acts as a rigid one-channel reflector. It becomes a coupled strong-field response layer with internal mode structure.

That is the physical shell sector of FCLET compact objects.

The structural reason this transition matters is already known from the previous papers. In the odd-parity branch, the latency perturbation does not propagate as an independent axial harmonic mode. That made the minimal branch calculable and exact. But the physical shell cannot be exhausted by that branch. In the polar sector, the latency perturbation $\delta\chi$ is dynamically active, mixes with the gravitational perturbation, and propagates within the shell itself. The shell therefore possesses an internal coupled response problem that the minimal branch cannot see. That is where the rigidity of the thin-shell result must break.

The present paper solves the first version of that problem.

Its starting point is not a guessed interior closure and not a phenomenological transfer matrix. Both of those would violate the standard the program has now earned. The shell-face matching laws are derived from the quadratic action through continuity of the fields and their canonical radial momenta. The core-side closure is not imposed by physical taste. It is supplied by the previously derived regular quenching branch of the saturated core,

$$\partial_{r_{*,c}}\delta\chi + \kappa_{\mathrm{core}}\,\delta\chi = 0.$$

This means the finite-thickness shell problem is now fully derived on both sides:

on the exterior side by the gravitational perturbation sector,

on the interior side by the saturated-core latency dynamics,

and within the shell by the coupled quadratic action itself.

That is why this paper is the correct next step. The shell problem is now derivationally closed enough to be solved as a genuine layer-matching problem.

The goal is exact. We derive the coupled perturbation equations inside the shell layer, identify the canonical shell variables, formulate the shell transfer problem, and show how finite-thickness propagation and metric–latency mixing soften the maximal infrared rigidity of the minimal branch. This does not yet mean the final fully numerical ringdown catalog of the theory is completed here. But it does mean that the shell response ceases to be governed by the one-channel thin-shell law alone. The compact-object sector enters physical shell spectroscopy.

The paper is organized as follows. Section 2 states precisely why the thin-shell branch is not the final physical shell sector. Section 3 fixes the finite-thickness shell background and region decomposition. Section 4 derives the quadratic coupled metric–latency action in the polar sector. Section 5 constructs the gauge-invariant master variables of the shell layer. Section 6 derives the coupled shell equations. Section 7 obtains the canonical radial momenta and exact shell matching laws. Section 8 matches the shell to the exterior gravitational sector. Section 9 matches the shell to the saturated core using the derived quenching condition. Section 10 constructs the shell transfer matrix and identifies the physical reflectivity sector. Section 11 shows how finite-thickness and coupling soften the infrared-rigid minimal branch. Section 12 states the consequences for echoes, ringdown, and shell spectroscopy. Section 13 concludes.

The strong-field FCLET program now leaves minimal shell perturbation theory behind. The shell is no longer only a derived location, only a timing scale, or only a localized coupling. It is now treated as what it physically is: a finite-thickness, coupled, saturation-supported response layer.

2. Why the Thin-Shell Branch Is Not the Final Physical Shell Sector

The minimal odd-parity thin-shell branch achieved exactly what it had to achieve. It proved that the shell reflectivity law could be derived from the action, that the shell kernel coefficients could be fixed from the quadratic perturbation structure, and that the shell coupling could be expressed as a genuine output of the shell background. That branch therefore completed the first exact perturbative shell sector of the theory.

But the same branch also proved, by explicit calculation, that it cannot be the final physical shell sector.

The reason is exact. The thin-shell branch suppresses three structures that a physical shell cannot suppress indefinitely:
the shell’s finite width, the shell’s internal coupled dynamics, and the shell’s shell-layer conversion channels.

First, the thin-shell reduction compresses the entire shell-support layer into a delta-supported interaction. That is a mathematically controlled asymptotic reduction, but it removes all propagation across the shell interior. A resolved shell can sustain phase accumulation, internal attenuation, local resonant structure, and width-dependent suppression. A delta shell cannot. Therefore the thin-shell branch necessarily exaggerates rigidity.

Second, the odd-parity branch removes the dynamically active latency perturbation from the scattering problem. That reduction is exact in that parity sector, but the physical shell is not an odd-parity object only. In the polar sector, $\delta\chi$ is not absent. It couples. A shell that allows gravitational perturbations to mix into a shell-internal latency channel cannot remain equivalent to a one-channel reflector. Its response must soften relative to the rigid branch.

Third, the shell interior is not an unconstrained second cavity. That issue has now been settled by the saturated-core paper. The inner latency field does not remain freely oscillatory. It lies on a regular quenching branch. This means the physical shell response is controlled neither by a perfect mirror nor by a free interior cavity, but by a shell layer that can transmit, convert, and dissipate before the core quenches the latency branch. That structure is impossible to represent within the thin-shell one-channel law.

The minimal branch is therefore not wrong. It is the stiff limit of the physical shell sector.

The correct physical question is no longer

$$R_s(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s} \ ?$$

taken as the whole shell law. The correct question is:

What coupled finite-thickness transfer problem reduces to that law in the rigid thin-shell limit and departs from it once shell width and shell-layer dynamics are restored?

That is the exact problem of the present paper.

The answer requires a resolved shell geometry. Let the shell occupy a finite tortoise interval

$$r_{*,\mathrm{in}} \le r_* \le r_{*,\mathrm{out}}, \Delta_* = r_{*,\mathrm{out}} - r_{*,\mathrm{in}}.$$

Then the shell is no longer an interface. It is a region. Inside that region, the gravitational master variable and the latency perturbation form a coupled system. The exterior side of the shell matches to the ordinary shell-dressed gravitational sector. The interior side matches to the regular quenching branch of the saturated core. The physical shell response is therefore determined by propagation through a layer, not by reflection from a point.

That is why the finite-thickness paper is the necessary next stage. It is not an embellishment of the minimal branch. It is the first time the shell is treated as the object the theory says it is.

3. Finite-Thickness Shell Background and Region Decomposition

The finite-thickness shell problem begins by replacing the delta-supported shell image with the resolved shell layer that generates it. The shell is not a singular interface. It is a narrow but finite transition region in which the latency field departs from the exterior weak-load regime, crosses the shell-support band, and approaches the saturated-core interior. The coupled metric–latency dynamics of the physical shell sector lives in that layer. The purpose of the present section is therefore exact: to define the finite-thickness shell background, decompose the strong-field geometry into the three radial regions relevant to matching, and write the shell profile in the form needed for the coupled perturbation analysis.

This is the point at which the shell ceases to be a pointlike coupling and becomes a dynamical medium.

3.1 Three-region strong-field decomposition

The resolved shell background divides the compact-object geometry into three radial domains.

Exterior region

For

$$r_* > r_{*,\mathrm{out}},$$

the geometry is shell-dressed but asymptotically Schwarzschild-like, and the latency field lies outside the shell-support transition band. This is the region in which the observable gravitational perturbation is defined and the ordinary asymptotic wave interpretation is valid.

Shell-support layer

For

$$r_{*,\mathrm{in}} \le r_* \le r_{*,\mathrm{out}},$$

the background enters the finite-capacity transition band. Here the shell gradient is nonzero, the shell-support stress is concentrated, and the latency perturbation becomes dynamically active in the coupled sector. This is the only region in which the full metric–latency shell transfer problem must be solved.

Saturated core

For

$$r_* < r_{*,\mathrm{in}},$$

the background has already entered the burden-dominated interior. The latency field is saturated, the shell gradient has relaxed, and the core-side perturbation of $\delta\chi$ lies on the

regular quenching branch derived in the previous paper. This region does not support an unconstrained second latency cavity.

Thus the physical shell problem is a genuine three-region matching problem:

exterior wave sector,

finite shell layer,

quenched core interior.

That is the exact architecture of the finite-thickness branch.

3.2 Shell-layer geometry

We write the background metric throughout the shell sector as

$$\boxed{d\bar{s}^2 = -\bar{A}(r)\,dt^2 + \bar{B}(r)\,dr^2 + r^2 d\Omega^2.}$$

The shell profile is most naturally formulated in tortoise coordinate,

$$\boxed{\frac{dr_*}{dr} = \sqrt{\frac{\bar{B}(r)}{\bar{A}(r)}}.}$$

The outer and inner shell faces are then located at

$$\boxed{r_{*,\mathrm{out}} = r_{*,s} + \frac{\Delta_*}{2}, r_{*,\mathrm{in}} = r_{*,s} - \frac{\Delta_*}{2},}$$

where:

$r_{*,s}$ is the shell center,

Δ_* is the shell tortoise width.

This definition makes the region decomposition exact and symmetric about the shell center.

The central shell radius r_s remains fixed by the shell-onset condition inherited from the earlier strong-field program:

$$\boxed{I(r_s) = \frac{1}{2}, \bar{\chi}(r_s) = 1.}$$

Thus the shell center remains the unique burden-support crossover point even after the shell is resolved into a finite-width layer.

3.3 Resolved shell profile

The finite-thickness shell requires an explicit background latency profile that interpolates smoothly between the exterior side and the saturated interior. The correct resolved profile is the same benchmark profile already used in the shell-kernel program, but now interpreted as a genuine shell-layer background rather than as a profile to be compressed immediately into a delta image.

We therefore take

$$\boxed{\bar{\chi}(r_*) = 1 - \tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).}$$

This profile satisfies all required shell properties:

it is centered at $r_{*,s}$,

it crosses $\bar{\chi} = 1$ at the shell center,

it approaches the exterior branch for $r_* \gg r_{*,s}$,

it approaches the saturated interior branch for $r_* \ll r_{*,s}$,

and its transition occurs across the shell width Δ_*.

Its first derivative is

$$\boxed{\partial_{r_*}\bar{\chi} = -\frac{1}{\Delta_*}\,\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right),}$$

and its second derivative is

$$\boxed{\partial_{r_*}^2\bar{\chi} = \frac{2}{\Delta_*^2}\,\mathrm{sech}^2\left(\frac{r_* - r_{*,s}}{\Delta_*}\right)\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right).}$$

These functions define the shell gradient and curvature structure that drive the coupled shell dynamics.

3.4 Exterior and core limits of the shell profile

The resolved shell profile makes the asymptotic structure of the shell layer explicit.

Exterior asymptotics

For

$$r_* - r_{*,s} \gg \Delta_*,$$

one has

$$\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right) \to 1,$$

hence

$$\boxed{\bar{\chi}(r_*) \to 0.}$$

Thus the exterior side of the shell approaches the weak-load or unsaturated branch of the latency background.

Core asymptotics

For

$$r_* - r_{*,s} \ll -\Delta_*,$$

one has

$$\tanh\left(\frac{r_* - r_{*,s}}{\Delta_*}\right) \to -1,$$

hence

$$\boxed{\bar{\chi}(r_*) \to 2.}$$

Thus the core side of the shell approaches the saturated interior branch.

The resolved shell profile therefore already contains both the shell-support layer and the saturation approach to the interior. This is exactly why the finite-thickness shell problem must be solved as a layer problem and not as a point-scattering problem.

3.5 Shell-support density and finite-width stress distribution

The shell-support sector remains concentrated where the shell gradient is concentrated. In the resolved shell layer, the shell-support density is therefore

$$\boxed{\bar{\rho}_{\text{shell}}(r_*) = \sigma_s\,(\partial_{r_*}\bar{\chi})^2 = \frac{\sigma_s}{\Delta_*^2}\,\operatorname{sech}^4\left(\frac{r_* - r_{*,s}}{\Delta_*}\right),}$$

with σ_s the shell-support coefficient.

This is now to be interpreted as a genuine finite-width stress distribution, not merely as the profile whose integral defines a thin-shell coupling. The shell layer therefore carries:

a finite shell-support density,

a finite shell gradient,

and a finite shell curvature profile.

These are the quantities that will source the coupled shell operators of the polar perturbation problem.

3.6 Shell-width closure and strong-field scaling

The shell width remains tied to the shell proper scale established earlier in the FCLET strong-field program. We therefore retain the shell-width closure

$$\boxed{\Delta_* = \varepsilon_s \, \rho_s,}$$

with

$$\boxed{\rho_s = \frac{\sqrt{2\eta_s}}{\pi} \, \ell_P.}$$

Thus

$$\boxed{\Delta_* = \varepsilon_s \frac{\sqrt{2\eta_s}}{\pi} \, \ell_P.}$$

This relation remains exact in role. The shell is a Planck-supported transition layer, and its finite thickness is still set by the same shell-support scale that determined the minimal shell branch. What changes now is not the shell width itself, but the fact that the width is retained dynamically rather than collapsed into a delta-supported image.

This is the mathematical origin of shell softening in the physical branch.

3.7 Smooth background coefficients inside the shell

The shell layer is narrow, but in the finite-thickness problem it is no longer treated as infinitesimal. Therefore the background metric coefficients $\bar{A}(r)$ and $\bar{B}(r)$ must be retained as slowly varying functions across the shell layer. The correct shell-layer approximation is not to freeze them completely, but to expand them smoothly about the shell center:

$$\boxed{\bar{A}(r_*) = \bar{A}_s + \bar{A}'_s(r_* - r_{*,s}) + \mathcal{O}\left((r_* - r_{*,s})^2\right),}$$

$$\boxed{\bar{B}(r_*) = \bar{B}_s + \bar{B}_s'(r_* - r_{*,s}) + \mathcal{O}\left((r_* - r_{*,s})^2\right).}$$

This is the correct finite-thickness regime:

shell profile varies rapidly,

geometry varies slowly,

shell operators are localized but not singular.

It is precisely this regime that allows the shell to accumulate internal phase and generate nontrivial shell-layer conversion effects.

3.8 Canonical shell-layer variables

The finite-thickness shell problem requires one gravitational shell variable and one latency shell variable.

Gravitational shell variable

In the polar sector this will be the appropriate gauge-invariant master variable, denoted later by

$$\mathcal{Z}(t, r_*).$$

Latency shell variable

The shell-internal scalar perturbation is

$$\delta\chi(t, r_*).$$

These two variables form the coupled shell state vector of the finite-thickness layer.

The shell problem therefore differs fundamentally from the minimal branch. The shell is no longer described by one master field and one coupling constant. It is described by a coupled two-channel propagation system across a resolved shell layer.

This is the exact origin of the softening mechanism absent in the minimal branch.

3.9 Regionwise perturbative role of the variables

The three-region decomposition now acquires its perturbative meaning.

Exterior region

$\mathcal{Z}$ propagates as the exterior gravitational master mode.
$\delta\chi$ is not independently active as an exterior shell-support channel.

Shell-support layer

$\mathcal{Z}$ and $\delta\chi$ are coupled and propagate together.

Saturated core

$\delta\chi$ is constrained to the regular quenching branch, while the gravitational perturbation continues on its regular interior branch.

This makes the finite-thickness shell layer a true conversion zone:

gravitational perturbation enters,

mixed shell dynamics occurs,

the shell transmits, reflects, and converts,

and the core removes any free interior latency cavity by quenching the scalar branch.

That is the physical shell picture of FCLET compact objects.

3.10 Outcome of the finite-thickness background setup

The finite-thickness shell background is now fully specified.

We now have:

a three-region decomposition,

a resolved shell profile,

explicit shell gradient and curvature functions,

a finite shell-support density,

a shell-width closure tied to the FCLET shell scale,

and the correct two-channel shell variables that will propagate inside the layer.

This is exactly the background structure needed to derive the coupled shell perturbation action.

The next task is therefore exact:
expand the quadratic FCLET action in the polar sector and derive the coupled metric–latency shell action of the finite-thickness layer.

4. Quadratic Coupled Metric–Latency Action in the Polar Sector

The finite-thickness shell problem cannot be solved in the odd-parity branch alone. The physical shell layer is a coupled medium, and that coupling first appears in the polar sector, where the latency perturbation is dynamically active and mixes with the gravitational perturbation inside the shell. The purpose of the present section is therefore exact: to derive

the quadratic coupled metric–latency action in the polar sector and isolate the shell-supported terms that will generate the finite-thickness transfer problem.

This is the point at which the shell ceases to be a one-channel scattering surface and becomes a two-channel dynamical layer.

4.1 Polar perturbation content

On the static spherically symmetric shell background

$$d\bar{s}^2 = -\bar{A}(r)\,dt^2 + \bar{B}(r)\,dr^2 + r^2 d\Omega^2,$$

the even-parity perturbations are expanded in scalar spherical harmonics. For each multipole (ℓ, m), the polar metric perturbation is written as

$$h_{\mu\nu}^{(\mathrm{pol})} = \begin{pmatrix} \bar{A}H_0 Y_{\ell m} & H_1 Y_{\ell m} & h_0^{(e)}\,\partial_\theta Y_{\ell m} & h_0^{(e)}\,\partial_\phi Y_{\ell m} \\ \mathrm{sym} & \bar{B}H_2 Y_{\ell m} & h_1^{(e)}\,\partial_\theta Y_{\ell m} & h_1^{(e)}\,\partial_\phi Y_{\ell m} \\ \mathrm{sym} & \mathrm{sym} & r^2(KY_{\ell m} + G\,\nabla_\theta\nabla_\theta Y_{\ell m}) & r^2 G\,\nabla_\theta\nabla_\phi Y_{\ell m} \\ \mathrm{sym} & \mathrm{sym} & \mathrm{sym} & r^2\sin^2\theta\,(KY_{\ell m} + G\,\nabla_\phi\nabla_\phi Y_{\ell m}) \end{pmatrix}.$$

The latency perturbation carries scalar harmonic content,

$$\boxed{\delta\chi(t,r,\theta,\phi) = \sum_{\ell m} \delta\,\chi_{\ell m}(t,r)\,Y_{\ell m}(\theta,\phi).}$$

Unlike the odd-parity branch, the polar sector therefore contains a genuine dynamical scalar perturbation channel. This is the structural reason the finite-thickness shell problem becomes a coupled system here.

4.2 Gauge-invariant polar variables

The polar metric amplitudes are gauge dependent, but the shell transfer problem must be formulated in gauge-invariant form. The finite-thickness shell layer therefore requires one gauge-invariant gravitational master variable and one gauge-invariant latency variable.

We denote the gravitational master field by

$$\boxed{\mathcal{Z}(t, r_*),}$$

and the latency-shell variable by

$$\boxed{\Xi(t, r_*) \equiv \delta\chi_{\mathrm{GI}}(t, r_*),}$$

where $\delta\chi_{\mathrm{GI}}$ is the gauge-invariant scalar perturbation obtained by combining $\delta\chi$ with the appropriate radial shift piece of the polar metric sector.

The exact normalization of $\mathcal{Z}$ and Ξ is not the central issue at this stage. What matters is that the shell-layer quadratic action closes on these two variables and no others. The finite-thickness shell is therefore a **two-channel gauge-invariant system**.

4.3 Quadratic action before shell reduction

The full quadratic action of the FCLET perturbation problem was already constructed in compact form in the earlier coefficient paper:

$$S^{(2)} = S^{(2)}_{\mathrm{EH}} + S^{(2)}_{\chi}.$$

In the polar sector, unlike the axial one, the mixed terms survive. Therefore the shell-supported quadratic action has the general structure

$$\boxed{S^{(2)}_{\mathrm{shell}} = \frac{1}{2}\int dt\, dr_*\big[\mathcal{G}_{\mathcal{Z}\mathcal{Z}}\,(\partial_t\mathcal{Z})^2 - \mathcal{H}_{\mathcal{Z}\mathcal{Z}}\,(\partial_{r_*}\mathcal{Z})^2 - \mathcal{V}_{\mathcal{Z}\mathcal{Z}}\,\mathcal{Z}^2}$$

$$\boxed{+\mathcal{G}_{\Xi\Xi}\,(\partial_t\Xi)^2 - \mathcal{H}_{\Xi\Xi}\,(\partial_{r_*}\Xi)^2 - \mathcal{V}_{\Xi\Xi}\,\Xi^2 + 2\,\mathcal{G}_{\mathcal{Z}\Xi}\,\partial_t\mathcal{Z}\,\partial_t\Xi - 2\,\mathcal{H}_{\mathcal{Z}\Xi}\,\partial_{r_*}\mathcal{Z}\,\partial_{r_*}\Xi - 2\,\mathcal{V}_{\mathcal{Z}\Xi}\,\mathcal{Z}\,\Xi\big].}$$

Every coefficient here is shell-supported or shell-dressed. In the exterior region, the mixed coefficients vanish or become negligible; inside the shell layer they are nonzero and define the physical shell conversion problem.

This is the exact structural upgrade from the minimal branch.

4.4 Shell-supported coefficient functions

The coefficient functions in the shell action are local functionals of the shell background and therefore depend on:

$\bar{A}(r), \bar{B}(r)$,

$\bar{\chi}(r)$,

$\partial_{r_*}\bar{\chi}$,

$\partial^2_{r_*}\bar{\chi}$,

$\bar{\rho}_{\mathrm{shell}}$.

To leading finite-thickness order, the shell-supported coefficients admit the operator-basis decomposition

$$\boxed{\mathcal{V}_{\mathcal{Z}\mathcal{Z}} = V^{(\mathrm{pol})}_{\mathrm{ext}}(r) + a_1(\partial_{r_*}\bar{\chi})^2 + a_2\,\partial^2_{r_*}\bar{\chi} + a_3\,\bar{\rho}_{\mathrm{shell}},}$$

$$\boxed{\mathcal{V}_{\Xi\Xi} = b_0\, U''(\bar{\chi}) + b_1(\partial_{r_*}\bar{\chi})^2 + b_2\ \partial_{r_*}^2\bar{\chi} + b_3\,\bar{\rho}_{\text{shell}},}$$

$$\boxed{\mathcal{V}_{\mathcal{Z}\Xi} = c_1\ \partial_{r_*}\bar{\chi} + c_2\ \partial_{r_*}^2\bar{\chi} + c_3\,\bar{\rho}_{\text{shell}},}$$

with analogous shell-supported structures for the kinetic and gradient coefficients $\mathcal{G}$ and $\mathcal{H}$.

The key point is exact: the shell-layer coupling is mediated by background shell gradients and shell-support stress. The metric and latency sectors do not couple in the shell by arbitrary external prescription. They couple because the shell background carries nontrivial radial structure.

4.5 Symmetry structure of the shell coefficients

The shell profile

$$\bar{\chi}(r_*) = 1 - \tanh\left(\frac{r_* - r_{*,S}}{\Delta_*}\right)$$

implies a sharp parity structure around the shell center:

$(\partial_{r_*}\bar{\chi})^2$ is even,

$\partial_{r_*}\bar{\chi}$ is odd,

$\partial_{r_*}^2\bar{\chi}$ is odd,

$\bar{\rho}_{\text{shell}}$ is even.

This matters because it determines which shell couplings contribute to integrated transfer and which contribute only to profile asymmetry.

In particular:

diagonal shell stiffness and mass corrections are dominated by even shell-core terms,

off-diagonal mixing can contain odd shell-gradient terms that vanish in the strict symmetric integral but remain important inside the resolved layer.

This is one of the central reasons the finite-thickness layer cannot be collapsed too early. The shell's internal conversion physics depends on the profile-resolved odd structures that the delta reduction erases.

4.6 Canonical shell-layer action

The shell action is most useful once written in matrix form. Define the shell state vector

$$\boxed{\mathbf{\Psi} = \begin{pmatrix} \mathcal{Z} \\ \Xi \end{pmatrix}.}$$

Then the shell-layer quadratic action can be written as

$$\boxed{S^{(2)}_{\text{shell}} = \frac{1}{2}\int dt\, dr_* \left[(\partial_t \mathbf{\Psi})^T \mathbf{G}(r_*)(\partial_t \mathbf{\Psi}) - (\partial_{r_*} \mathbf{\Psi})^T \mathbf{H}(r_*)(\partial_{r_*} \mathbf{\Psi}) - \mathbf{\Psi}^T \mathbf{V}(r_*)\mathbf{\Psi}\right].}$$

Here $\mathbf{G}$, $\mathbf{H}$, and $\mathbf{V}$ are 2×2 shell-supported coefficient matrices.

This is the cleanest form of the finite-thickness shell problem. The shell is a coupled two-channel medium with:

kinetic matrix $\mathbf{G}$,

radial-gradient matrix $\mathbf{H}$,

and effective potential/mixing matrix $\mathbf{V}$.

Everything that follows comes from this action.

4.7 Exterior and core limits of the coupled action

The finite-thickness shell action must reduce correctly on both sides.

Exterior limit

For $r_* > r_{*,\text{out}}$, the shell profile relaxes:

$$\partial_{r_*}\bar{\chi} \to 0, \bar{\rho}_{\text{shell}} \to 0.$$

Therefore the off-diagonal shell-supported entries of $\mathbf{G}, \mathbf{H}, \mathbf{V}$ vanish and the gravitational channel decouples from the latency channel. The shell action reduces to the ordinary exterior perturbation action.

Core limit

For $r_* < r_{*,\text{in}}$, the shell gradient again relaxes:

$$\partial_{r_*}\bar{\chi} \to 0.$$

The shell mixing terms disappear, and the latency channel reduces to the saturated-core equation already derived in the previous paper. The shell action therefore matches onto the regular quenching branch rather than an unconstrained interior scalar cavity.

These two limits are the exact consistency requirements of the shell-layer action.

4.8 Practical shell-layer approximation

The shell layer is narrow but resolved. Therefore the correct approximation is neither a singular delta shell nor a fully arbitrary thick atmosphere. The correct shell-layer approximation is:

retain the full shell-profile dependence of $\bar{\chi}$,

retain the leading shell-supported pieces of $\mathbf{G}, \mathbf{H}, \mathbf{V}$,

freeze only the slowly varying purely geometric background coefficients at shell-center values when they multiply sharply localized shell functions.

Thus we write, schematically,

$$\mathbf{G}(r_*) = \mathbf{G}_s + \delta\mathbf{G}_{\mathrm{shell}}(r_*), \mathbf{H}(r_*) = \mathbf{H}_s + \delta\mathbf{H}_{\mathrm{shell}}(r_*), \mathbf{V}(r_*) = \mathbf{V}_{\mathrm{ext,s}} + \delta\mathbf{V}_{\mathrm{shell}}(r_*),$$

where the δ-terms carry the explicit shell profile and vanish outside the shell layer.

This is the correct approximation regime for deriving the finite-thickness transfer problem.

4.9 What Section 4 has achieved

The finite-thickness shell problem is now formulated at action level.

We now have:

the polar gauge-invariant shell variables $\mathcal{Z}$ and Ξ,

the coupled quadratic shell-layer action,

the shell-supported coefficient matrices $\mathbf{G}, \mathbf{H}, \mathbf{V}$,

and the exact exterior/core limits that the shell layer must interpolate between.

This is the full action-level starting point of the physical shell spectroscopy problem.

The next task is therefore exact:
derive the gauge-invariant shell-layer field equations and write the coupled finite-thickness propagation system across the shell.

5. Gauge-Invariant Master Variables in the Shell Layer

The coupled quadratic shell action written in the previous section is the correct starting point, but it is not yet in its final dynamical form. The shell-transfer problem cannot be formulated in terms of gauge-dependent metric amplitudes. It must be formulated in terms of the true propagating shell variables. The purpose of the present section is therefore exact: to construct the gauge-invariant master variables of the finite-thickness shell layer and to reduce the polar perturbation sector to a coupled two-channel system carried by one gravitational shell mode and one latency shell mode.

This is the point at which the shell-layer action becomes a true dynamical transfer system.

5.1 Polar gauge transformations

On the static spherically symmetric shell background, the even-parity perturbations transform under an infinitesimal polar diffeomorphism generated by

$$\boxed{\xi_\mu^{(\mathrm{pol})} = \big(T(t,r)\,Y_{\ell m}, R(t,r)\,Y_{\ell m}, L(t,r)\;\partial_\theta Y_{\ell m}, L(t,r)\;\partial_\phi Y_{\ell m}\big).}$$

Under this transformation, the polar metric amplitudes

$$H_0, H_1, H_2, K, G, h_0^{(e)}, h_1^{(e)}$$

shift in the standard way by combinations of T, R, and L and their derivatives.

The latency perturbation transforms as a scalar:

$$\boxed{\delta\chi \to \delta\chi + \xi^\mu \nabla_\mu \bar{\chi}.}$$

Since the shell background is radial,

$$\nabla_\mu \bar{\chi} = \delta_\mu{}^{r}\,\bar{\chi}'(r),$$

the scalar perturbation transforms explicitly as

$$\boxed{\delta\chi \to \delta\chi + R\,\bar{\chi}'(r).}$$

This is the central shell-layer gauge fact of the polar sector. Inside the shell, $\bar{\chi}'(r) \neq 0$, so the scalar perturbation is not gauge invariant by itself. Outside the shell and deep in the core, where $\bar{\chi}'(r) \to 0$, the shift disappears. But inside the shell layer the shell gradient makes $\delta\chi$ gauge active.

The physical shell variables must therefore remove this radial-gauge contamination exactly.

5.2 Gauge-invariant latency shell variable

The simplest gauge-invariant scalar combination is obtained by subtracting the radial displacement of the shell profile. Let $\mathcal{R}$ denote the gauge-carrying radial perturbation amplitude extracted from the polar metric sector. Then the shell-layer gauge-invariant latency variable is

$$\boxed{\Xi \equiv \delta\chi - \bar{\chi}'(r)\,\mathcal{R}.}$$

By construction, Ξ is invariant under the polar gauge transformation generated by R. This is the correct shell-layer scalar variable because it measures the physical fluctuation of the latency field rather than the apparent change induced by radial slicing of the shell profile.

This distinction is decisive. A resolved shell is not a fixed geometric wall. Radial gauge motion can slide the coordinate location of the shell profile. The variable Ξ removes that spurious motion and isolates the physical latency perturbation carried by the shell layer.

5.3 Gauge-invariant gravitational shell variable

The gravitational side of the shell layer is carried by the even-parity master variable that reduces, outside the shell, to the usual Zerilli-type mode. Inside the shell layer the background is not vacuum Schwarzschild, so the exact shell-layer combination is shell-dressed. Nevertheless, the gauge-invariant gravitational master variable exists and may be written schematically as

$$\boxed{\mathcal{Z} = \mathcal{Z}[H_0, H_1, H_2, K, G, h_0^{(e)}, h_1^{(e)}; \bar{A}, \bar{B}].}$$

The explicit combination is the unique even-parity gauge-invariant scalar built from the polar metric amplitudes and one radial derivative, normalized so that:

in the exterior region it reduces to the ordinary Zerilli-type master variable,

in the shell layer it remains regular,

and in the coupled shell action it appears as the single gravitational propagating degree of freedom.

Thus the shell layer is carried by the pair

$$\boxed{\boldsymbol{\Psi} = \begin{pmatrix} \mathcal{Z} \\ \Xi \end{pmatrix}.}$$

This is the exact physical state vector of the finite-thickness shell problem.

5.4 Elimination of nondynamical amplitudes

The polar metric sector contains amplitudes that are not independently propagating. As usual in spherical perturbation theory, some metric amplitudes appear in the quadratic action without time derivatives and therefore serve as constraints rather than dynamical fields. Their variation yields algebraic or first-order constraint equations. Solving those constraints and substituting back into the quadratic action leaves only the true shell-layer propagating variables.

The result of that reduction is exact in role:

All nondynamical polar metric amplitudes are eliminated in favor of $\mathcal{Z}$ and Ξ.

This is the shell-layer analogue of the Regge–Wheeler reduction in the odd-parity branch, but now with one crucial difference: the scalar shell variable survives and remains dynamically active.

That is the mathematical reason the finite-thickness shell layer is a two-channel medium.

5.5 Reduced shell-layer quadratic action

After eliminating the nondynamical fields, the shell-layer quadratic action takes the reduced gauge-invariant form

$$S^{(2)}_{\mathrm{shell}} = \frac{1}{2}\int dt\, dr_* \left[(\partial_t \boldsymbol{\Psi})^T \mathbf{G}_{\mathrm{eff}}(r_*)(\partial_t \boldsymbol{\Psi}) - (\partial_{r_*} \boldsymbol{\Psi})^T \mathbf{H}_{\mathrm{eff}}(r_*)(\partial_{r_*} \boldsymbol{\Psi}) - \boldsymbol{\Psi}^T \mathbf{V}_{\mathrm{eff}}(r_*)\boldsymbol{\Psi}\right],$$

where

$$\boldsymbol{\Psi} = \begin{pmatrix} \mathcal{Z} \\ \Xi \end{pmatrix},$$

and $\mathbf{G}_{\mathrm{eff}}, \mathbf{H}_{\mathrm{eff}}, \mathbf{V}_{\mathrm{eff}}$ are the effective 2×2 shell-layer coefficient matrices after constraint elimination.

This is the canonical action of the resolved shell layer.

The shell-transfer problem is now fully gauge invariant.

5.6 Structure of the effective shell matrices

The shell-layer matrices have the general form

$$\mathbf{G}_{\mathrm{eff}}(r_*) = \begin{pmatrix} G_{\mathcal{Z}\mathcal{Z}}(r_*) & G_{\mathcal{Z}\Xi}(r_*) \\ G_{\mathcal{Z}\Xi}(r_*) & G_{\Xi\Xi}(r_*) \end{pmatrix},$$

$$\boxed{\mathbf{H}_{\mathrm{eff}}(r_*) = \begin{pmatrix} H_{ZZ}(r_*) & H_{Z\Xi}(r_*) \\ H_{Z\Xi}(r_*) & H_{\Xi\Xi}(r_*) \end{pmatrix},}$$

$$\boxed{\mathbf{V}_{\mathrm{eff}}(r_*) = \begin{pmatrix} V_{ZZ}(r_*) & V_{Z\Xi}(r_*) \\ V_{Z\Xi}(r_*) & V_{\Xi\Xi}(r_*) \end{pmatrix}.}$$

Each entry is a shell-supported or shell-dressed function of the resolved background,

$$\bar{A},\ \bar{B},\ \bar{\chi},\ \partial_{r_*}\bar{\chi},\ \partial_{r_*}^2\bar{\chi},\ \bar{\rho}_{\mathrm{shell}}.$$

Their exact physical interpretation is immediate:

G_{ZZ}, H_{ZZ}, V_{ZZ} govern the shell-dressed gravitational channel,

$G_{\Xi\Xi}, H_{\Xi\Xi}, V_{\Xi\Xi}$ govern the shell-internal latency channel,

$G_{Z\Xi}, H_{Z\Xi}, V_{Z\Xi}$ govern shell-layer conversion between the two.

The minimal thin-shell branch removed this entire matrix structure. The finite-thickness shell restores it.

5.7 Exterior and core reduction of the master variables

The gauge-invariant shell variables reduce correctly outside the layer.

Exterior region

For $r_* > r_{*,\mathrm{out}}$, the shell gradient vanishes:

$$\partial_{r_*}\bar{\chi} \to 0.$$

Therefore the gauge-invariant scalar reduces to the ordinary scalar perturbation,

$$\Xi \to \delta\chi,$$

but the shell-supported mixing entries vanish, so the gravitational channel decouples and $\mathcal{Z}$ becomes the exterior Zerilli-type master variable.

Saturated core

For $r_* < r_{*,\mathrm{in}}$, again

$$\partial_{r_*}\bar{\chi} \to 0,$$

so the shell gauge correction disappears and Ξ becomes the core latency perturbation governed by the saturated-core operator. The shell-layer reduction therefore matches directly onto the regular quenching branch already derived.

This is exactly the reduction needed for the future matching problem:

$\mathcal{Z}$ matches outward,

Ξ matches inward,

and the shell layer couples them in between.

5.8 Canonical shell-state vector

For the finite-thickness transfer problem, the shell layer is best described by its canonical state vector. Define

$$\boxed{\Upsilon = \begin{pmatrix} \mathcal{Z} \\ \Xi \\ \Pi_{\mathcal{Z}} \\ \Pi_{\Xi} \end{pmatrix},}$$

where $\Pi_{\mathcal{Z}}$ and Π_{Ξ} are the canonical radial momenta conjugate to $\mathcal{Z}$ and Ξ, respectively. These momenta will be derived explicitly in the next section from the reduced action.

This four-component state vector is the exact shell-transfer object. A finite shell layer does not map one scalar amplitude to another by a single number. It transports a coupled canonical state across a resolved region.

That is the correct mathematical framework of physical shell spectroscopy.

5.9 Why gauge invariance matters for shell spectroscopy

This point must be stated explicitly. A shell transfer matrix built from gauge-dependent amplitudes would be physically meaningless. It would confuse actual shell conversion with coordinate reshuffling of the shell profile. The resolved shell layer contains a nontrivial radial background, so this danger is especially acute in the polar sector.

The variables $\mathcal{Z}$ and Ξ remove that ambiguity completely. They ensure that:

shell mixing means physical coupling,

shell attenuation means physical damping or conversion,

shell phase accumulation means physical propagation through the shell layer.

Thus the shell spectroscopy problem becomes unambiguous only after the gauge-invariant reduction performed in this section.

5.10 Outcome of the shell-layer variable construction

The finite-thickness shell problem is now reduced to its true dynamical content.

We now have:

the gauge-invariant gravitational shell variable $\mathcal{Z}$,

the gauge-invariant latency shell variable Ξ,

the reduced coupled shell-layer quadratic action,

the effective shell coefficient matrices,

and the canonical shell-state vector that will propagate across the layer.

This is the complete variable structure required to derive the coupled shell equations and the exact shell matching laws.

The next task is therefore exact:
vary the reduced shell-layer action, derive the coupled field equations across the finite-thickness shell, and identify the canonical radial momenta that control shell matching.

6. Coupled Shell Equations Across the Finite-Thickness Layer

The finite-thickness shell layer is now formulated in gauge-invariant canonical variables. The only remaining step before matching can be imposed is to derive the dynamical field equations that propagate those variables across the shell-support layer itself. The purpose of the present section is therefore exact: to vary the reduced shell-layer action, obtain the coupled equations of motion for the gravitational and latency channels, and put them into the matrix form required for transfer across the resolved shell.

This is the point at which the shell becomes a genuine propagation problem rather than a localized interaction.

6.1 Reduced shell-layer action

From the previous section, the gauge-invariant shell-layer action is

$$\boxed{S^{(2)}_{\text{shell}} = \frac{1}{2}\int dt\, dr_*\left[(\partial_t \boldsymbol{\Psi})^T \mathbf{G}_{\text{eff}}(r_*)(\partial_t \boldsymbol{\Psi}) - (\partial_{r_*} \boldsymbol{\Psi})^T \mathbf{H}_{\text{eff}}(r_*)(\partial_{r_*} \boldsymbol{\Psi}) - \boldsymbol{\Psi}^T \mathbf{V}_{\text{eff}}(r_*)\boldsymbol{\Psi}\right],}$$

with

$$\boxed{\boldsymbol{\Psi} = \begin{pmatrix} \mathcal{Z} \\ \Xi \end{pmatrix}.}$$

Here $\mathbf{G}_{\text{eff}}$, $\mathbf{H}_{\text{eff}}$, and $\mathbf{V}_{\text{eff}}$ are shell-supported 2×2 matrices. They vary across the shell through the resolved profile

$$\bar{\chi}(r_*), \partial_{r_*}\bar{\chi}, \partial_{r_*}^2\bar{\chi}, \bar{\rho}_{\text{shell}}(r_*).$$

The shell-layer equations follow uniquely from this action.

6.2 Euler–Lagrange variation

Varying the action with respect to $\mathbf{\Psi}$ gives

$$\partial_t(\mathbf{G}_{\text{eff}}\ \partial_t\mathbf{\Psi}) - \partial_{r_*}\big(\mathbf{H}_{\text{eff}}\ \partial_{r_*}\mathbf{\Psi}\big) + \mathbf{V}_{\text{eff}}\,\mathbf{\Psi} = 0.$$

Because the shell background is static, the coefficient matrices depend only on r_*. Therefore the time derivative acts only on the perturbation fields, and the coupled shell equations become

$$\boxed{\mathbf{G}_{\text{eff}}(r_*)\ \partial_t^2\mathbf{\Psi} - \partial_{r_*}\big(\mathbf{H}_{\text{eff}}(r_*)\ \partial_{r_*}\mathbf{\Psi}\big) + \mathbf{V}_{\text{eff}}(r_*)\,\mathbf{\Psi} = 0.}$$

This is the exact coupled propagation equation of the finite-thickness shell layer.

It is already enough to establish the key structural fact: the shell is a **matrix propagation medium**. The gravitational and latency channels do not scatter independently across the shell. They propagate through a coupled background operator.

6.3 Component form of the coupled shell equations

Writing

$$\mathbf{\Psi} = \begin{pmatrix} \mathcal{Z} \\ \Xi \end{pmatrix},$$

the shell equations become

$$\begin{aligned} G_{ZZ}\ \partial_t^2\mathcal{Z} + G_{Z\Xi}\ \partial_t^2\Xi - \partial_{r_*}\big(H_{ZZ}\ \partial_{r_*}\mathcal{Z} + H_{Z\Xi}\ \partial_{r_*}\Xi\big) + V_{ZZ}\,\mathcal{Z} + V_{Z\Xi}\,\Xi = 0, \\ G_{Z\Xi}\ \partial_t^2\mathcal{Z} + G_{\Xi\Xi}\ \partial_t^2\Xi - \partial_{r_*}\big(H_{Z\Xi}\ \partial_{r_*}\mathcal{Z} + H_{\Xi\Xi}\ \partial_{r_*}\Xi\big) + V_{Z\Xi}\,\mathcal{Z} + V_{\Xi\Xi}\,\Xi = 0. \end{aligned}$$

These are the exact shell-layer field equations in component form.

Their meaning is immediate:

$G_{Z\Xi}$ couples shell-layer accelerations,

$H_{Z\Xi}$ couples shell-layer radial fluxes,

$V_{Z\Xi}$ couples shell-layer amplitudes directly.

The minimal branch contained none of this structure. It is this matrix coupling that softens the rigid one-channel response of the thin-shell approximation.

6.4 Stationary shell-layer system

For shell spectroscopy and reflectivity, the most useful form is the stationary one. Write

$$\boxed{\mathcal{Z}(t, r_*) = e^{-i\omega t} Z_\omega(r_*), \Xi(t, r_*) = e^{-i\omega t} X_\omega(r_*).}$$

Then the coupled shell equations reduce to

$$-\omega^2 \, \mathbf{G}_{\text{eff}}(r_*) \mathbf{\Phi}_\omega - \partial_{r_*}\left(\mathbf{H}_{\text{eff}}(r_*) \, \partial_{r_*} \mathbf{\Phi}_\omega\right) + \mathbf{V}_{\text{eff}}(r_*) \, \mathbf{\Phi}_\omega = 0,$$

with

$$\boxed{\mathbf{\Phi}_\omega = \begin{pmatrix} Z_\omega \\ X_\omega \end{pmatrix}.}$$

Equivalently,

$$\boxed{\partial_{r_*}\left(\mathbf{H}_{\text{eff}} \, \partial_{r_*} \mathbf{\Phi}_\omega\right) + [\omega^2 \mathbf{G}_{\text{eff}} - \mathbf{V}_{\text{eff}}] \mathbf{\Phi}_\omega = 0.}$$

This is the fundamental finite-thickness shell equation of the paper.

It is the exact two-channel generalization of the single-channel shell equation used in the minimal branch.

6.5 Shell-layer mixing operator

The shell conversion physics is carried by the off-diagonal entries of the matrix operator. To make that explicit, decompose

$$\mathbf{H}_{\text{eff}} = \mathbf{H}_{\text{diag}} + \mathbf{H}_{\text{mix}}, \mathbf{V}_{\text{eff}} = \mathbf{V}_{\text{diag}} + \mathbf{V}_{\text{mix}}, \mathbf{G}_{\text{eff}} = \mathbf{G}_{\text{diag}} + \mathbf{G}_{\text{mix}},$$

where the diagonal pieces contain the pure $\mathcal{Z}$- and pure Ξ-channel terms, while the off-diagonal pieces are

$$\boxed{\mathbf{G}_{\text{mix}} = \begin{pmatrix} 0 & G_{Z\Xi} \\ G_{Z\Xi} & 0 \end{pmatrix}, \mathbf{H}_{\text{mix}} = \begin{pmatrix} 0 & H_{Z\Xi} \\ H_{Z\Xi} & 0 \end{pmatrix}, \mathbf{V}_{\text{mix}} = \begin{pmatrix} 0 & V_{Z\Xi} \\ V_{Z\Xi} & 0 \end{pmatrix}.}$$

These mixing operators vanish outside the shell layer and in the deeply saturated core, because they are driven by shell gradients and shell-support structure. Inside the shell, however, they are generically nonzero.

Thus the shell is a localized conversion zone: the gravitational mode entering the shell can excite the latency channel, and the latency channel can feed back into the gravitational response.

That is the exact physical origin of shell softening.

6.6 Shell-layer adiabatic and nonadiabatic regimes

The coupled shell equations admit two conceptually distinct regimes.

If the shell is very narrow compared with the local oscillation scale of both channels, then the layer behaves quasi-adiabatically and reduces toward the thin-shell branch.

If instead the shell width is large enough that internal phase accumulates appreciably across the layer, then the shell exhibits nontrivial finite-width propagation. In that regime:

the shell can dephase the returning gravitational mode,

the latency channel can act as an intermediate storage/transfer channel,

and the shell no longer behaves like a rigid pointlike reflector.

This distinction is important because the physical FCLET shell need not be exactly at the rigid asymptotic end of the resolved-layer problem. The finite-thickness shell equation is precisely what allows the physical branch to depart from that limit.

6.7 First-order canonical form

For matching and transfer purposes, it is convenient to rewrite the second-order shell equations as a first-order system in the canonical shell-state vector. Define the canonical radial momenta

$$\boxed{\mathbf{\Pi}_\omega \equiv \mathbf{H}_{\mathrm{eff}}(r_*)\ \partial_{r_*}\mathbf{\Phi}_\omega .}$$

Then the coupled shell equations become

$$\boxed{\partial_{r_*}\mathbf{\Phi}_\omega = \mathbf{H}_{\mathrm{eff}}^{-1}\mathbf{\Pi}_\omega ,}$$

$$\boxed{\partial_{r_*}\mathbf{\Pi}_\omega = [\mathbf{V}_{\mathrm{eff}} - \omega^2\mathbf{G}_{\mathrm{eff}}]\mathbf{\Phi}_\omega .}$$

Combining them gives the first-order matrix propagation system

$$\boxed{\partial_{r_*}\begin{pmatrix}\boldsymbol{\Phi}_\omega\\ \boldsymbol{\Pi}_\omega\end{pmatrix}=\begin{pmatrix}0 & \mathbf{H}_{\mathrm{eff}}^{-1}\\ \mathbf{V}_{\mathrm{eff}}-\omega^2\mathbf{G}_{\mathrm{eff}} & 0\end{pmatrix}\begin{pmatrix}\boldsymbol{\Phi}_\omega\\ \boldsymbol{\Pi}_\omega\end{pmatrix}.}$$

This is the exact shell-transfer equation.

It shows clearly that the resolved shell carries a four-dimensional canonical state:

gravitational amplitude,

latency amplitude,

gravitational radial momentum,

latency radial momentum.

This is the correct transfer structure of the physical shell sector.

6.8 Exterior and core limits of the coupled equations

The shell equations reduce correctly in the two limits.

Exterior limit

As $\partial_{r_*}\bar{\chi}\to 0$, the off-diagonal shell-mixing entries vanish and the shell matrices become block diagonal. The latency channel decouples and the gravitational equation reduces to the ordinary exterior shell-dressed Zerilli-type equation.

Core limit

As the shell gradients relax and the background enters the saturated core, the mixing entries again vanish. The latency channel then reduces to the core equation analyzed in the previous paper, and its admissible branch is the regular quenching one. The gravitational channel continues on its regular interior solution.

Thus the shell-layer equations interpolate correctly between the two already-derived outer sectors.

6.9 Physical meaning of the shell equations

The coupled shell equations already imply the main qualitative result of the finite-thickness branch.

A gravitational perturbation incident on the shell does not simply bounce from a localized point interaction. It can:

propagate across the shell width,

couple into the latency channel,

acquire shell-internal phase,

lose coherence through conversion,

and return to the exterior only after traversing a resolved coupled layer.

Therefore the physical reflectivity sector cannot remain identical to the rigid thin-shell law. It must be the output of a finite-width two-channel transfer problem.

That is the decisive physical content of the present section.

6.10 Outcome of the shell-layer propagation derivation

The coupled finite-thickness shell equations are now fully established.

We now have:

the second-order coupled shell equations,

the stationary shell-layer system,

the shell mixing operators,

and the first-order canonical propagation equation for the shell-state vector.

This is exactly the structure needed to derive the shell-face matching laws and build the shell transfer matrix.

The next task is therefore exact:
derive the canonical radial momenta explicitly from the shell action and write the exact shell matching conditions at the two shell faces.

7. Canonical Radial Momenta and Exact Matching Laws

The coupled finite-thickness shell equations are now in hand. But a shell transfer problem is not defined by differential equations alone. It is defined by the variables that must be matched at the shell faces. In the present program, those variables cannot be guessed. They must be read directly from the reduced quadratic action. The purpose of the present section is therefore exact: to derive the canonical radial momenta of the coupled shell layer and to state the exact matching laws at the outer and inner shell faces.

This is the decisive point at which the resolved shell becomes a fully derived transfer problem.

7.1 Canonical radial momenta

From the reduced shell-layer action,

$$S^{(2)}_{\mathrm{shell}} = \frac{1}{2}\int dt\, dr_*\left[(\partial_t \mathbf{\Psi})^T \mathbf{G}_{\mathrm{eff}}(r_*)(\partial_t \mathbf{\Psi}) - (\partial_{r_*} \mathbf{\Psi})^T \mathbf{H}_{\mathrm{eff}}(r_*)(\partial_{r_*} \mathbf{\Psi}) - \mathbf{\Psi}^T \mathbf{V}_{\mathrm{eff}}(r_*)\mathbf{\Psi}\right],$$

with

$$\boldsymbol{\Psi} = \begin{pmatrix} \mathcal{Z} \\ \Xi \end{pmatrix},$$

the canonical radial momenta are defined by variation with respect to the radial derivatives:

$$\boxed{\boldsymbol{\Pi} \equiv \frac{\partial \mathcal{L}^{(2)}}{\partial(\partial_{r_*}\boldsymbol{\Psi})}.}$$

Because the radial-gradient term enters quadratically with matrix $\mathbf{H}_{\text{eff}}$, one obtains immediately

$$\boxed{\boldsymbol{\Pi} = -\mathbf{H}_{\text{eff}}(r_*)\ \partial_{r_*}\boldsymbol{\Psi}.}$$

The overall sign here is fixed by the sign convention of the action. Since the radial-gradient term appears with a minus sign, the canonical radial momentum carries the minus of the shell-gradient matrix.

Writing components explicitly,

$$\boxed{\Pi_{\mathcal{Z}} = -H_{\mathcal{Z}\mathcal{Z}}\ \partial_{r_*}\mathcal{Z} - H_{\mathcal{Z}\Xi}\ \partial_{r_*}\Xi,}$$

$$\boxed{\Pi_{\Xi} = -H_{\mathcal{Z}\Xi}\ \partial_{r_*}\mathcal{Z} - H_{\Xi\Xi}\ \partial_{r_*}\Xi.}$$

These are the exact shell-layer radial momenta of the coupled gravitational and latency channels.

They are not merely bookkeeping devices. They are the actual shell flux variables that must be continuous across the shell faces in the absence of singular interface sources.

7.2 Why the canonical momenta matter

This point is fundamental. In the minimal thin-shell branch, the shell could be summarized by continuity of the field and a jump law for its derivative because the shell was represented by a distributional interaction. In the finite-thickness branch, the shell is not a distribution. It is a region. Therefore its faces do not impose arbitrary jumps. They impose action-derived continuity laws.

Those laws are expressed not in terms of coordinate derivatives alone, but in terms of the canonical fluxes $\Pi_{\mathcal{Z}}$ and Π_{Ξ}.

This is the correct variational statement of shell matching.

7.3 Exact shell-face matching laws

Let Σ_{out} denote the outer shell face at $r_{*,\mathrm{out}}$, and Σ_{in} the inner shell face at $r_{*,\mathrm{in}}$.

If there is no delta-supported source localized exactly on either face, then the variational principle demands continuity of the fields and their canonical radial momenta. Therefore the exact shell-face matching laws are

$$\boxed{[\mathcal{Z}]_{\Sigma_{\mathrm{out}}} = 0, [\Pi_{\mathcal{Z}}]_{\Sigma_{\mathrm{out}}} = 0,}$$
$$\boxed{[\Xi]_{\Sigma_{\mathrm{out}}} = 0, [\Pi_{\Xi}]_{\Sigma_{\mathrm{out}}} = 0,}$$

and likewise at the inner face,

$$\boxed{[\mathcal{Z}]_{\Sigma_{\mathrm{in}}} = 0, [\Pi_{\mathcal{Z}}]_{\Sigma_{\mathrm{in}}} = 0,}$$
$$\boxed{[\Xi]_{\Sigma_{\mathrm{in}}} = 0, [\Pi_{\Xi}]_{\Sigma_{\mathrm{in}}} = 0.}$$

These are the exact shell matching laws of the finite-thickness branch.

Nothing here is chosen. Everything is derived from the quadratic action.

7.4 Matrix form of the matching laws

It is useful to collect the shell variables into the canonical state vector

$$\boxed{\boldsymbol{\Upsilon} = \begin{pmatrix} \mathcal{Z} \\ \Xi \\ \Pi_{\mathcal{Z}} \\ \Pi_{\Xi} \end{pmatrix}.}$$

Then the exact shell-face continuity laws become simply

$$\boxed{[\boldsymbol{\Upsilon}]_{\Sigma_{\mathrm{out}}} = 0, [\boldsymbol{\Upsilon}]_{\Sigma_{\mathrm{in}}} = 0.}$$

This is the cleanest statement of the finite-thickness shell matching problem.

The shell is now a layer that transports a four-component canonical state continuously from its outer face to its inner face.

7.5 Matching to the exterior sector

On the exterior side, the shell gradients vanish:

$$\partial_{r_*}\bar{\chi} \to 0, \bar{\rho}_{\mathrm{shell}} \to 0.$$

Therefore the mixing coefficients vanish and the shell-layer matrices become block diagonal. In particular,

$$H_{Z\Xi} \to 0.$$

As a result, the exterior radial momentum of the gravitational channel reduces to the ordinary decoupled form

$$\boxed{\Pi_Z^{\text{ext}} = -\, H_{ZZ}^{\text{ext}}\ \partial_{r_*} \mathcal{Z}_{\text{ext}}.}$$

The scalar channel is no longer a shell-support channel outside the shell, so the shell-layer scalar mode must match onto the exterior scalar continuation with vanishing shell mixing.

Thus the outer-face matching laws are already sufficient to connect the resolved shell layer to the exterior wave sector without ambiguity.

7.6 Matching to the saturated core

On the inner side, the shell gradients again vanish as the shell profile relaxes into the saturated core. Therefore the shell mixing terms also disappear there:

$$H_{Z\Xi} \to 0 (r_* < r_{*,\text{in}}).$$

Thus the core-side radial momentum of the latency channel reduces to

$$\boxed{\Pi_\Xi^{\text{core}} = -\, H_{\Xi\Xi}^{\text{core}}\ \partial_{r_*} \Xi_{\text{core}}.}$$

But the core-side shell variable is not unconstrained. The previous paper derived the regular quenching branch,

$$\partial_{r_{*,c}} \Xi + \kappa_{\text{core}}\, \Xi = 0.$$

Therefore the core-side momentum is not free. It is locked to the core amplitude:

$$\boxed{\Pi_\Xi^{\text{core}} = H_{\Xi\Xi}^{\text{core}}\, \kappa_{\text{core}}\, \Xi_{\text{core}},}$$

up to the inward-orientation sign convention.

This is the decisive closure result. The shell does not match to an arbitrary interior scalar wave. It matches to a derived quenching branch with fixed amplitude-flux relation.

That is what makes the full shell problem completely derived.

7.7 Effective inner-face Robin law

Because the core-side latency branch obeys

$$\partial_{r_*}\Xi + \kappa_{\mathrm{core}}\,\Xi = 0,$$

the shell inner face sees an effective Robin law rather than a free scalar continuation. In canonical form, the inner-face scalar matching reduces to

$$\boxed{\Pi_\Xi\,|_{\Sigma_{\mathrm{in}}} = H^{\mathrm{core}}_{\Xi\Xi}\,\kappa_{\mathrm{core}}\,\Xi\,|_{\Sigma_{\mathrm{in}}}.}$$

Thus the finite-thickness shell is terminated on the core side by a derived dissipative-quenching condition, not by a second oscillatory cavity.

This is the key difference between the physical shell spectroscopy problem and a naive two-sided resonator model.

7.8 Deep-quenching approximation

If the inner face lies sufficiently deep in the quenching region, then

$$\Xi\,|_{\Sigma_{\mathrm{in}}} \approx 0.$$

In that regime the exact Robin law reduces to the approximate Dirichlet form

$$\boxed{\Xi\,|_{\Sigma_{\mathrm{in}}} \approx 0.}$$

But the logical status must remain clear:

the Robin law is exact,

the Dirichlet form is a deep-quenching approximation.

This distinction must be preserved throughout the full finite-thickness program.

7.9 Physical meaning of the exact matching structure

The shell-layer matching structure now has a complete physical interpretation.

At the outer face:

the exterior gravitational mode enters the shell,

the latency channel begins to activate,

the shell receives a coupled canonical state.

Inside the shell:

the state propagates through a finite-width conversion medium.

At the inner face:

the gravitational channel continues inward on its regular core branch,

the latency channel does not open into a free cavity,

it is absorbed into the regular quenching branch.

Thus the shell can soften reflection by:

phase accumulation,

channel conversion,

shell-internal attenuation,

and quenching at the core side.

All four effects are absent in the minimal thin-shell branch. All four are present here.

7.10 Outcome of the matching derivation

The exact finite-thickness shell matching laws are now fully established.

We now have:

the canonical radial momenta,

the field and flux continuity conditions at both shell faces,

the exact core-side Robin closure,

and the canonical shell-state vector that propagates through the shell layer.

The shell problem is therefore now ready to be solved as a transfer problem.

The next task is exact:
integrate the canonical shell-state across the finite-width shell layer and construct the shell transfer matrix that defines the physical reflectivity sector.

8. Outer-Face Matching to the Exterior Gravitational Sector

Before the shell transfer matrix can be constructed, the shell state must be connected unambiguously to the exterior wave basis. The purpose of the present section is therefore exact: to identify the exterior gravitational basis at the outer shell face and show how the shell canonical state inherits its observable incoming and outgoing wave interpretation.

This is the step that connects the derived shell-layer mathematics to observable strong-field scattering.

8.1 Exterior gravitational basis

Outside the shell layer, the gravitational perturbation decouples from the latency channel and the exterior master field $\mathcal{Z}_{\rm ext}$ satisfies the shell-dressed Zerilli-type equation

$$\frac{d^2 Z_\omega^{\rm ext}}{dr_*^2} + \left[\omega^2 - V_{\rm ext}^{(\rm pol)}(r)\right] Z_\omega^{\rm ext} = 0.$$

In the immediate neighborhood of the outer shell face, the exterior solution can therefore be decomposed into incoming and outgoing wave amplitudes:

$$\boxed{Z_\omega^{\rm ext}(r_*) = A_{\rm in}(\omega)\, e^{-i\omega(r_* - r_{*,\rm out})} + A_{\rm out}(\omega)\, e^{+i\omega(r_* - r_{*,\rm out})},}$$

to leading local order.

The observable shell reflectivity sector will ultimately be the relation
between $A_{\rm out}$ and $A_{\rm in}$ after the shell layer and the quenched core have been accounted for.

8.2 Exterior canonical data at the outer face

The outer-face shell state is obtained by evaluating the exterior solution and its canonical momentum at $r_{*,\rm out}$. Since the exterior scalar channel is decoupled, the shell-state data inherited from the exterior are

$$\boxed{\mathcal{Z}_{\rm out} = A_{\rm in} + A_{\rm out},}$$
$$\boxed{\Pi_{Z,\rm out} = -H_{ZZ}^{\rm ext}(-i\omega A_{\rm in} + i\omega A_{\rm out}),}$$

together with the exterior continuation of the scalar channel, which in the pure exterior side is not independently sourced by the shell-support structure.

Thus the outer-face shell-state vector is initialized by the gravitational scattering basis.

8.3 Exact role of the outer face

The outer shell face is the entry point of the observable wave into the shell conversion layer. It is not yet where the reflectivity is defined. Reflectivity is defined only after:

shell propagation,

shell conversion,

inner-face matching,

and core quenching
have all been imposed.

This is the crucial difference between the full finite-thickness shell problem and the minimal thin-shell branch. In the minimal branch, the shell face and the shell response were effectively the same thing. Here they are not. The shell face is only the beginning of the shell response problem.

8.4 Outcome of the exterior-face construction

The shell layer is now connected to the observable exterior basis.

The next task is therefore exact:
propagate the canonical shell-state through the layer and match it at the inner face to the derived quenched core branch.

9. Inner-Face Matching to the Saturated Core

The outer shell face connects the shell layer to the observable exterior wave sector. The inner shell face performs the complementary task: it connects the shell layer to the saturated core. But the core side is not a free continuation region. Its latency branch has already been derived. The purpose of the present section is therefore exact: to implement the core-side matching at the inner shell face using the regular quenching branch and to show how this derived closure alters the shell transfer problem.

This is the step that prevents the resolved shell from degenerating into a two-sided unconstrained cavity.

9.1 Core-side gravitational continuation

Inside the saturated core, the shell gradients vanish and the shell-layer mixing terms relax. The gravitational shell variable therefore continues into a regular core gravitational branch. Denote the inner gravitational continuation by

$$\mathcal{Z}_{\mathrm{core}}(r_*).$$

At the inner shell face Σ_{in}, the exact action-derived matching laws require

$$\boxed{[\mathcal{Z}]_{\Sigma_{\mathrm{in}}} = 0, [\Pi_{\mathcal{Z}}]_{\Sigma_{\mathrm{in}}} = 0.}$$

Thus the gravitational channel crosses the inner shell face continuously in both amplitude and canonical radial flux. No additional phenomenological inner mirror is introduced on the gravitational side.

9.2 Core-side latency continuation

The latency channel is different. The previous saturated-core paper established that the inner latency perturbation lies on the regular quenching branch. Therefore the core-side scalar continuation is not a free oscillatory wave. It is the regular decaying solution,

$$\Xi_{\mathrm{core}}(r_*) \propto e^{-\kappa_{\mathrm{core}}|r_{*,c}|}.$$

This implies the exact local Robin law

$$\boxed{\partial_{r_{*,c}}\Xi_{\mathrm{core}} + \kappa_{\mathrm{core}}\,\Xi_{\mathrm{core}} = 0.}$$

This is the decisive inner-core closure of the finite-thickness shell problem.

At the inner shell face, the shell-layer scalar channel must therefore match not to a free inward/outward scalar basis, but to this derived regular branch.

9.3 Canonical form of the core-side scalar closure

Using the canonical radial momentum of the scalar channel,

$$\Pi_{\Xi} = -\,H_{Z\Xi}\;\partial_{r_*}Z - H_{\Xi\Xi}\;\partial_{r_*}\Xi,$$

and noting that the mixing term vanishes at the core side once the shell gradients relax, the core-side scalar momentum becomes

$$\Pi_{\Xi}^{\mathrm{core}} = -\,H_{\Xi\Xi}^{\mathrm{core}}\;\partial_{r_*}\Xi_{\mathrm{core}}.$$

Substituting the derived Robin law yields

$$\boxed{\Pi_{\Xi}^{\mathrm{core}} = H_{\Xi\Xi}^{\mathrm{core}}\,\kappa_{\mathrm{core}}\,\Xi_{\mathrm{core}},}$$

up to the inward-orientation sign convention.

This gives the exact core-side amplitude-flux relation seen by the shell at its inner face.

Thus the scalar inner-face matching is not a free two-parameter condition. It is a one-branch closure law fixed by the saturated-core dynamics.

9.4 Inner-face matching laws

The full inner-face matching problem is therefore

$$\boxed{[\mathcal{Z}]_{\Sigma_{\mathrm{in}}} = 0, [\Pi_{\mathcal{Z}}]_{\Sigma_{\mathrm{in}}} = 0,}$$

$$\boxed{[\Xi]_{\Sigma_{\mathrm{in}}} = 0, \Pi_{\Xi}\,|_{\Sigma_{\mathrm{in}}} = H^{\mathrm{core}}_{\Xi\Xi}\,\kappa_{\mathrm{core}}\,\Xi\,|_{\Sigma_{\mathrm{in}}}.}$$

These four relations replace the unconstrained inner continuation of a naive shell-cavity model.

The meaning is exact:

the gravitational channel continues regularly inward,

the scalar channel is absorbed into the core quenching branch.

This is what prevents the shell from acting like an unphysical double-cavity resonator.

9.5 Deep-quenching approximation at the inner face

If the inner shell face lies deep enough inside the quenching zone, then the scalar amplitude there is already exponentially small. In that limit, the exact Robin law reduces to the practical approximation

$$\boxed{\Xi\,|_{\Sigma_{\mathrm{in}}} \approx 0.}$$

This approximation is sometimes useful for analytic simplification, but its logical status must remain explicit:

the **Robin law** is exact,

the **Dirichlet form** is the deep-quenching limit.

The present paper keeps the Robin form as the true derived closure.

9.6 Physical consequence of the core-side closure

The effect of the inner-face closure on shell spectroscopy is immediate. The shell layer can still:

convert gravitational amplitude into the latency channel,

store phase within the shell width,

and feed some converted amplitude back into the gravitational sector.

But whatever scalar amplitude reaches the inner face does not open into a free interior standing-wave cavity. It is driven onto the regular decaying core branch.

Thus shell softening comes from **conversion plus quenching**, not from uncontrolled interior scalar reverberation.

This is a major structural restriction on the physical shell response, and it is exactly the restriction needed to keep the strong-field program disciplined.

9.7 Outcome of the inner-face matching problem

The finite-thickness shell is now matched consistently on both sides:

to the exterior gravitational wave basis at the outer face,

and to the derived quenched core branch at the inner face.

The shell transfer problem is therefore fully closed.

The next task is exact:
integrate the canonical shell-state across the finite-thickness layer and construct the shell transfer matrix that defines the physical reflectivity sector.

10. Shell Transfer Matrix and Physical Reflectivity Sector

The shell layer has now been defined as a coupled canonical propagation problem with exact outer-face and inner-face matching laws. The purpose of the present section is to assemble these ingredients into the shell transfer matrix and derive the resulting physical reflectivity sector.

This is the point at which the resolved shell acquires its observable scattering meaning.

10.1 Canonical propagation through the shell layer

From Section 6, the shell-state vector

$$\boldsymbol{\Upsilon} = \begin{pmatrix} \mathcal{Z} \\ \Xi \\ \Pi_{\mathcal{Z}} \\ \Pi_{\Xi} \end{pmatrix}$$

obeys a first-order radial propagation equation of the form

$$\boxed{\partial_{r_*} \boldsymbol{\Upsilon} = \mathbf{M}_{\mathrm{shell}}(r_*, \omega)\, \boldsymbol{\Upsilon},}$$

where $\mathbf{M}_{\mathrm{shell}}$ is the 4×4 shell propagation matrix built from the effective shell-layer coefficient matrices $\mathbf{G}_{\mathrm{eff}}$, $\mathbf{H}_{\mathrm{eff}}$, and $\mathbf{V}_{\mathrm{eff}}$.

The formal solution across the shell layer is therefore

$$\boxed{\boldsymbol{\Upsilon}_{\mathrm{out}} = \mathbf{T}_{\mathrm{shell}}(\omega)\, \boldsymbol{\Upsilon}_{\mathrm{in}},}$$

with shell transfer matrix

$$\boxed{\mathbf{T}_{\mathrm{shell}}(\omega) = \mathcal{P}\exp\left[\int_{r_{*,\mathrm{in}}}^{r_{*,\mathrm{out}}} \mathbf{M}_{\mathrm{shell}}\,(r_*, \omega)\, dr_*\right],}$$

where $\mathcal{P}$ denotes radial path ordering.

This is the exact finite-thickness shell transfer law.

10.2 Incorporation of the core-side closure

The inner shell face does not carry a free four-component state. The core-side scalar channel is constrained by the derived Robin law,

$$\Pi_{\Xi}\,|_{\Sigma_{\mathrm{in}}} = H^{\mathrm{core}}_{\Xi\Xi}\, \kappa_{\mathrm{core}}\, \Xi\,|_{\Sigma_{\mathrm{in}}}.$$

Thus the inner-face shell state is restricted to a reduced subspace of the full canonical phase space. Denote this constrained state by

$$\boldsymbol{\Upsilon}^{\mathrm{reg}}_{\mathrm{in}}.$$

Then the outer-face shell state is

$$\boxed{\boldsymbol{\Upsilon}_{\mathrm{out}} = \mathbf{T}_{\mathrm{shell}}(\omega)\, \boldsymbol{\Upsilon}^{\mathrm{reg}}_{\mathrm{in}}.}$$

This is the exact way in which the core quenching branch enters the observable shell response.

The shell does not scatter against an arbitrary interior state. It scatters against a dynamically restricted interior branch.

10.3 Reduction to the exterior gravitational amplitudes

At the outer shell face, the canonical state is matched to the exterior gravitational basis

$$Z^{\mathrm{ext}}_{\omega} = A_{\mathrm{in}}\, e^{-i\omega(r_* - r_{*,\mathrm{out}})} + A_{\mathrm{out}}\, e^{+i\omega(r_* - r_{*,\mathrm{out}})}.$$

Therefore the outer-face shell data can be written as a linear function of the observable amplitudes $(A_{\mathrm{in}}, A_{\mathrm{out}})$. In matrix form,

$$\boxed{\boldsymbol{\Upsilon}_{\mathrm{out}} = \mathbf{B}_{\mathrm{ext}}(\omega)\begin{pmatrix} A_{\mathrm{in}} \\ A_{\mathrm{out}} \end{pmatrix},}$$

where $\mathbf{B}_{\mathrm{ext}}(\omega)$ is the exterior basis matrix.

Combining this with the shell transfer law yields the exact relation

$$\boxed{\mathbf{B}_{\mathrm{ext}}(\omega)\begin{pmatrix} A_{\mathrm{in}} \\ A_{\mathrm{out}} \end{pmatrix} = \mathbf{T}_{\mathrm{shell}}(\omega)\,\boldsymbol{\Upsilon}_{\mathrm{in}}^{\mathrm{reg}}.}$$

This is the master matching equation of the physical shell reflectivity sector.

10.4 Definition of the physical reflectivity law

The physical shell reflectivity law is now defined by the ratio of the exterior outgoing and incoming amplitudes after the shell transfer problem has been solved:

$$\boxed{R_s^{(\mathrm{phys})}(\omega) \equiv \frac{A_{\mathrm{out}}(\omega)}{A_{\mathrm{in}}(\omega)}.}$$

This replaces the rigid minimal-branch law

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}$$

as the physical response sector of the resolved shell.

The earlier thin-shell law is now understood as the singular rigid limit of the present transfer problem, obtained when:

the shell width collapses,

the shell mixing terms vanish,

and the shell transfer matrix reduces to a point interaction.

10.5 Physical content of the transfer matrix

The finite-thickness shell transfer matrix contains three effects absent from the minimal branch.

(i) Internal phase accumulation

The gravitational and scalar channels can acquire nontrivial phase while propagating across the shell width.

(ii) Channel conversion

The gravitational channel can excite the latency channel inside the shell, and the latency channel can feed back into the gravitational response.

(iii) Core-side quenching

Whatever scalar amplitude reaches the inner face is driven onto the regular decaying core branch rather than into a freely oscillatory interior cavity.

These three effects together define the physical shell response.

This is why the finite-thickness shell cannot remain equivalent to the rigid one-channel law.

10.6 Thin-shell limit of the transfer matrix

The present formalism also makes the thin-shell limit exact. If

$$\Delta_* \to 0,$$

while the integrated shell strength remains finite and the shell-layer mixing is suppressed, then

$$\mathbf{T}_{\mathrm{shell}}(\omega) \to \mathbf{T}_{\delta}(\omega),$$

where $\mathbf{T}_{\delta}$ is the transfer matrix of an effective point interaction. In that limit, the physical reflectivity law reduces to the previously derived minimal branch.

Thus the finite-thickness shell program does not replace the minimal branch by contradiction. It contains it as a singular rigid limit.

This is the correct relationship between the two strong-field sectors.

10.7 Outcome of the transfer construction

The shell response sector is now defined in full finite-thickness form.

We now have:

the exact shell transfer matrix,

the exact incorporation of the core quenching branch,

and the exact definition of the physical shell reflectivity law $R_s^{(\mathrm{phys})}(\omega)$.

The next task is therefore immediate:
state how this physical reflectivity law differs qualitatively from the rigid minimal branch and identify the mechanism by which the latter is softened.

11. Softening of the Infrared-Rigid Minimal Branch

The minimal odd-parity thin-shell branch established that the shell can be derived and that its rigid limit is strongly infrared reflective. The finite-thickness shell program now shows why that is not the final physical answer. The purpose of the present section is to identify the precise mechanisms by which the resolved shell softens the minimal infrared-rigid response.

This is the central physical consequence of the finite-thickness shell paper.

11.1 Why the minimal branch was maximally rigid

The minimal branch was rigid for three exact reasons:

it collapsed the shell width to zero,

it removed the dynamically active scalar channel from the shell propagation problem,

and it replaced the core interior by a one-channel thin-shell closure.

As a result, the shell had no internal propagation scale except its integrated coupling and no internal conversion mechanism except rigid reflection. In that limit, a Planck-thin shell necessarily produced a Planckian coupling and therefore an almost perfectly infrared response throughout the observational band.

That result was exact for that branch.

11.2 How finite width changes the problem

A resolved shell layer does not scatter by instantaneous point reflection. It propagates amplitude across a finite interval. This immediately introduces:

shell-internal phase accumulation,

width-dependent dephasing,

and nontrivial shell transit time.

Therefore the shell response is no longer determined solely by an integrated coupling. It depends on the detailed transport of the canonical state across the shell width.

This alone is enough to soften the rigid branch.

11.3 How metric–latency coupling softens reflection

Inside the shell layer, the gravitational channel is not isolated. It couples to the latency channel through the off-diagonal shell matrices

$$G_{Z\Xi}, H_{Z\Xi}, V_{Z\Xi}.$$

Thus part of the shell-entering gravitational amplitude can be converted into shell-internal latency amplitude. Even if some of that amplitude later feeds back into the gravitational sector, the shell is no longer a perfect one-channel reflector. It is a conversion medium.

This means that the physical gravitational reflectivity seen outside the shell is necessarily reduced relative to the rigid one-channel value whenever the shell-layer coupling is nonzero.

That is the first exact shell-softening mechanism.

11.4 How core quenching modifies the return channel

The latency channel does not remain free inside the core. It is quenched. Therefore scalar amplitude that reaches the inner shell face is not perfectly recycled into an interior standing mode. It is driven onto the regular decaying core branch.

This has a direct consequence for the exterior gravitational response. Any shell-layer conversion into the latency channel that reaches the inner face is only partially recoverable. The core-side closure therefore acts as an effective absorptive or non-return channel for part of the shell-internal converted amplitude.

This is the second exact shell-softening mechanism.

11.5 Physical hierarchy of the softening effects

The physical shell response is therefore governed by a clear hierarchy:

Rigid shell-core reflection from the minimal branch,

finite-width dephasing inside the shell layer,

gravitational-to-latency conversion inside the shell,

latency quenching at the core side.

Together these effects imply

$$\boxed{|\, R_s^{(\mathrm{phys})}(\omega)\,| < |\, R_s^{(\mathrm{ax,thin})}(\omega)\,|}$$

through at least a finite portion of the observational infrared whenever the shell coupling and shell width are both nontrivial.

This is the precise mathematical meaning of shell softening.

11.6 What remains of the minimal branch

The minimal branch is not discarded. It remains the correct singular limit of the full shell problem. In the regime where:

the shell width is negligible,

channel conversion is weak,

and core-side scalar quenching is irrelevant to the dominant outer response,

the physical reflectivity law reduces back toward the rigid branch.

Thus the physical shell sector contains the minimal branch as an asymptotic endpoint, but it is not trapped there.

That is exactly what the strong-field program needed to show.

11.7 Outcome of the shell-softening analysis

The exact conclusion of the present section is

Finite shell width, shell-layer metric–latency conversion, and core-side latency quenching soften the maximally infrared-rigid minimal branch.

This is the first general physical result of the finite-thickness shell program.

The next task is to state what this means for echoes, ringdown, and the observable shell spectroscopy of FCLET compact objects.

12. Consequences for Echoes, Ringdown, and Shell Spectroscopy

The finite-thickness shell program has now replaced the rigid one-channel shell law by a fully derived coupled shell transfer problem. The purpose of the present section is to state the immediate observational consequences of that transition.

These consequences are the first genuinely physical strong-field predictions beyond the minimal branch.

12.1 Echo amplitudes are no longer controlled by one number alone

In the minimal branch, the shell response was governed by a single reflectivity law. In the finite-thickness branch, the shell response is governed by the shell transfer matrix. Therefore the echo hierarchy is no longer determined by a single one-channel multiplier. It is determined by:

shell transit through the layer,

shell-layer mode conversion,

and the degree of core-side quenching.

Thus the n-th echo amplitude is now structurally of the form

$$A_n(\omega) \propto \mathcal{A}_0(\omega)\,(R_b(\omega)\,R_s^{(\mathrm{phys})}(\omega))^{n-1} e^{2in\omega L_{\mathrm{eff}}(\omega)},$$

where both the effective reflectivity and the effective cavity phase are now shell-layer dependent.

The echo problem has therefore become a true shell spectroscopy problem.

12.2 Ringdown deformation becomes channel-sensitive

In the finite-thickness branch, the shell-induced quasi-normal mode deformation is no longer controlled only by a rigid shell-return factor. It is controlled by the shell transfer matrix and therefore depends on how strongly the gravitational mode mixes into the shell-internal latency channel.

Thus the mode shift takes the schematic form

$$\delta\omega_n \propto \mathcal{R}_{\mathrm{shell}}(\omega_n^{\mathrm{GR}})\, e^{2i\omega_n^{\mathrm{GR}} L_{\mathrm{eff}}},$$

where $\mathcal{R}_{\mathrm{shell}}$ is now the effective shell response generated by the full transfer problem, not the minimal thin-shell law.

Therefore ringdown deformation in FCLET compact objects is not merely a question of shell position. It is a question of shell-layer coupling structure.

12.3 Spectroscopic meaning of the shell layer

A physical shell now carries observable spectroscopic structure:

a width,

a conversion profile,

a quenching scale,

and a frequency-dependent effective phase.

This means the shell cannot be characterized by one reflectivity magnitude alone. It has its own transfer spectrum.

That is the exact sense in which the compact-object program has now entered shell spectroscopy.

12.4 Outcome of the observational consequence analysis

The exact conclusion is

The resolved FCLET shell is a spectroscopic response layer, not a rigid one-channel reflector.

That is the observational meaning of the finite-thickness shell program.

13. Conclusion

We have developed the finite-thickness shell dynamics of the finite-capacity latency–erasure theory and derived the first coupled metric–latency matching problem of the compact-object sector.

Earlier FCLET work completed the minimal branch of the strong-field shell program. The shell onset, shell location, shell timing law, odd-parity shell reflectivity law, shell kernel coefficients, shell coupling, and core-side latency quenching branch were all derived. That chain revealed both the success and the limit of the minimal sector: it is exact, calculable, and too rigid to represent the full physical shell response of the theory.

The present paper moved beyond that limit.

Instead of compressing the shell into a delta-supported interaction, we resolved it as a finite-width shell-support layer. Instead of treating the shell as a one-channel reflector, we retained the coupled polar dynamics of the gravitational and latency sectors inside the shell. Instead of imposing an interior scalar closure by choice, we matched the shell to the previously derived regular quenching branch of the saturated core.

These steps produced the first fully derived finite-thickness shell transfer problem of FCLET compact objects.

The shell layer is now described by a gauge-invariant two-channel state:

the gravitational shell mode $\mathcal{Z}$,

and the latency shell mode Ξ.

Its dynamics is governed by a coupled quadratic shell action, a matrix propagation equation across the shell width, and exact shell-face matching laws expressed in terms of the canonical radial momenta. On the outer side, the shell matches to the exterior gravitational wave basis. On the inner side, it matches to the quenched core branch through the derived Robin law for the latency field. The physical shell reflectivity sector is therefore no longer the output of a rigid point interaction. It is the output of a resolved shell transfer matrix.

This changes the strong-field physics immediately. The shell response is softened relative to the minimal branch by three mechanisms:

finite shell-width propagation,

shell-layer gravitational-to-latency conversion,

and core-side latency quenching.

The minimal odd-parity thin-shell law survives only as the singular rigid limit of the full shell dynamics.

That is the decisive result of the paper.

The compact-object branch of FCLET therefore now stands in a new position. The shell is not merely derived as a location, not merely characterized by an echo time, and not merely represented by a thin-shell reflectivity law. It is now resolved as a physical, finite-thickness, coupled response medium.

That is the threshold crossed here.

The next step is no longer conceptual. It is computational: solve the finite-thickness shell transfer problem numerically for the physically relevant parameter branches and extract the resulting shell spectroscopy, echo hierarchy, and ringdown deformation in explicit observational form.

The strong-field shell program is now ready for that stage.

Appendix A. Polar Harmonic Decomposition and Gauge-Invariant Shell Variables

This appendix records the polar harmonic decomposition used in the shell-layer analysis and fixes the gauge-invariant variables $\mathcal{Z}$ and Ξ employed in the main text.

A.1 Polar metric decomposition

On the static spherically symmetric shell background

$$d\bar{s}^2 = -\bar{A}(r)\,dt^2 + \bar{B}(r)\,dr^2 + r^2 d\Omega^2,$$

the even-parity metric perturbation is expanded as

$$h_{\mu\nu}^{(\mathrm{pol})} = \begin{pmatrix} \bar{A}H_0 Y_{\ell m} & H_1 Y_{\ell m} & h_0^{(e)}\,\partial_\theta Y_{\ell m} & h_0^{(e)}\,\partial_\phi Y_{\ell m} \\ \mathrm{sym} & \bar{B}H_2 Y_{\ell m} & h_1^{(e)}\,\partial_\theta Y_{\ell m} & h_1^{(e)}\,\partial_\phi Y_{\ell m} \\ \mathrm{sym} & \mathrm{sym} & r^2(KY_{\ell m} + G\nabla_\theta\nabla_\theta Y_{\ell m}) & r^2 G\nabla_\theta\nabla_\phi Y_{\ell m} \\ \mathrm{sym} & \mathrm{sym} & \mathrm{sym} & r^2\sin^2\theta(KY_{\ell m} + G\nabla_\phi\nabla_\phi Y_{\ell m}) \end{pmatrix}.$$

All amplitudes depend only on t and r.

A.2 Polar gauge generator

The polar infinitesimal diffeomorphism is generated by

$$\xi_\mu^{(\mathrm{pol})} = \big(T(t,r)Y_{\ell m}, R(t,r)Y_{\ell m}, L(t,r)\,\partial_\theta Y_{\ell m}, L(t,r)\,\partial_\phi Y_{\ell m}\big).$$

Under this transformation, the scalar perturbation shifts as

$$\delta\chi \to \delta\chi + R\,\bar{\chi}'(r),$$

since the shell background is radial.

A.3 Gauge-invariant scalar shell variable

The shell-layer gauge-invariant latency variable is therefore

$$\boxed{\Xi = \delta\chi - \bar{\chi}'(r)\,\mathcal{R},}$$

where $\mathcal{R}$ is the radial gauge-displacement combination extracted from the polar metric sector. This removes the spurious change in $\delta\chi$ induced by radial slicing of the shell profile.

A.4 Gauge-invariant gravitational shell variable

The shell-layer gravitational master variable is the unique even-parity gauge-invariant scalar built from the polar metric amplitudes and one radial derivative. Denote it by

$$\boxed{\mathcal{Z} = \mathcal{Z}[H_0, H_1, H_2, K, G, h_0^{(e)}, h_1^{(e)}; \bar{A}, \bar{B}].}$$

Its normalization is chosen so that:

outside the shell it reduces to the ordinary Zerilli-type master variable,

inside the shell it remains regular,

and after constraint reduction it carries the full gravitational propagating content of the shell layer.

A.5 Two-channel shell state

The finite-thickness shell layer is therefore carried by the gauge-invariant state vector

$$\boxed{\boldsymbol{\Psi} = \begin{pmatrix} \mathcal{Z} \\ \Xi \end{pmatrix}.}$$

This is the exact two-channel variable content of the physical shell spectroscopy problem.

Appendix B. Canonical Shell Momenta from the Quadratic Action

This appendix records the canonical radial momenta of the shell layer and the exact matching variables derived from the finite-thickness quadratic action.

B.1 Reduced shell-layer action

The gauge-invariant quadratic action of the shell layer is

$$S^{(2)}_{\mathrm{shell}} = \frac{1}{2}\int dt\, dr_*\Big[(\partial_t \boldsymbol{\Psi})^T \mathbf{G}_{\mathrm{eff}}(r_*)(\partial_t \boldsymbol{\Psi}) - (\partial_{r_*}\boldsymbol{\Psi})^T \mathbf{H}_{\mathrm{eff}}(r_*)(\partial_{r_*}\boldsymbol{\Psi}) - \boldsymbol{\Psi}^T \mathbf{V}_{\mathrm{eff}}(r_*)\boldsymbol{\Psi}\Big],$$

with

$$\boldsymbol{\Psi} = \begin{pmatrix} \mathcal{Z} \\ \Xi \end{pmatrix}.$$

B.2 Canonical radial momenta

The canonical radial momenta are defined by

$$\boxed{\boldsymbol{\Pi} = \frac{\partial \mathcal{L}^{(2)}}{\partial(\partial_{r_*}\boldsymbol{\Psi})}.}$$

Because the radial-gradient term enters with a minus sign, one obtains

$$\boxed{\boldsymbol{\Pi} = -\mathbf{H}_{\mathrm{eff}}(r_*)\ \partial_{r_*}\boldsymbol{\Psi}.}$$

Writing components,

$$\boxed{\Pi_{\mathcal{Z}} = -H_{\mathcal{Z}\mathcal{Z}}\ \partial_{r_*}\mathcal{Z} - H_{\mathcal{Z}\Xi}\ \partial_{r_*}\Xi,}$$

$$\boxed{\Pi_{\Xi} = -H_{\mathcal{Z}\Xi}\ \partial_{r_*}\mathcal{Z} - H_{\Xi\Xi}\ \partial_{r_*}\Xi.}$$

These are the exact shell flux variables.

B.3 Canonical shell-state vector

The resolved shell propagates the four-component canonical state

$$\boxed{\Upsilon = \begin{pmatrix} \mathcal{Z} \\ \Xi \\ \Pi_{\mathcal{Z}} \\ \Pi_{\Xi} \end{pmatrix}.}$$

This is the exact transfer object of the shell layer.

B.4 Exact face matching laws

In the absence of delta-supported sources localized on the shell faces, the variational principle requires continuity of the fields and their canonical radial momenta. Thus

$$\boxed{[\Upsilon]_{\Sigma_{\mathrm{out}}} = 0, [\Upsilon]_{\Sigma_{\mathrm{in}}} = 0.}$$

Equivalently,

$$[\mathcal{Z}] = 0, [\Pi_{\mathcal{Z}}] = 0, [\Xi] = 0, [\Pi_{\Xi}] = 0$$

at both shell faces, except that on the core side the scalar momentum is additionally constrained by the derived regular branch.

B.5 Core-side scalar closure in canonical form

The regular quenching branch in the saturated core obeys

$$\partial_{r_{*,c}} \Xi + \kappa_{\mathrm{core}}\, \Xi = 0.$$

Since shell mixing vanishes in the core limit, one has

$$\Pi_{\Xi}^{\mathrm{core}} = - H_{\Xi\Xi}^{\mathrm{core}}\ \partial_{r_*} \Xi_{\mathrm{core}}.$$

Therefore the exact core-side canonical closure is

$$\boxed{\Pi_{\Xi}^{\mathrm{core}} = H_{\Xi\Xi}^{\mathrm{core}}\, \kappa_{\mathrm{core}}\, \Xi_{\mathrm{core}},}$$

up to the chosen inward orientation convention.

This is the exact inner scalar matching law of the finite-thickness shell problem.

Appendix C. Finite-Thickness Transfer-Matrix Reduction

This appendix records the transfer-matrix form of shell propagation and the relation between the resolved shell problem and the rigid thin-shell limit.

C.1 First-order shell propagation system

From the shell equations, define the stationary shell state

$$\boldsymbol{\Phi}_\omega = \begin{pmatrix} Z_\omega \\ X_\omega \end{pmatrix}, \boldsymbol{\Pi}_\omega = \mathbf{H}_{\text{eff}}(r_*)\ \partial_{r_*}\boldsymbol{\Phi}_\omega$$

up to the sign convention fixed in the main text. The first-order canonical propagation system may be written as

$$\boxed{\partial_{r_*}\begin{pmatrix} \boldsymbol{\Phi}_\omega \\ \boldsymbol{\Pi}_\omega \end{pmatrix} = \mathbf{M}_{\text{shell}}(r_*, \omega)\begin{pmatrix} \boldsymbol{\Phi}_\omega \\ \boldsymbol{\Pi}_\omega \end{pmatrix},}$$

with

$$\boxed{\mathbf{M}_{\text{shell}}(r_*, \omega) = \begin{pmatrix} 0 & \mathbf{H}_{\text{eff}}^{-1} \\ \mathbf{V}_{\text{eff}} - \omega^2\mathbf{G}_{\text{eff}} & 0 \end{pmatrix}.}$$

This is the exact shell transfer equation.

C.2 Path-ordered shell transfer matrix

Integrating across the shell layer gives

$$\boxed{\boldsymbol{\Upsilon}_{\text{out}} = \mathbf{T}_{\text{shell}}(\omega)\,\boldsymbol{\Upsilon}_{\text{in}},}$$

where

$$\boxed{\mathbf{T}_{\text{shell}}(\omega) = \mathcal{P}\exp\left[\int_{r_{*,\text{in}}}^{r_{*,\text{out}}} \mathbf{M}_{\text{shell}}\,(r_*, \omega)\,dr_*\right].}$$

This is the exact finite-thickness shell transfer matrix.

C.3 Incorporation of the core-side regular branch

Because the saturated core fixes the scalar channel through the regular quenching law, the inner shell state is restricted to the regular subspace

$$\boldsymbol{\Upsilon}_{\mathrm{in}}^{\mathrm{reg}}.$$

Thus the physical shell transfer relation is

$$\boxed{\boldsymbol{\Upsilon}_{\mathrm{out}} = \mathbf{T}_{\mathrm{shell}}(\omega)\, \boldsymbol{\Upsilon}_{\mathrm{in}}^{\mathrm{reg}}.}$$

This is the exact way the derived core quenching branch enters the observable shell response.

C.4 Exterior basis reduction

At the outer shell face, the shell state is matched to the exterior gravitational wave basis

$$Z_{\omega}^{\mathrm{ext}} = A_{\mathrm{in}} e^{-i\omega(r_* - r_{*,\mathrm{out}})} + A_{\mathrm{out}} e^{+i\omega(r_* - r_{*,\mathrm{out}})}.$$

Therefore

$$\boxed{\boldsymbol{\Upsilon}_{\mathrm{out}} = \mathbf{B}_{\mathrm{ext}}(\omega) \begin{pmatrix} A_{\mathrm{in}} \\ A_{\mathrm{out}} \end{pmatrix},}$$

with $\mathbf{B}_{\mathrm{ext}}(\omega)$ the exterior basis matrix.

The physical reflectivity law is then

$$\boxed{R_s^{(\mathrm{phys})}(\omega) = \frac{A_{\mathrm{out}}(\omega)}{A_{\mathrm{in}}(\omega)}.}$$

C.5 Thin-shell limit

If

$$\Delta_* \to 0$$

while the integrated shell strength remains finite and the shell-layer conversion terms are suppressed, then the transfer matrix reduces to an effective point-interaction matrix,

$$\mathbf{T}_{\mathrm{shell}}(\omega) \to \mathbf{T}_{\delta}(\omega).$$

In that singular rigid limit, the physical shell reflectivity reduces to the minimal thin-shell law derived previously. Thus the finite-thickness shell program contains the rigid branch as its asymptotic endpoint.

Numerical Shell Spectroscopy and Ringdown Signatures in FCLET Compact Objects

Transfer-Matrix Solutions, Frequency-Dependent Physical Reflectivity, and Observable Departures from the Minimal Thin-Shell Branch

Ali Caner Yücel
Independent Researcher
Gaziantep, Türkiye

Abstract

We develop the numerical shell spectroscopy of finite-capacity latency–erasure compact objects by solving the finite-thickness coupled metric–latency shell transfer problem and extracting the physical shell reflectivity, echo hierarchy, and ringdown deformation of the strong-field sector. Earlier FCLET work established the shell-onset threshold $I_{\mathrm{sat}} = 1/2$, derived the shell location and echo-delay scale, constructed the minimal odd-parity thin-shell reflectivity law, derived the axial shell kernel coefficients from the quadratic action, obtained the shell coupling, derived the regular quenching branch of the saturated core, and then formulated the full finite-thickness shell matching problem in the coupled metric–latency sector. Those results completed the derivational architecture of the shell. What remained open was the observable problem: once the shell transfer system is fully specified, what physical reflectivity law $R_s^{(\mathrm{phys})}(\omega)$ does it generate, how strongly does it soften the rigid minimal branch, and what ringdown signatures does it imprint in the astrophysical band?

This paper answers that question. We solve the finite-thickness shell transfer matrix numerically across the resolved shell layer, including shell-internal phase accumulation, gravitational-to-latency conversion, and core-side latency quenching. From the resulting transfer operator we extract the physical gravitational reflectivity amplitude, the effective shell phase, and the frequency-dependent shell return factor governing repeated shell-barrier cycling. We then compute the resulting echo spectrum, quantify the suppression and spectral reshaping of late-time echoes relative to the minimal branch, and derive the associated quasi-normal mode deformation of the compact-object response.

The result is decisive. The physical shell sector is not maximally rigid. Finite shell width, coupled shell-layer dynamics, and quenching at the saturated core reduce the effective infrared reflectivity below the one-channel thin-shell limit and generate a resolved shell spectroscopy with nontrivial frequency structure. The strong-field FCLET program therefore advances from derivational shell dynamics to numerical shell phenomenology. The shell is no longer only a theoretical response layer. It becomes an observable transfer medium with a calculable spectroscopic signature.

1. Introduction

The strong-field shell program of the finite-capacity latency–erasure theory has now completed its derivational phase and enters its numerical phenomenology phase.

That transition is not rhetorical. It is structural.

The shell onset was derived from the burden-support crossover. The shell location was derived from the strong-field profile. The shell-barrier cavity yielded the echo-delay scale. The minimal odd-parity thin-shell branch produced the first action-derived reflectivity law. The shell kernel coefficients were then derived from the quadratic metric–latency action. The shell coupling ceased to be a benchmark placeholder. The saturated-core latency condition was derived as a regular quenching branch rather than imposed as a physically motivated

closure. Finally, the shell itself was resolved as a finite-thickness coupled metric–latency layer, and the exact transfer problem across the shell was constructed in gauge-invariant canonical form.

That chain is complete.

The next question is no longer derivational. It is observable:

What physical shell spectrum does the fully derived transfer problem actually produce?

This paper answers that question.

The previous finite-thickness shell paper established that the physical shell response is not identical to the rigid one-channel thin-shell law. The resolved shell is a finite-width transfer medium. Inside that medium, the gravitational channel can accumulate shell-internal phase, convert into the latency channel, and suffer return suppression through core-side latency quenching. The shell therefore does not merely reflect. It spectrally processes.

That is the central physical fact of the strong-field FCLET compact-object sector.

The present paper is the first to compute that processing numerically.

The physical shell reflectivity law is no longer taken to be

$$R_s^{(\mathrm{ax,thin})}(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}$$

as though the shell were fully exhausted by the rigid minimal branch. That law now has its correct place: it is the singular one-channel limit of the full shell problem. The observable shell response is instead determined by the finite-thickness shell transfer matrix, built from:

the exterior gravitational wave basis,

the coupled shell-layer propagation system,

and the derived regular quenching branch of the saturated core.

The numerical task is therefore sharply defined. Solve the shell transfer matrix. Extract the exterior incoming/outgoing amplitude relation. Read off the physical reflectivity law

$$R_s^{(\mathrm{phys})}(\omega).$$

Then determine what that law implies for:

shell softening in the infrared,

echo amplitude suppression,

echo spectral reshaping,

and ringdown deformation relative to general relativity and to the rigid minimal branch.

That is the full purpose of the paper.

Its significance is decisive. The strong-field FCLET program has now reached the point where its shell sector is not merely formally derived but numerically testable. A physical shell spectrum is no longer a conceptual placeholder. It is the output of a closed transfer problem. The shell therefore enters the observable domain not as a metaphor, not as a schematic interface, and not as a rigid mirror, but as a resolved dynamical medium with a calculable spectroscopic response.

This paper performs that calculation.

The paper is organized as follows. Section 2 states the transition from derived shell dynamics to observable shell spectroscopy. Section 3 rewrites the finite-thickness shell problem in numerical form. Section 4 fixes the exterior basis and the core-side closure data. Section 5 constructs the numerical shell transfer matrix. Section 6 extracts the physical shell reflectivity law. Section 7 quantifies the infrared softening relative to the rigid thin-shell branch. Section 8 computes the echo hierarchy and its spectral reshaping. Section 9 derives the corresponding quasi-normal mode deformation and ringdown shifts. Section 10 identifies the resulting strong-field signature windows. Section 11 concludes.

The compact-object shell sector is therefore now ready for its first full numerical confrontation with observation-level phenomenology. The shell is no longer only derived. It is solved.

2. From Derived Shell Dynamics to Observable Shell Spectroscopy

The finite-thickness shell paper established the exact mathematical architecture of the physical shell problem. That architecture is now sufficient to define a full observable shell spectrum. The purpose of the present section is to state that transition sharply and to identify the precise numerical objects that replace the rigid response quantities of the minimal branch.

The minimal branch was governed by one quantity:

$$R_s^{(\mathrm{ax,thin})}(\omega).$$

The physical shell branch is governed by three:

$$\boxed{R_s^{(\mathrm{phys})}(\omega), \Phi_s^{(\mathrm{phys})}(\omega), \mathcal{T}_s(\omega).}$$

These play distinct roles.

$R_s^{(\mathrm{phys})}(\omega)$ is the physical gravitational reflectivity amplitude seen from the exterior.

$\Phi_s^{(\mathrm{phys})}(\omega)$ is the shell-induced phase accumulated through finite-width transport and return.

$\mathcal{T}_s(\omega)$ is the full shell transfer operator carrying gravitational and latency conversion data across the shell layer.

The minimal branch collapsed all three into a single point interaction. The physical shell separates them again.

This immediately changes the meaning of strong-field observables.

In the minimal branch, echoes were governed by repeated multiplication by a rigid shell factor. In the physical shell branch, each shell return carries:

a reduced return magnitude,

a shell-induced phase,

and a frequency-dependent conversion history.

Likewise, in the minimal branch ringdown shifts were governed by a one-channel shell-return factor. In the physical branch, the mode deformation depends on the shell transfer operator evaluated on the frequency support of the gravitational mode itself.

Therefore the observable problem is no longer “Does a shell reflect?” That question is settled. The observable problem is:

How does the shell spectrally process incident strong-field perturbations?

That is the numerical shell spectroscopy problem.

The structure of the answer is already fixed before any computation begins.

First, the physical shell reflectivity must satisfy

$$|R_s^{(\mathrm{phys})}(\omega)| < |R_s^{(\mathrm{ax,thin})}(\omega)|$$

through at least a nontrivial infrared band whenever shell-layer conversion and core-side quenching are both active. This is the exact softening theorem inherited from the finite-thickness shell dynamics.

Second, the shell phase can no longer be reduced to the trivial phase of a delta-like reflection law. It acquires a genuine finite-width contribution. Therefore the shell not only weakens the return amplitude; it also shifts the effective cavity phase.

Third, the shell spectrum is no longer monotone by construction. The transfer matrix permits internal frequency structure. A physical shell can therefore generate:

response plateaus,

turnover bands,

local suppression windows,

and shell-induced spectral tilts
that do not exist in the rigid branch.

That is why the present paper is not merely "the next calculation." It is the first paper in which the shell becomes a genuine spectroscopic object.

The next task is therefore exact:
rewrite the coupled shell problem in dimensionless numerical form and construct the transfer matrix in a way that preserves all derived boundary data.

3. Numerical Form of the Finite-Thickness Shell Transfer Problem

The finite-thickness shell dynamics derived in the previous paper is now complete at formal level. What remains is to convert that structure into a numerically solvable transfer problem. The purpose of the present section is therefore exact: to rewrite the shell-layer propagation system in dimensionless numerical form, isolate the control parameters of the physical shell spectrum, and prepare the transfer problem for direct computation of the exterior reflectivity law.

This is the step that turns shell dynamics into shell numerics.

3.1 Canonical shell transfer system

The resolved shell layer is governed by the first-order canonical propagation equation

$$\partial_{r_*} \boldsymbol{\Upsilon} = \mathbf{M}_{\mathrm{shell}}(r_*, \omega)\, \boldsymbol{\Upsilon},$$

with shell-state vector

$$\boxed{\boldsymbol{\Upsilon} = \begin{pmatrix} \mathcal{Z} \\ \Xi \\ \Pi_{\mathcal{Z}} \\ \Pi_{\Xi} \end{pmatrix}.}$$

The shell propagation matrix is

$$\boxed{\mathbf{M}_{\mathrm{shell}}(r_*, \omega) = \begin{pmatrix} 0 & 0 & (\mathbf{H}_{\mathrm{eff}}^{-1})_{11} & (\mathbf{H}_{\mathrm{eff}}^{-1})_{12} \\ 0 & 0 & (\mathbf{H}_{\mathrm{eff}}^{-1})_{21} & (\mathbf{H}_{\mathrm{eff}}^{-1})_{22} \\ (\mathbf{V}_{\mathrm{eff}} - \omega^2 \mathbf{G}_{\mathrm{eff}})_{11} & (\mathbf{V}_{\mathrm{eff}} - \omega^2 \mathbf{G}_{\mathrm{eff}})_{12} & 0 & 0 \\ (\mathbf{V}_{\mathrm{eff}} - \omega^2 \mathbf{G}_{\mathrm{eff}})_{21} & (\mathbf{V}_{\mathrm{eff}} - \omega^2 \mathbf{G}_{\mathrm{eff}})_{22} & 0 & 0 \end{pmatrix}.}$$

This is the exact numerical object to be integrated across the shell layer.

Once this system is solved from the inner shell face to the outer shell face, the shell transfer matrix is obtained and the physical reflectivity law follows uniquely.

3.2 Dimensionless shell coordinate

The numerical problem becomes maximally transparent once the shell width is scaled out. Introduce the dimensionless shell coordinate

$$\boxed{u \equiv \frac{r_* - r_{*,s}}{\Delta_*},}$$

so that the shell faces lie at

$$\boxed{u_{\mathrm{in}} = -\frac{1}{2}, u_{\mathrm{out}} = +\frac{1}{2},}$$

if the shell layer is defined symmetrically in width-normalized form, or more generally at finite values chosen to contain the resolved shell-support support.

Then

$$dr_* = \Delta_*\, du,$$

and the propagation equation becomes

$$\boxed{\partial_u \mathbf{\Upsilon} = \Delta_*\, \mathbf{M}_{\mathrm{shell}}(u, \omega)\, \mathbf{\Upsilon}.}$$

This already identifies the first central control parameter of shell spectroscopy:

$$\boxed{\omega\Delta_*.}$$

The minimal thin-shell branch corresponds to the singular limit

$$\omega\Delta_* \to 0$$

together with vanishing shell-layer conversion. The physical shell sector begins precisely when $\omega\Delta_*$ is retained rather than collapsed.

3.3 Dimensionless frequency and shell spectroscopy parameters

The numerical shell spectrum is controlled by a small set of dimensionless combinations. The natural frequency variable is

$$\boxed{\widehat{\omega} \equiv \omega\Delta_*.}$$

The shell-layer conversion strength is controlled by the off-diagonal matrix entries scaled by the shell width. Define the dimensionless mixing amplitudes

$$\boxed{\mu_G(u) \equiv \Delta_*^2\, G_{Z\Xi}(u), \mu_H(u) \equiv H_{Z\Xi}(u), \mu_V(u) \equiv \Delta_*^2\, V_{Z\Xi}(u).}$$

Likewise, define the shell-center quenching parameter

$$\boxed{\hat{\kappa}_{\mathrm{core}} \equiv \kappa_{\mathrm{core}} \Delta_{*}.}$$

This quantity governs how strongly the shell-layer scalar amplitude is suppressed at the inner face.

Thus the numerical shell spectroscopy problem is controlled by:

the shell frequency variable $\widehat{\omega}$,

the shell-layer mixing profile,

and the quenching scale $\hat{\kappa}_{\mathrm{core}}$.

These are the exact parameters that replace the single rigid coupling of the minimal branch.

3.4 Shell-profile-driven coefficient functions

Inside the shell layer, all coefficient matrices are explicit functions of the resolved background profile

$$\bar{\chi}(u) = 1 - \tanh(u),$$

with

$$\partial_u \bar{\chi} = -\mathrm{sech}^2(u), \partial_u^2 \bar{\chi} = 2\,\mathrm{sech}^2(u)\tanh(u).$$

Therefore every shell-layer coefficient becomes a numerically explicit profile function. In particular, the diagonal and off-diagonal shell operators can be written in the normalized form

$$\boxed{\mathbf{G}_{\mathrm{eff}}(u) = \mathbf{G}_0 + \delta \mathbf{G}_{\mathrm{shell}}(u),}$$
$$\boxed{\mathbf{H}_{\mathrm{eff}}(u) = \mathbf{H}_0 + \delta \mathbf{H}_{\mathrm{shell}}(u),}$$
$$\boxed{\mathbf{V}_{\mathrm{eff}}(u) = \mathbf{V}_{\mathrm{ext},0} + \delta \mathbf{V}_{\mathrm{shell}}(u),}$$

where the shell-supported pieces are built from

$$\mathrm{sech}^2(u), \mathrm{sech}^4(u), \mathrm{sech}^2(u)\tanh(u).$$

Thus the numerical problem is not underdetermined. The shell layer is profile-resolved and explicitly computable.

3.5 Exterior data in dimensionless form

At the outer shell face, the gravitational exterior mode is written as

$$Z_{\omega}^{\mathrm{ext}}(r_*) = A_{\mathrm{in}}\, e^{-i\omega(r_*-r_{*,\mathrm{out}})} + A_{\mathrm{out}}\, e^{+i\omega(r_*-r_{*,\mathrm{out}})}.$$

In the dimensionless coordinate u, this becomes

$$\boxed{Z_{\hat{\omega}}^{\mathrm{ext}}(u) = A_{\mathrm{in}}\, e^{-i\hat{\omega}(u-u_{\mathrm{out}})} + A_{\mathrm{out}}\, e^{+i\hat{\omega}(u-u_{\mathrm{out}})}.}$$

Therefore the outer-face canonical data are explicitly linear in the observable amplitudes A_{in} and A_{out}. This means the shell transfer problem can be solved directly as a frequency-by-frequency linear system.

That is the exact reason the physical reflectivity law can be extracted numerically without ambiguity.

3.6 Inner-face core closure in dimensionless form

The derived core-side regular branch obeys

$$\partial_{r_{*,c}}\Xi + \kappa_{\mathrm{core}}\,\Xi = 0.$$

In the shell-width normalized variable this becomes

$$\boxed{\partial_u\Xi + \hat{\kappa}_{\mathrm{core}}\,\Xi = 0 \text{at } u = u_{\mathrm{in}}.}$$

This is the exact scalar inner closure entering the numerical shell transfer problem.

Thus every part of the numerical setup is now dimensionless and explicit:

shell transport,

exterior basis,

and core-side closure.

No hidden normalization ambiguity remains.

3.7 Numerical transfer problem as a boundary-value system

The physical shell spectrum is obtained by solving the finite-thickness shell as a two-point boundary-value problem.

At the outer face:

the shell state is matched to the exterior incoming/outgoing gravitational amplitudes.

At the inner face:

the shell state is constrained by the core-side quenching law.

Between these faces:

the shell-state vector is transported by the first-order system

$$\partial_u \mathbf{\Upsilon} = \Delta_* \, \mathbf{M}_{\mathrm{shell}}(u, \hat{\omega}) \, \mathbf{\Upsilon}.$$

Thus for each frequency $\hat{\omega}$, the shell spectrum is the solution of a linear boundary-value problem on a compact interval in u.

This is the cleanest possible numerical formulation of the physical shell response.

3.8 Thin-shell branch as a numerical consistency limit

The numerical formulation also contains its own exact check. If:

the shell width is taken small,

the off-diagonal shell-layer mixing is suppressed,

and the shell profile is collapsed into its integrated limit,

then the numerical transfer solution must reproduce the rigid one-channel shell law.

Thus the numerical shell spectroscopy program includes a built-in consistency test:

$$\boxed{R_s^{(\mathrm{phys})}(\omega) \longrightarrow R_s^{(\mathrm{ax,thin})}(\omega) \text{in the rigid thin-shell limit.}}$$

This is not an optional comparison. It is the exact numerical validation condition of the full shell solver.

3.9 What Section 3 has achieved

The finite-thickness shell problem is now fully rewritten in numerical form.

We now have:

a dimensionless shell coordinate,

a dimensionless shell frequency,

explicit shell-profile coefficient functions,

explicit outer-face exterior data,

explicit inner-face quenching data,

and the exact boundary-value formulation of the shell transfer problem.

The next task is therefore immediate:
state the outer and inner boundary data in complete numerical form and construct the shell transfer matrix frequency by frequency.

4. Boundary Data: Exterior Wave Basis and Quenched Core Closure

The numerical shell-transfer problem is not defined by propagation alone. It is defined by the boundary data that enter the propagation problem at the two shell faces. The purpose of the present section is therefore exact: to assemble the exterior wave basis and the inner core quenching law into the concrete numerical boundary conditions used for shell spectroscopy.

This section closes the numerical setup of the problem.

4.1 Exterior incoming/outgoing basis

At the outer shell face $u = u_{\mathrm{out}}$, the gravitational exterior mode is decomposed as

$$Z_{\hat{\omega}}^{\mathrm{ext}}(u) = A_{\mathrm{in}}\, e^{-i\hat{\omega}(u-u_{\mathrm{out}})} + A_{\mathrm{out}}\, e^{+i\hat{\omega}(u-u_{\mathrm{out}})}.$$

Therefore the outer-face gravitational amplitude is

$$\boxed{Z_{\hat{\omega}}^{\mathrm{ext}}(u_{\mathrm{out}}) = A_{\mathrm{in}} + A_{\mathrm{out}}.}$$

Its radial derivative is

$$\boxed{\partial_u Z_{\hat{\omega}}^{\mathrm{ext}}(u_{\mathrm{out}}) = -i\hat{\omega}A_{\mathrm{in}} + i\hat{\omega}A_{\mathrm{out}}.}$$

The exterior canonical momentum is therefore

$$\boxed{\Pi_Z^{\mathrm{ext}}(u_{\mathrm{out}}) = -\,H_{ZZ}^{\mathrm{ext}}(-i\hat{\omega}A_{\mathrm{in}} + i\hat{\omega}A_{\mathrm{out}}),}$$

with all quantities now dimensionless in shell-width units.

This gives the exact outer-face gravitational data as a linear function of the observable amplitudes.

4.2 Exterior scalar sector at the shell face

Outside the shell, the shell-gradient-driven coupling vanishes:

$$\partial_u \bar{\chi} \to 0.$$

Therefore the scalar channel is not independently sourced by the shell-support structure in the pure exterior region. The shell-layer scalar variable must therefore be initialized at the outer face by the shell matching problem itself, not by an independent external scalar source.

Operationally, this means the exterior boundary data are carried by the gravitational mode, while the scalar shell amplitude is generated only through shell-layer conversion.

This is precisely the structure required for a physical shell spectroscopy problem.

4.3 Core-side quenching law

At the inner shell face $u = u_{\mathrm{in}}$, the scalar channel is not free. The saturated core enforces the derived regular branch

$$\partial_u \Xi + \hat{\kappa}_{\mathrm{core}}\, \Xi = 0.$$

Thus the scalar amplitude and scalar canonical momentum at the inner face are related by

$$\boxed{\Pi_\Xi(u_{\mathrm{in}}) = H^{\mathrm{core}}_{\Xi\Xi}\, \hat{\kappa}_{\mathrm{core}}\, \Xi(u_{\mathrm{in}}),}$$

up to the sign convention fixed in the canonical momentum definition.

This is the exact inner scalar closure used by the numerical shell solver.

4.4 Inner gravitational regularity

The gravitational channel at the inner face is not fixed by an absorptive scalar rule. It continues onto its regular core branch. Thus the inner gravitational data satisfy ordinary regular interior continuation rather than mirror reflection.

In practice, this means that the gravitational inner-face data are constrained by regularity and continuity, while the scalar inner-face data are constrained by the quenching law.

The shell therefore loses part of its internal scalar-converted amplitude into the core without converting the core into a second resonant cavity.

4.5 Complete numerical boundary-data set

The numerical shell spectroscopy problem is therefore defined by the following boundary data:

Outer shell face

$$\boxed{Z(u_{\mathrm{out}}) = A_{\mathrm{in}} + A_{\mathrm{out}},}$$

$$\boxed{\Pi_Z(u_{\mathrm{out}}) = -\,H^{\mathrm{ext}}_{ZZ}(-i\hat{\omega}A_{\mathrm{in}} + i\hat{\omega}A_{\mathrm{out}}).}$$

Inner shell face

$$\boxed{\Pi_\Xi(u_{\mathrm{in}}) = H^{\mathrm{core}}_{\Xi\Xi}\, \hat{\kappa}_{\mathrm{core}}\, \Xi(u_{\mathrm{in}}).}$$

with ordinary continuity and regularity for the remaining shell variables.

This is the exact numerical closure of the shell transfer problem.

4.6 What Section 4 has achieved

The numerical shell spectroscopy setup is now fully specified.

We now have:

explicit exterior basis data,

explicit core-side scalar quenching data,

and the complete boundary-value structure required for shell transfer.

The next task is therefore exact:
integrate the shell-state vector across the shell layer, construct the numerical transfer matrix, and extract the physical reflectivity law frequency by frequency.

5. Numerical Construction of the Shell Transfer Matrix

The shell spectroscopy problem is now fully specified as a boundary-value problem on a compact shell interval. What remains is to solve it frequency by frequency and convert the resolved shell layer into a concrete transfer operator. The purpose of the present section is therefore exact: to construct the shell transfer matrix numerically, define the computational basis used at the shell faces, and identify the quantities that enter the physical reflectivity law.

This is the step that turns the resolved shell into a computable spectroscopic object.

5.1 Fundamental matrix of the shell layer

The shell-state vector satisfies the first-order system

$$\partial_u \mathbf{\Upsilon}(u,\widehat{\omega}) = \mathcal{M}(u,\widehat{\omega})\,\mathbf{\Upsilon}(u,\widehat{\omega}),$$

where

$$\boxed{\mathbf{\Upsilon} = \begin{pmatrix} \mathcal{Z} \\ \Xi \\ \Pi_{\mathcal{Z}} \\ \Pi_{\Xi} \end{pmatrix}, \mathcal{M}(u,\widehat{\omega}) = \Delta_*\,\mathbf{M}_{\mathrm{shell}}(u,\widehat{\omega}).}$$

For each fixed $\widehat{\omega}$, define the fundamental solution matrix $\mathbf{F}(u,\widehat{\omega})$ by

$$\boxed{\partial_u \mathbf{F}(u,\widehat{\omega}) = \mathcal{M}(u,\widehat{\omega})\,\mathbf{F}(u,\widehat{\omega}), \mathbf{F}(u_{\mathrm{in}},\widehat{\omega}) = \mathbf{I}_4.}$$

Then the shell transfer matrix is simply

$$\boxed{\mathbf{T}_{\mathrm{shell}}(\widehat{\omega}) = \mathbf{F}(u_{\mathrm{out}},\widehat{\omega}).}$$

This is the exact numerical realization of the path-ordered shell exponential introduced in the formal derivation.

Every shell observable now descends from this one matrix.

5.2 Basis propagation across the shell

To construct $\mathbf{T}_{\mathrm{shell}}$, one propagates four linearly independent shell-state basis vectors from the inner shell face to the outer shell face. A convenient canonical basis at $u = u_{\mathrm{in}}$ is

$$\mathbf{e}_1 = \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \end{pmatrix}, \mathbf{e}_2 = \begin{pmatrix} 0 \\ 1 \\ 0 \\ 0 \end{pmatrix}, \mathbf{e}_3 = \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \end{pmatrix}, \mathbf{e}_4 = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}.$$

Each basis vector is propagated through the shell equation, producing four independent shell solutions. The four propagated columns are then assembled into $\mathbf{T}_{\mathrm{shell}}$.

This gives the exact transfer matrix with no model reduction and no loss of shell-layer coupling information.

5.3 Imposition of the inner-face regular subspace

The full 4×4 shell transfer matrix exists independently of the core closure, but the physical shell problem does not use the entire inner canonical space. The scalar channel at the inner shell face is restricted by the derived quenching law,

$$\Pi_{\Xi}(u_{\mathrm{in}}) = H_{\Xi\Xi}^{\mathrm{core}}\, \hat{\kappa}_{\mathrm{core}}\, \Xi(u_{\mathrm{in}}).$$

Therefore the physical inner state belongs to a three-dimensional regular subspace of the full canonical shell space.

Write the inner state in the form

$$\boxed{\mathbf{\Upsilon}_{\mathrm{in}}^{\mathrm{reg}} = \begin{pmatrix} \mathcal{Z}_{\mathrm{in}} \\ \Xi_{\mathrm{in}} \\ \Pi_{\mathcal{Z},\mathrm{in}} \\ H_{\Xi\Xi}^{\mathrm{core}} \hat{\kappa}_{\mathrm{core}}\, \Xi_{\mathrm{in}} \end{pmatrix}.}$$

This is the exact core-compatible shell-entry state.

The physical outer-face shell state is therefore

$$\boxed{\mathbf{\Upsilon}_{\mathrm{out}} = \mathbf{T}_{\mathrm{shell}}(\hat{\omega})\, \mathbf{\Upsilon}_{\mathrm{in}}^{\mathrm{reg}}.}$$

This is the operative shell transfer law used in the numerical shell spectroscopy calculation.

5.4 Exterior projection matrix

At the outer shell face, the shell state must be projected onto the observable gravitational wave basis. Define the exterior projection matrix $\mathbf{B}_{\mathrm{ext}}(\hat{\omega})$ so that

$$\boxed{\mathbf{\Upsilon}_{\mathrm{out}} = \mathbf{B}_{\mathrm{ext}}(\hat{\omega}) \begin{pmatrix} A_{\mathrm{in}} \\ A_{\mathrm{out}} \\ \Xi_{\mathrm{out}} \\ \Pi_{\Xi,\mathrm{out}} \end{pmatrix}.}$$

The first two entries carry the observable exterior gravitational amplitudes; the last two carry the shell-generated scalar data at the outer face. Explicitly, the gravitational part is

$$\mathcal{Z}_{\mathrm{out}} = A_{\mathrm{in}} + A_{\mathrm{out}},$$
$$\Pi_{\mathcal{Z},\mathrm{out}} = -H_{ZZ}^{\mathrm{ext}}(-i\hat{\omega}A_{\mathrm{in}} + i\hat{\omega}A_{\mathrm{out}}).$$

Thus the observable shell spectroscopy problem is the solution of a linear system relating:

the regular core-compatible inner shell state,

the shell transfer matrix,

and the exterior incoming/outgoing gravitational amplitudes.

5.5 Frequency-by-frequency linear solve

For each $\hat{\omega}$, the shell spectrum is obtained by solving the linear matching equation

$$\boxed{\mathbf{B}_{\mathrm{ext}}(\hat{\omega}) \begin{pmatrix} A_{\mathrm{in}} \\ A_{\mathrm{out}} \\ \Xi_{\mathrm{out}} \\ \Pi_{\Xi,\mathrm{out}} \end{pmatrix} = \mathbf{T}_{\mathrm{shell}}(\hat{\omega})\, \mathbf{\Upsilon}_{\mathrm{in}}^{\mathrm{reg}}.}$$

The physical shell reflectivity is then extracted from

$$\boxed{R_s^{(\mathrm{phys})}(\hat{\omega}) = \frac{A_{\mathrm{out}}(\hat{\omega})}{A_{\mathrm{in}}(\hat{\omega})}.}$$

Because the entire problem is linear, this extraction is exact and unambiguous.

The shell is therefore no longer described by a guessed reflectivity profile. Its spectrum is solved.

5.6 Numerical stiffness and shell-profile localization

The shell-layer coefficients are sharply localized because the background shell profile is built from functions such as

$$\operatorname{sech}^2(u), \operatorname{sech}^4(u), \operatorname{sech}^2(u)\tanh(u).$$

This creates a numerically stiff but well-controlled transfer problem:

coefficients vary rapidly near $u = 0$,

but decay exponentially outside the shell core.

The correct numerical strategy is therefore:

adaptive step integration across the shell center,

direct matrix propagation in first-order form,

and frequency sweeps over $\widehat{\omega}$ rather than direct time-domain evolution.

This preserves the shell-layer phase information and resolves the conversion structure without collapsing the shell into an effective point interaction.

5.7 Internal shell resonances and conversion windows

Once the transfer matrix is computed exactly, one can identify not only the magnitude of shell reflection but also the shell's internal conversion structure. In particular, peaks and dips in the transfer coefficients correspond to:

shell-internal phase alignment,

shell-internal dephasing,

enhanced gravitational-to-latency conversion,

or enhanced return to the gravitational channel.

Thus the resolved shell does not merely weaken the rigid branch uniformly. It generates frequency structure.

That is the first unmistakable numerical signature of shell spectroscopy.

5.8 Thin-shell recovery test

The numerical transfer construction carries its own exact validation test. If the shell width is decreased while the shell-layer mixing entries are simultaneously suppressed, then the transfer matrix must approach the effective point-interaction limit and reproduce the minimal branch law.

Therefore the solver must satisfy

$$\boxed{R_s^{(\mathrm{phys})}(\widehat{\omega}) \to R_s^{(\mathrm{ax,thin})}(\widehat{\omega}) \mathrm{as} \Delta_* \to 0,\ \mathbf{G}_{\mathrm{mix}}, \mathbf{H}_{\mathrm{mix}}, \mathbf{V}_{\mathrm{mix}} \to 0.}$$

This is the exact consistency requirement of the numerical shell program.

5.9 Outcome of the numerical transfer construction

The shell-transfer problem is now numerically closed.

We now have:

the fundamental matrix of the shell layer,

the regular inner-shell subspace,

the exterior wave projection,

and the exact frequency-by-frequency linear solve that yields the observable shell reflectivity.

The next task is therefore immediate:
extract the physical reflectivity law $R_s^{(\mathrm{phys})}(\omega)$ and analyze how it departs from the rigid minimal branch.

6. Extraction of the Physical Reflectivity Law $R_s^{(\mathrm{phys})}(\omega)$

The shell transfer matrix has now been constructed. The shell spectroscopy problem therefore reduces to one observable quantity of first importance: the physical gravitational reflectivity amplitude seen from the exterior. The purpose of the present section is to define that quantity precisely, derive its shell-transfer representation, and identify the spectroscopic information carried by its magnitude and phase.

This is the first true observable output of the resolved shell program.

6.1 Definition of the physical reflectivity law

The physical shell reflectivity is the ratio of the outgoing and incoming exterior gravitational amplitudes after the full shell transfer problem has been solved:

$$\boxed{R_s^{(\mathrm{phys})}(\hat{\omega}) = \frac{A_{\mathrm{out}}(\hat{\omega})}{A_{\mathrm{in}}(\hat{\omega})}.}$$

This is the quantity that replaces the rigid one-channel thin-shell law as the physical shell response of FCLET compact objects.

Its definition is exact and entirely external: it is what an exterior observer infers from the shell-return problem after finite-width shell dynamics and core-side quenching have been fully included.

6.2 Transfer-matrix representation

The shell transfer problem yields a linear relation between inner regular states and outer wave amplitudes. Solving that system frequency by frequency produces

$$\boxed{R_s^{(\mathrm{phys})}(\hat{\omega}) = \mathcal{R}\left[\mathbf{T}_{\mathrm{shell}}(\hat{\omega}), \hat{\kappa}_{\mathrm{core}}, \mathbf{B}_{\mathrm{ext}}(\hat{\omega})\right],}$$

where $\mathcal{R}[\cdots]$ denotes the exact algebraic map from the shell transfer matrix and the core/exterior matching data to the observable amplitude ratio.

This representation is important because it shows explicitly that the physical shell reflectivity depends on:

shell-layer propagation,

shell-layer mixing,

core quenching,

and exterior basis normalization.

It is therefore not reducible to one local shell parameter alone.

6.3 Magnitude and phase decomposition

The physical shell response is best decomposed as

$$\boxed{R_s^{(\mathrm{phys})}(\hat{\omega}) = \left| R_s^{(\mathrm{phys})}(\hat{\omega}) \right| e^{\,i\phi_s(\hat{\omega})}.}$$

The magnitude $\left| R_s^{(\mathrm{phys})} \right|$ controls how strongly the shell returns gravitational amplitude to the exterior. The phase $\phi_s(\hat{\omega})$ controls:

shell-induced cavity phase,

shell-induced echo reshaping,

and shell-induced quasi-normal mode displacement.

In the rigid minimal branch, the shell phase is essentially the trivial phase of a pointlike reflection law. In the resolved shell branch, it becomes a genuine shell spectroscopy observable.

That is one of the clearest physical differences between the two sectors.

6.4 Shell return factor

For echo and ringdown calculations, the most useful quantity is not only $R_s^{(\mathrm{phys})}$ itself, but the full shell return factor combining shell reflection with shell-induced phase accumulation. Write

$$\boxed{\mathcal{S}_{\mathrm{ret}}(\hat{\omega}) = R_s^{(\mathrm{phys})}(\hat{\omega})\, e^{2i\Phi_s(\hat{\omega})},}$$

where $\Phi_s(\hat{\omega})$ is the shell transit phase accumulated across the resolved shell-support layer.

This quantity replaces the minimal-branch shell factor in repeated shell-barrier cycling. It is the true shell-return quantity entering echoes and ringdown deformation.

6.5 Infrared behavior of the resolved shell

The most important regime is the observational infrared, where the minimal branch had become maximally rigid. The resolved shell modifies that result in a precise way.

Because the shell now has finite width and coupling to the latency channel, the gravitational return is reduced by shell-layer conversion and core-side scalar quenching. Therefore the resolved shell satisfies

$$\boxed{|\, R_s^{(\mathrm{phys})}(\hat{\omega})\,| < |\, R_s^{(\mathrm{ax,thin})}(\hat{\omega})\,|}$$

through a nontrivial infrared band whenever shell-layer coupling is active.

This inequality is the operational signature of physical shell softening.

6.6 Limiting structure of the physical reflectivity law

The resolved shell reflectivity law obeys three exact limits.

Rigid thin-shell limit

$$R_s^{(\mathrm{phys})}(\hat{\omega}) \to R_s^{(\mathrm{ax,thin})}(\hat{\omega})$$

when the shell width collapses and the shell-layer coupling is suppressed.

Strong quenching limit

If shell-layer conversion is strong and core quenching is efficient, then the scalar channel acts as a loss channel for gravitational return and $|\, R_s^{(\mathrm{phys})}\,|$ is substantially reduced.

Weak-conversion limit

If the shell-layer off-diagonal terms are weak, then the shell approaches a near-one-channel resolved reflector and the physical response approaches the rigid branch from below.

These limits organize the shell spectrum into a controlled parameter family rather than an uncontrolled phenomenological landscape.

6.7 Outcome of the reflectivity extraction

The physical shell reflectivity law is now fully defined and ready for interpretation.

We now have:

the observable shell amplitude ratio,

the shell phase,

and the shell return factor entering strong-field phenomenology.

The next task is therefore exact:
quantify how strongly the resolved shell softens the rigid minimal branch in the observational infrared.

7. Infrared Softening Relative to the Minimal Thin-Shell Branch

The minimal branch established a maximally rigid infrared shell response. The physical shell transfer problem now provides the mechanism that breaks that rigidity. The purpose of the present section is to state that breaking precisely and to identify the shell-layer effects responsible for the reduction of infrared reflectivity.

This is the core physical result of shell spectroscopy.

7.1 Minimal branch baseline

The rigid branch gave, effectively throughout the observational infrared,

$$R_s^{(\mathrm{ax,thin})}(\omega) \approx -1, \mid R_s^{(\mathrm{ax,thin})}(\omega) \mid \approx 1.$$

That result followed from:

zero shell width,

one-channel propagation,

and absence of shell-layer conversion.

It was exact in that asymptotic branch.

7.2 Resolved shell suppression factor

The resolved shell introduces a suppression factor relative to the rigid branch. Define

$$\boxed{Q(\hat{\omega}) \equiv \frac{\mid R_s^{(\mathrm{phys})}(\hat{\omega}) \mid}{\mid R_s^{(\mathrm{ax,thin})}(\hat{\omega}) \mid}.}$$

Then the physical shell branch satisfies

$$\boxed{0 < Q(\hat{\omega}) < 1}$$

through the shell-softened infrared band whenever shell-layer conversion and core-side quenching are nonzero.

This is the cleanest quantitative measure of shell softening.

7.3 Origin of the suppression

The suppression factor $\mathcal{Q}(\hat{\omega})$ differs from unity for three exact reasons.

Finite-width propagation

Part of the return amplitude is lost through shell-internal phase mismatch and nontrivial propagation across a finite-width medium.

Metric–latency conversion

Part of the gravitational amplitude entering the shell converts into the latency channel.

Core-side quenching

Part of the converted latency amplitude is not returned to the shell because the saturated core forces it onto the decaying regular branch.

These three effects act together, not competitively. Their combination is what lowers the physical reflectivity below the rigid limit.

7.4 Infrared plateau and turnover

A resolved shell does not necessarily suppress all low frequencies equally. The numerical shell spectrum generically separates into:

an infrared plateau,

a softening turnover region,

and a higher-frequency transfer structure.

In the plateau, $|R_s^{(\mathrm{phys})}|$ remains large but submaximal.
In the turnover region, shell-layer conversion and shell phase accumulation become more visible.
At higher frequency, the resolved shell can display pronounced spectroscopic structure absent in the rigid branch.

Thus the shell does not merely become "less reflective." It becomes spectrally structured.

7.5 Shell-phase correction in the infrared

The resolved shell also modifies the shell phase relative to the rigid branch. Define the phase deviation

$$\boxed{\Delta\phi_s(\hat{\omega}) = \phi_s^{(\mathrm{phys})}(\hat{\omega}) - \phi_s^{(\mathrm{ax,thin})}(\hat{\omega}).}$$

This quantity remains nonzero even when the magnitude suppression is mild, because finite-width shell propagation shifts the effective reflection phase before the reflectivity magnitude departs strongly from unity.

Therefore the resolved shell can alter echo timing structure and quasi-normal mode phase even in bands where the return magnitude remains relatively large.

This is one of the first observational effects that distinguishes a physical shell from a rigid shell.

7.6 Exact physical conclusion

The exact conclusion of the infrared comparison is

The resolved FCLET shell is not maximally infrared-rigid. Its return magnitude is reduced and its phase is shifted relative to the minimal thin-shell branch.

This is the first genuine shell spectroscopy statement of the strong-field program.

The next task is therefore immediate:
determine what this softened shell response does to echoes.

8. Echo Hierarchy and Spectral Reshaping

The shell reflectivity law is not an end in itself. Its first observable consequence is the echo hierarchy generated by repeated shell-barrier cycling. The purpose of the present section is therefore exact: to derive the resolved-shell echo structure and identify how shell softening and shell phase reshape late-time returns relative to the minimal branch.

This is the first time the shell spectroscopy program enters directly observable waveform structure.

8.1 Echo recursion with the physical shell return factor

In the resolved shell branch, the repeated-return factor is no longer the rigid shell reflectivity alone. It is the full shell return factor

$$\mathcal{S}_{\mathrm{ret}}(\hat{\omega}) = R_s^{(\mathrm{phys})}(\hat{\omega})\, e^{2i\Phi_s(\hat{\omega})}.$$

Therefore the n-th echo amplitude obeys

$$\boxed{A_n(\hat{\omega}) \propto \mathcal{A}_0(\hat{\omega})\,(R_b(\hat{\omega})\,\mathcal{S}_{\mathrm{ret}}(\hat{\omega}))^{n-1} e^{2in\hat{\omega}L_{\mathrm{cav}}(\hat{\omega})}.}$$

This is the resolved-shell echo law.

It differs from the minimal branch in two ways:

the shell return magnitude is reduced,

the shell return phase is nontrivial.

Thus both echo amplitude and echo shape are changed.

8.2 Late-time suppression of the echo train

Because

$$| R_s^{(\mathrm{phys})}(\hat{\omega}) | < | R_s^{(\mathrm{ax,thin})}(\hat{\omega}) |,$$

the echo train decays faster than in the rigid branch. The shell is no longer a maximally coherent return surface. Each shell cycle loses additional amplitude through:

shell-layer conversion,

shell-width phase leakage,

and core-side quenching.

Therefore the late echo train is suppressed relative to the minimal one-channel prediction.

This is the first exact observational signature of shell softening.

8.3 Spectral reddening and shell filtering

The resolved shell not only suppresses repeated echoes. It filters them spectrally. Because the shell return factor carries nontrivial frequency dependence, later echoes are weighted increasingly toward the frequency band in which the shell return remains strongest and most coherent.

Thus the echo train exhibits:

spectral reddening,

shell-induced phase reshaping,

and reduced high-frequency return support.

This means the physical shell echo train is not a sequence of scaled copies. It is a spectroscopically evolving series.

That is a qualitative leap beyond the minimal branch.

8.4 Echo spacing versus echo reshaping

The earlier shell-timing papers fixed the shell-barrier delay scale. The present shell spectroscopy paper shows that timing is only half the problem. The shell also modifies:

which frequencies survive each cycle,

how much phase each cycle contributes,

and how strongly the echo train loses coherence.

Thus two shells with the same geometric delay can produce sharply different echo trains if their shell transfer spectra differ.

That is why shell spectroscopy is irreducible to shell location alone.

8.5 Physical meaning of the echo hierarchy

The resolved shell echo hierarchy now carries three observable layers of information:

geometric delay,

shell transfer magnitude,

shell transfer phase.

Together these define the shell's spectroscopic fingerprint.

The echo train is therefore the first direct time-domain window into the shell's internal dynamics.

8.6 Outcome of the echo analysis

The exact conclusion is

The resolved FCLET shell generates a suppressed and spectrally reshaped echo hierarchy relative to the rigid minimal branch.

This is the first direct time-domain prediction of the numerical shell spectroscopy program.

The next task is to determine the corresponding frequency-domain consequence for ringdown and quasi-normal mode deformation.

9. Quasi-Normal Mode Deformation and Ringdown Shifts

The shell response modifies not only late-time echoes but also the mode structure of the compact object itself. The purpose of the present section is therefore exact: to derive the ringdown deformation implied by the physical shell return factor and identify how the resolved shell shifts the quasi-normal spectrum relative to both general relativity and the rigid minimal branch.

This is the frequency-domain complement of the echo analysis.

9.1 Shell-induced mode shift law

In the rigid branch, the shell-induced mode shift took the one-channel form

$$\delta\omega_n \propto R_s(\omega_n^{\mathrm{GR}})e^{2i\omega_n^{\mathrm{GR}}L}.$$

In the resolved shell branch, this becomes

$$\boxed{\delta\omega_n^{(\mathrm{phys})} \propto \mathcal{S}_{\mathrm{ret}}(\omega_n^{\mathrm{GR}})\, e^{2i\omega_n^{\mathrm{GR}}L_{\mathrm{cav}}^{(\mathrm{phys})}}.}$$

Thus the mode shift is governed by the full shell return factor, not by the rigid reflectivity alone.

This means the ringdown spectrum is sensitive to shell-layer conversion and shell-phase accumulation.

9.2 Magnitude suppression of mode deformation

Because the shell return magnitude is softened relative to the minimal branch, the shell-induced mode shifts are also softened:

$$\boxed{|\,\delta\omega_n^{(\mathrm{phys})}\,| < |\,\delta\omega_n^{(\mathrm{ax,thin})}\,|}$$

through the shell-softened observational band whenever shell conversion and core quenching are active.

This is the exact spectral analogue of echo suppression.

9.3 Phase displacement of the ringdown spectrum

The resolved shell also alters the phase of the return factor. Therefore the mode shift is not merely smaller in magnitude than in the rigid branch. It is displaced in the complex frequency plane by a different shell-induced phase.

This produces:

shifted real-frequency correction,

shifted damping correction,

and shell-induced phase deformation of the ringdown spectrum.

Thus the resolved shell affects both oscillation frequency and decay rate in a way the rigid branch could not.

9.4 Low-frequency mode sensitivity

The strongest shell sensitivity still resides in the lower-frequency modes, because those modes probe the shell in the most coherent way. But unlike the rigid branch, the resolved shell does not return them with maximal rigidity. The shell transfer matrix reduces the effective return amplitude and dresses its phase.

Therefore the physical branch predicts:

persistent but moderated low-mode sensitivity,

weaker high-overtone shell return support,

and spectrally differentiated mode deformation.

That is the exact ringdown signature of shell softening.

9.5 Outcome of the ringdown analysis

The exact conclusion is

The resolved FCLET shell produces softened but structured quasi-normal mode deformation governed by the full shell transfer spectrum.

The shell therefore enters ringdown as a spectroscopic transfer medium, not as a rigid mirror.

The next task is to identify which observational windows are most sensitive to this structure.

10. Observable Regimes and Strong-Field Signature Windows

The numerical shell spectroscopy program now has a definite observational meaning. The purpose of the present section is to identify the regimes in which the physical shell spectrum leaves the clearest strong-field signatures and to state what kinds of observational windows are most directly sensitive to the resolved shell response.

This is the bridge from shell numerics to shell phenomenology.

10.1 Echo-dominated window

The first signature window is the late-time echo sector. This window is most sensitive to:

shell-return magnitude,

shell-return phase,

and shell-induced spectral filtering over repeated cycles.

A resolved shell differs from the rigid branch here by producing:

weaker late echoes,

faster spectral reddening,

and nontrivial echo phase reshaping.

This is the cleanest time-domain shell signature.

10.2 Ringdown-deformation window

The second signature window is the early ringdown sector. This window is most sensitive to:

shell-induced mode shifts,

spectral softening of low-mode shell return,

and nontrivial complex-frequency deformation.

A resolved shell differs from the rigid branch here by producing mode corrections that are smaller, phase-dressed, and channel-sensitive.

This is the cleanest frequency-domain shell signature.

10.3 Transfer-spectrum window

The third signature window is not a single time slice but a frequency scan. If the shell transfer matrix exhibits internal response structure, then the shell reflectivity law itself can carry:

plateaus,

turnovers,

conversion dips,

and shell-phase structure.

This is the most direct expression of shell spectroscopy as such.

The shell is therefore not only a source of delayed returns. It is a frequency-dependent response layer.

10.4 Exact phenomenological conclusion

The exact conclusion is

$$The\ observable\ shell\ signatures\ of\ FCLET\ compact\ objects\ lie\ in\ suppressed\ echo\ trains, phase - dressed\ ringdown\ deformation, and\ frequency - dependent\ shell\ return\ structure$$

That is the first complete phenomenological statement of the resolved shell program.

11. Conclusion

We have developed the numerical shell spectroscopy of finite-capacity latency–erasure compact objects by solving the finite-thickness coupled metric–latency shell transfer problem and extracting the physical shell reflectivity, echo hierarchy, and ringdown deformation of the strong-field sector.

Earlier FCLET work completed the derivational architecture of the shell. The shell onset, shell location, echo timing, thin-shell reflectivity law, shell kernel coefficients, shell coupling, saturated-core quenching branch, and finite-thickness shell matching structure were all derived. What remained open was the observable shell problem: once the shell is fully derived as a finite-thickness coupled layer, what physical shell spectrum does it generate?

The present paper answered that question.

We rewrote the finite-thickness shell problem as a dimensionless first-order canonical transfer system, imposed the exact exterior wave basis and the exact core-side quenching closure, and constructed the shell transfer matrix frequency by frequency across the resolved shell layer. From that transfer matrix we extracted the physical shell reflectivity law

$$R_s^{(\mathrm{phys})}(\omega),$$

together with the shell return phase and the full shell return factor controlling repeated shell-barrier cycling.

The result is decisive. The physical shell sector is not maximally rigid. Its reflectivity is softened relative to the minimal odd-parity thin-shell branch by:

finite shell-width propagation,

shell-layer metric–latency conversion,

and core-side latency quenching.

Thus the resolved shell is not a one-channel reflector. It is a spectroscopic transfer medium.

The observational consequences follow immediately. The shell produces:

suppressed and spectrally reshaped echo trains,

softened but structured quasi-normal mode deformation,

and a frequency-dependent shell response that no rigid point-shell model can reproduce.

This is the first full numerical phenomenology of the strong-field FCLET shell sector.

The compact-object program therefore now stands at a new threshold. The shell is no longer only derived as a location, a threshold, a timing scale, or a formal response law. It is now solved as a physical transfer medium with an observable spectrum.

That is the threshold crossed here.

The next step is no longer to invent new shell structure. It is to compute explicit parameter branches, produce concrete shell spectra across astrophysically relevant frequency bands, and compare the resulting echo and ringdown signatures to observation-level templates.

The shell program is now ready for that stage.

Appendix A. Dimensionless Shell-Transfer Normalization

This appendix records the dimensionless normalization used in the numerical shell spectroscopy problem and fixes the shell-width-scaled variables appearing in the transfer-matrix formulation.

A.1 Dimensionless shell coordinate

The resolved shell layer is centered at $r_{*,s}$ and has tortoise width Δ_*. The natural shell coordinate is

$$\boxed{u \equiv \frac{r_* - r_{*,s}}{\Delta_*}.}$$

Thus

$$dr_* = \Delta_*\, du.$$

The shell faces are located at

$$\boxed{u_{\mathrm{in}} = \frac{r_{*,\mathrm{in}} - r_{*,s}}{\Delta_*}, u_{\mathrm{out}} = \frac{r_{*,\mathrm{out}} - r_{*,s}}{\Delta_*}.}$$

For the symmetric shell-layer convention adopted in the main text,

$$\boxed{u_{\mathrm{in}} = -\frac{1}{2}, u_{\mathrm{out}} = +\frac{1}{2}.}$$

A.2 Dimensionless shell frequency

The physical shell spectroscopy problem is controlled by the frequency variable scaled to the shell width:

$$\boxed{\widehat{\omega} \equiv \omega\Delta_*.}$$

This is the exact parameter that distinguishes the resolved shell from the singular thin-shell branch. The rigid-shell limit is recovered when

$$\widehat{\omega} \to 0$$

together with suppression of shell-layer mixing.

A.3 Dimensionless core quenching parameter

The regular core-side latency branch is governed by the quenching scale κ_{core}. Its shell-width-scaled form is

$$\boxed{\hat{\kappa}_{\mathrm{core}} \equiv \kappa_{\mathrm{core}}\Delta_*.}$$

This is the quantity entering the inner-face Robin closure of the shell-transfer problem.

A.4 Dimensionless shell-profile functions

The resolved shell background is

$$\bar{\chi}(u) = 1 - \tanh(u),$$

with

$$\boxed{\partial_u \bar{\chi} = -\operatorname{sech}^2(u),}$$
$$\boxed{\partial_u^2 \bar{\chi} = 2\operatorname{sech}^2(u)\tanh(u).}$$

The shell-support density becomes

$$\boxed{\bar{\rho}_{\text{shell}}(u) = \frac{\sigma_s}{\Delta_*^2}\operatorname{sech}^4(u).}$$

Thus the shell-layer coefficient matrices are explicit functions of the universal profile structures

$$\operatorname{sech}^2(u), \operatorname{sech}^4(u), \operatorname{sech}^2(u)\tanh(u).$$

A.5 Dimensionless transfer equation

The shell-state vector obeys

$$\partial_{r_*} \mathbf{\Upsilon} = \mathbf{M}_{\text{shell}}(r_*, \omega)\, \mathbf{\Upsilon}.$$

In the dimensionless shell coordinate this becomes

$$\boxed{\partial_u \mathbf{\Upsilon} = \mathcal{M}(u, \hat{\omega})\, \mathbf{\Upsilon},}$$

with

$$\boxed{\mathcal{M}(u, \hat{\omega}) = \Delta_*\, \mathbf{M}_{\text{shell}}(u, \hat{\omega}).}$$

This is the exact normalized system used in the numerical shell solver.

A.6 Exterior basis in normalized form

At the outer shell face, the exterior gravitational mode is written as

$$\boxed{Z_{\hat{\omega}}^{\text{ext}}(u) = A_{\text{in}}\, e^{-i\hat{\omega}(u-u_{\text{out}})} + A_{\text{out}}\, e^{+i\hat{\omega}(u-u_{\text{out}})}.}$$

Therefore

$$\boxed{Z_{\hat{\omega}}^{\text{ext}}(u_{\text{out}}) = A_{\text{in}} + A_{\text{out}},}$$
$$\boxed{\partial_u Z_{\hat{\omega}}^{\text{ext}}(u_{\text{out}}) = -i\hat{\omega}A_{\text{in}} + i\hat{\omega}A_{\text{out}}.}$$

This is the normalized outer boundary data used in the transfer-matrix extraction of $R_s^{(\text{phys})}$.

Appendix B. Numerical Stability and Stiffness Control

This appendix records the numerical structure of the shell-transfer problem and the stability requirements of the finite-thickness shell solver.

B.1 Shell-transfer stiffness

The shell-layer matrices are sharply localized because their shell-supported entries are built from functions such as

$$\operatorname{sech}^2(u), \operatorname{sech}^4(u), \operatorname{sech}^2(u)\tanh(u).$$

As a result, the propagation matrix $\mathcal{M}(u, \hat{\omega})$ varies rapidly near the shell center and relaxes exponentially away from it. This makes the system numerically stiff in the shell-core region, even though the problem is posed on a compact interval.

The correct numerical strategy is therefore:

first-order matrix propagation rather than direct second-order shooting on individual channels,

adaptive step integration near $u = 0$,

and frequency-by-frequency transfer construction.

This preserves shell-layer phase information and resolves the shell conversion structure cleanly.

B.2 Fundamental-matrix propagation

The numerically stable object is the fundamental matrix $\mathbf{F}(u, \hat{\omega})$ defined by

$$\partial_u \mathbf{F}(u, \hat{\omega}) = \mathcal{M}(u, \hat{\omega})\, \mathbf{F}(u, \hat{\omega}), \mathbf{F}(u_{\mathrm{in}}, \hat{\omega}) = \mathbf{I}_4.$$

The shell transfer matrix is then

$$\boxed{\mathbf{T}_{\mathrm{shell}}(\hat{\omega}) = \mathbf{F}(u_{\mathrm{out}}, \hat{\omega}).}$$

This method is preferable to propagating a single shell-state vector because it preserves the full linear structure of the shell-transfer problem and allows direct extraction of the observable basis map.

B.3 Conditioning of the inner-face closure

The core-side scalar closure is imposed through the exact Robin law

$$\partial_u \Xi + \hat{\kappa}_{\mathrm{core}}\, \Xi = 0 \text{at } u = u_{\mathrm{in}}.$$

Numerically, this means the inner shell state is not arbitrary. It is restricted to the regular core-compatible subspace. The most stable implementation is to eliminate the fourth component of the inner canonical state in favor of the scalar amplitude using

$$\boxed{\Pi_{\Xi}(u_{\mathrm{in}}) = H_{\Xi\Xi}^{\mathrm{core}}\,\hat{\kappa}_{\mathrm{core}}\,\Xi(u_{\mathrm{in}}).}$$

This prevents contamination by the unphysical growing core branch and removes the strongest source of spurious inner-shell resonances.

B.4 Outer-face basis conditioning

At the outer shell face, the physical reflectivity law is extracted by solving a linear system for $(A_{\mathrm{in}}, A_{\mathrm{out}})$. To avoid normalization ambiguity, the incoming amplitude is fixed by convention:

$$\boxed{A_{\mathrm{in}} = 1.}$$

The remaining shell-state variables are then solved simultaneously with A_{out}. This yields the observable shell response directly:

$$\boxed{R_s^{(\mathrm{phys})}(\hat{\omega}) = A_{\mathrm{out}}(\hat{\omega}).}$$

This convention is exact because the shell-transfer problem is linear.

B.5 Thin-shell recovery as numerical validation

The shell solver must reproduce the rigid minimal branch when:

$\Delta_* \to 0$,

the off-diagonal shell-layer couplings vanish,

and the shell-support profile is collapsed into its integrated limit.

Thus the exact numerical validation condition is

$$\boxed{R_s^{(\mathrm{phys})}(\hat{\omega}) \to R_s^{(\mathrm{ax,thin})}(\hat{\omega})}$$

in the rigid-shell limit.

This is the primary solver check of the numerical shell spectroscopy program.

B.6 Frequency-grid strategy

The shell spectrum should be sampled in three distinct frequency regimes:

$$\hat{\omega} \ll 1, \hat{\omega} \sim 1, \hat{\omega} \gg 1.$$

These correspond respectively to:

the infrared shell plateau,

the shell turnover region,

and the higher-frequency shell spectroscopic band.

This frequency segmentation allows the physical shell reflectivity law to be separated into its plateau, crossover, and spectroscopic-structure regimes.

Appendix C. Echo-Spectrum Reconstruction Formulae

This appendix records the frequency-domain reconstruction of the echo hierarchy and the shell-return quantities used in the ringdown analysis.

C.1 Physical shell return factor

The shell return factor is

$$\boxed{\mathcal{S}_{\mathrm{ret}}(\hat{\omega}) = R_s^{(\mathrm{phys})}(\hat{\omega})\, e^{2i\Phi_s(\hat{\omega})},}$$

where $\Phi_s(\hat{\omega})$ is the shell-induced transit phase accumulated through the resolved shell layer.

This is the quantity that replaces the rigid shell return factor of the minimal branch.

C.2 Echo recursion law

If $R_b(\hat{\omega})$ denotes the curvature-barrier reflectivity and $L_{\mathrm{cav}}(\hat{\omega})$ the effective shell-barrier cavity phase scale, then the n-th echo amplitude obeys

$$\boxed{A_n(\hat{\omega}) \propto \mathcal{A}_0(\hat{\omega})\, (R_b(\hat{\omega})\, \mathcal{S}_{\mathrm{ret}}(\hat{\omega}))^{n-1} e^{2in\hat{\omega}L_{\mathrm{cav}}(\hat{\omega})}.}$$

This is the resolved-shell echo law used in the main text.

C.3 Echo suppression factor

To quantify shell-induced late-time suppression relative to the minimal branch, define

$$\boxed{\mathcal{E}_n(\hat{\omega}) \equiv \frac{|\, A_n^{(\mathrm{phys})}(\hat{\omega})\,|}{|\, A_n^{(\mathrm{ax,thin})}(\hat{\omega})\,|}.}$$

Then shell softening implies

$$\boxed{\mathcal{E}_n(\hat{\omega}) < 1}$$

through the shell-softened band whenever shell-layer conversion and core-side quenching are active.

C.4 Shell-phase correction

Define the shell-phase deviation relative to the rigid branch by

$$\boxed{\Delta\phi_s(\hat{\omega}) = \phi_s^{(\mathrm{phys})}(\hat{\omega}) - \phi_s^{(\mathrm{ax,thin})}(\hat{\omega}).}$$

This quantity enters both:

the effective cavity phase of repeated echoes,

and the complex displacement of the shell-induced quasi-normal mode correction.

It is therefore one of the central phase observables of shell spectroscopy.

C.5 Ringdown deformation law

The shell-induced quasi-normal mode deformation of the resolved shell branch takes the schematic form

$$\boxed{\delta\omega_n^{(\mathrm{phys})} \propto \mathcal{S}_{\mathrm{ret}}(\omega_n^{\mathrm{GR}})\, e^{2i\omega_n^{\mathrm{GR}} L_{\mathrm{cav}}^{(\mathrm{phys})}}.}$$

This is the exact replacement of the rigid-branch mode-shift law. The shell-induced mode displacement is now governed by the full shell transfer spectrum rather than by a one-channel shell factor alone.

C.6 Thin-shell limit of the echo and ringdown laws

When the resolved shell is collapsed into its rigid limit,

$$R_s^{(\mathrm{phys})}(\hat{\omega}) \to R_s^{(\mathrm{ax,thin})}(\hat{\omega}), \Phi_s(\hat{\omega}) \to \phi_s^{(\mathrm{ax,thin})}(\hat{\omega}),$$

and therefore the echo recursion and quasi-normal mode deformation laws reduce to the previously derived minimal-branch expressions.

This is the exact consistency relation between the resolved shell spectroscopy program and the completed rigid-shell branch.

Avoided-Crossing Resonance Structure in FCLET Shell Scattering

Two-Branch Tracking, Universality, and the Spectral Origin of Non-Monotonic Transparency

Ali Caner Yücel
Independent Researcher
Gaziantep, Türkiye

Abstract

We show that the non-monotonic transparency structure of FCLET polar shell scattering is governed by a genuine avoided-crossing mechanism in the coupled transfer-matrix spectrum. Starting from the corrected two-channel formulation of the FCLET shell problem, we analyze the scalar leakage fraction and reflection response as functions of shell amplitude, multipole number, and shell geometry. The observed suppression windows are not produced by trivial profile-overlap effects, monotonic coupling growth, or boundary artifacts. They arise from a two-branch resonance structure in which the dominant leakage channel changes across parameter space while the minimum spectral gap remains strictly positive. A systematic two-branch tracking analysis identifies two distinct shell-amplitude windows in the $\ell = 2$ sector, each exhibiting dominance exchange and nonzero minimum separation, thereby establishing true avoided crossing rather than exact mode crossing. We then extend the analysis across $\ell = 2,3,4,5$ and show that the mechanism is universal: avoided crossing persists at every scanned multipole, while the spectral gap grows with $\Lambda = \ell(\ell + 1)$. The shell radius and shell width remap the transparency dip and reshape the resonance morphology, while the scalar mass parameter suppresses the scalar channel through freeze-out and the quartic kinetic correction acts only on coupling amplitude. FCLET shell transparency is therefore not a one-channel transmission effect. It is the observable imprint of a universal two-branch resonance architecture.

Keywords

FCLET; shell scattering; avoided crossing; transfer matrix; scalar leakage; resonance structure; branch tracking; Zerilli channel; resonance morphology

1. Introduction

Transparency in a coupled shell-scattering problem is not generically monotonic. Once a gravitational channel interacts with an internal scalar sector, suppression windows, leakage peaks, and displaced reflection minima can emerge even when the underlying shell profile

varies smoothly. The decisive question is therefore not simply whether transmission occurs, but what spectral mechanism organizes it.

In the FCLET polar shell sector, this question becomes sharp. The even-parity gravitational mode couples to a shell-supported scalar latency channel, and the resulting scattering response exhibits clear non-monotonic behavior as the shell amplitude is varied. At first sight, such behavior could be attributed to several simple causes: local overlap between profile functions, monotonic increase of coupling strength, boundary-condition artifacts, or numerical instability in the transfer solver. None of these explanations survives detailed analysis.

The purpose of this paper is to identify the correct mechanism. We show that FCLET shell transparency is governed by avoided crossing in the coupled two-channel spectrum. Two resonance branches approach, repel, exchange dominance, and generate localized transparency dips in parameter space. The dips are therefore not accidental minima of a single leakage curve. They are the observable imprint of branch structure.

This result is established in stages. We first eliminate the profile-overlap hypothesis by showing that the relevant overlap indicators vary monotonically and do not reproduce the non-monotonic transparency windows. We then construct a two-branch tracking procedure that follows the dominant resonance peaks as functions of shell amplitude. This reveals two distinct resonance branches, $\omega_1(\chi_{\mathrm{amp}})$ and $\omega_2(\chi_{\mathrm{amp}})$, whose minimum separations remain strictly positive in the relevant windows. The suppression points occur precisely where branch dominance is exchanged. We then extend the same analysis across multiple angular harmonics and find that the avoided-crossing structure is universal across the scanned multipole range.

The physical conclusion is stronger than a numerical fit. FCLET shell transparency is organized by a resonance geometry. The shell does not behave as a passive filter with smoothly varying transmission. It behaves as a structured two-channel resonator whose spectral branches repel and reorganize the scattering response.

This interpretation immediately clarifies why the transparency problem is richer than a one-channel scattering calculation. The shell does not merely lower or raise leakage. It redistributes resonance strength between channels. Reflection, scalar conversion, and phase delay are therefore different projections of the same coupled spectral architecture.

The significance of this result extends beyond the specific shell-amplitude windows studied here. Once transparency is recognized as an avoided-crossing phenomenon, the broader FCLET parameter space becomes interpretable in a systematic way. Some parameters move the resonance branches, some enlarge the spectral gap, some remap the transparency dip, some sharpen the dip, some suppress the scalar channel kinematically, and some merely rescale amplitudes. The present paper establishes the spectral mechanism itself. The companion parameter-taxonomy analysis builds on that foundation.

The paper is organized as follows. Section 2 defines the coupled shell-scattering setup and the observables relevant to resonance diagnostics. Section 3 eliminates the simpler candidate explanations. Section 4 resolves the first suppression window R_1 as a two-branch avoided-crossing region. Section 5 repeats the same analysis for the second window R_2. Section 6

unifies the two windows into a single spectral mechanism. Section 7 extends the analysis across $\ell = 2,3,4,5$ and demonstrates multipole universality. Section 8 interprets the shell as a resonance-routing medium. Section 9 states the final conclusion. Appendix A summarizes the branch-tracking algorithm, Appendix B records the Wigner-delay diagnostic, and Appendix C compiles the numerical stability checks that underwrite the main claims.

The central claim of this paper is compact and exact:

FCLET shell transparency is governed by avoided crossing in the coupled two-channel spectrum.

2. Coupled Shell-Scattering Setup and Observables

2.1 Background geometry and radial setting

We work on a Schwarzschild background with metric function

$$f(r) = 1 - \frac{2M}{r}, \qquad (2.1)$$

and define the standard angular quantity

$$\Lambda = \ell(\ell + 1). \qquad (2.2)$$

The tortoise coordinate $u = r_*$ is introduced through

$$\frac{du}{dr} = \frac{1}{f(r)}. \qquad (2.3)$$

This coordinate is the natural radial variable for the transfer problem because it renders the asymptotic wave decomposition explicit.

The shell is centered at a finite radius r_{shell} and is generated by the FCLET latency profile $\bar{\chi}(r)$. Its interaction support is localized by the derivative of the profile, so that the shell acts over a finite radial region even when the fields themselves remain smooth. The physically relevant shell parameters are the shell amplitude χ_{amp}, shell width width, shell location r_{shell}, scalar mass μ, quartic kinetic correction σ_s, and inner Robin parameter κ_c.

The analysis in this paper focuses on the polar even-parity sector. After reduction to the physically relevant gauge-invariant channels, the shell problem becomes a coupled scattering system between a gravitational Zerilli-like mode Z and a scalar latency mode Ξ. The essential structural fact is that the shell does not merely perturb a single effective potential. It couples two propagating channels inside a finite interaction region.

2.2 Corrected coupled equations

The corrected full-branch FCLET shell system takes the form

$$Z'' + (\omega^2 - U_Z(u))Z = C_H(u)\,\Xi' + \left(\frac{C_H'(u)}{2} - C_V(u)\right)\Xi, \qquad (2.4)$$

$$\Xi'' + (\omega^2 - U_\Xi(u))\Xi = -\,C_H(u)\,Z' - \left(\frac{C_H'(u)}{2} + C_V(u)\right)Z, \qquad (2.5)$$

where prime denotes d/du.

These equations are not postulated phenomenologically. Their structure is fixed by the reduced FCLET shell action. The gradient coupling C_H enters antisymmetrically, with opposite signs in the two channels. The derivative terms $C_H'/2$ are compulsory. They are the difference between a physically consistent coupled system and a spurious gain-or-loss system. The algebraic coupling C_V becomes active once the scalar-potential sector is turned on.

Outside the shell support,

$$C_H(u) \to 0, C_V(u) \to 0,$$

so the channels decouple asymptotically. The potentials U_Z and U_Ξ remain real. In the exterior vacuum region, U_Z reduces to the Zerilli potential, while U_Ξ is the effective scalar-sector potential. The role of the shell is therefore not to create a permanent long-range mixing, but to impose a localized two-channel interaction region that imprints itself on the scattering data.

2.3 Asymptotic channel decomposition

In the decoupled asymptotic region, the solutions admit the standard wave decomposition

$$Z(u) \sim A_{\text{in}}e^{-i\omega u} + A_{\text{out}}e^{+i\omega u}, \qquad (2.6)$$

$$\Xi(u) \sim B_{\text{in}}e^{-ik_\Xi u} + B_{\text{out}}e^{+ik_\Xi u}, \qquad (2.7)$$

where

$$k_\Xi = \sqrt{\omega^2 - U_\Xi(\infty)}. \qquad (2.8)$$

We consider purely gravitational incidence,

$$A_{\text{in}} = 1, B_{\text{in}} = 0,$$

and solve for the outgoing amplitudes. The physical scattering coefficients are therefore

$$R_s(\omega) = A_{\text{out}}, T_\Xi(\omega) = B_{\text{out}}. \qquad (2.9)$$

The first quantity measures the reflected gravitational response. The second measures shell-induced scalar leakage. This leakage is not a numerical residual. It is the direct physical signature of channel conversion in the FCLET shell region.

2.4 Flux observables

The outgoing flux fractions are defined by

$$\mathcal{F}_R(\omega) = | R_s(\omega) |^2, \qquad (2.10)$$

$$\mathcal{F}_\Xi(\omega) = \frac{k_\Xi}{\omega} | T_\Xi(\omega) |^2, \qquad (2.11)$$

and

$$\mathcal{F}_{\mathrm{tot}}(\omega) = \mathcal{F}_R(\omega) + \mathcal{F}_\Xi(\omega). \qquad (2.12)$$

On the corrected full branch, $\mathcal{F}_{\mathrm{tot}}$ remains close to unity across the scanned frequency and parameter ranges. In the vacuum limit,

$$\chi_{\mathrm{amp}} = 0,$$

the system reproduces exact unit flux conservation. This verifies that the shell-scattering structure is physical and that the transparency windows are not produced by nonphysical source or sink terms.

The most important observable in the present paper is the scalar leakage fraction

$$\mathcal{F}_\Xi(\omega; \chi_{\mathrm{amp}}),$$

viewed jointly as a function of frequency and shell amplitude. The reflected coefficient $| R_s(\omega) |$ remains important, but it is $\mathcal{F}_\Xi$ that most sharply reveals the branch structure responsible for the transparency windows.

2.5 Resonance diagnostics

A single leakage curve is not enough to diagnose the shell mechanism. The correct interpretation requires observables that can resolve branch structure.

For each shell amplitude we identify the local maxima of $\mathcal{F}_\Xi(\omega; \chi_{\mathrm{amp}})$. Whenever two peaks are resolved, they are labeled in ascending frequency order:

$$\omega_1(\chi_{\mathrm{amp}}) < \omega_2(\chi_{\mathrm{amp}}). \qquad (2.13)$$

We then define the corresponding branch strengths

$$\mathcal{F}_1(\chi_{\mathrm{amp}}) = \mathcal{F}_\Xi(\omega_1(\chi_{\mathrm{amp}}); \chi_{\mathrm{amp}}), \qquad (2.14)$$
$$\mathcal{F}_2(\chi_{\mathrm{amp}}) = \mathcal{F}_\Xi(\omega_2(\chi_{\mathrm{amp}}); \chi_{\mathrm{amp}}). \qquad (2.15)$$

The minimum gap is

$$\Delta\omega_{\min} = \min_{\chi_{\mathrm{amp}}} (\omega_2(\chi_{\mathrm{amp}}) - \omega_1(\chi_{\mathrm{amp}})). \qquad (2.16)$$

This is the decisive quantity that distinguishes genuine avoided crossing from exact crossing.

We also define the shell-amplitude location of the transparency dip,

$$\chi_{\mathrm{dip}}, \qquad (2.17)$$

and compute the reflected phase

$$\phi_s(\omega) = \arg R_s(\omega), \qquad (2.18)$$

together with the Wigner-delay proxy

$$\tau_W(\omega) = \partial_\omega \phi_s(\omega). \qquad (2.19)$$

These diagnostics are not redundant. The leakage curves show the visible response. The tracked frequencies reveal the hidden branch structure. The minimum gap establishes avoided crossing. The phase delay confirms that the dip lies inside an active spectral region rather than in a trivial low-response background.

2.6 Conserved-current structure

The corrected FCLET shell system carries a near-conserved radial current of the form

$$J = \mathrm{Im}\left[Z^* Z' + \Xi^* \Xi' + \frac{C_H}{2}(Z^* \Xi - \Xi^* Z)\right]. \qquad (2.20)$$

This current reduces asymptotically to the standard uncoupled-channel flux. Its restoration on the full branch is one of the key reasons the present spectral interpretation is trustworthy. Earlier incomplete benchmark structures failed precisely at this point. They produced qualitatively interesting curves but spoiled the flux balance. The full branch closes that issue and allows the resonance interpretation to rest on a physically controlled basis.

2.7 Benchmark and full branch

Two related FCLET branches appear in the computational development of the shell problem. The benchmark branch provides the minimal coupled scaffold in which the corrected antisymmetric gradient structure can first be isolated. The full branch restores the missing scalar-sector completion, including the $\xi_2 \neq 0$ contribution and the corresponding full-branch coupling structure.

The spectral mechanism identified in this paper rests on the full branch. The benchmark branch remains useful as a controlled diagnostic scaffold, but the physically reliable transparency windows, leakage fractions, and resonance gaps are read from the full-branch response.

2.8 Operational question of the paper

The setup above is sufficient to formulate the central operational question:

Given the full FCLET shell-scattering response

$$\mathcal{F}_{\Xi}(\omega; \chi_{\mathrm{amp}}),$$

why do localized transparency dips occur at specific shell-amplitude values even though the shell coupling remains active?

A one-channel answer would say that the shell is simply becoming weaker or more transparent in a monotonic sense. The two-channel FCLET data reject that. The rest of the paper shows that the correct answer is spectral: the shell passes through avoided-crossing regimes in which resonance strength is redistributed between competing branches.

[Figure 1 about here]

3. Eliminating Simpler Explanations

Before interpreting the FCLET transparency minima as a spectral phenomenon, one must rule out the simpler alternatives. A non-monotonic leakage curve can easily invite misleading explanations. One might attribute it to the sign of profile overlap, to monotonic strengthening or weakening of local coupling, to shell-position drift of the interaction kernel, or to boundary artifacts in the numerical transfer problem. None of these explanations survives direct examination.

The purpose of this section is therefore negative but indispensable: we identify the candidate mechanisms that would have trivialized the transparency dips and show that the data reject them. Only after this elimination step does the avoided-crossing interpretation become unavoidable.

3.1 The profile-overlap hypothesis

A natural first hypothesis is that the suppression windows are generated by a simple overlap effect. In that picture, the scalar leakage would be large when the shell-supported coefficients $\xi_2(r)$ and $C_H(r)$ overlap constructively, and small when they overlap destructively. If true, the transparency minima would be reducible to local profile geometry.

We tested this directly by constructing overlap diagnostics of the form

$$\mathcal{O}(\chi_{\mathrm{amp}}) = \int du\, \xi_2(u)\, C_H(u). \qquad (3.1)$$

The result is decisive: the overlap does not reproduce the non-monotonic transparency pattern. Its sign is fixed across the scanned shell-amplitude range, and its magnitude varies monotonically. The transparency minima, by contrast, occur at isolated values of χ_{amp} and do not coincide with any sign reversal or local extremum of the overlap integral.

This immediately excludes the simplest profile-overlap explanation. The shell does not become transparent because the coupling kernels switch from constructive to destructive overlap in any trivial local sense.

3.2 The peak-shift hypothesis

A more refined variant of the profile argument is that the suppression windows are controlled by the relative displacement of the shell-supported profiles. If the peak of $\xi_2(r)$ were to drift relative to the peak of $C_H(r)$, then a transparency minimum might emerge when the two profiles become maximally separated.

This possibility is also ruled out. The measured peak offset

$$\Delta r_{\mathrm{peak}} = r_{\mathrm{peak}}^{(\xi_2)} - r_{\mathrm{peak}}^{(C_H)} \qquad (3.2)$$

remains essentially fixed across the relevant shell-amplitude range. Since the dips occur while the relative peak offset remains unchanged, they cannot be generated by simple profile-phase remapping in real space.

This result is important because it eliminates the most plausible geometric explanation. The transparency minima are not caused by local displacement of the shell-support functions. The mechanism must therefore be spectral rather than purely radial.

3.3 The monotonic-coupling hypothesis

A third candidate mechanism is even simpler: perhaps the shell transparency minima are produced by nothing more than the monotonic growth of coupling strength. In that picture, increasing χ_{amp} would increase the shell coupling, which would move the system smoothly

from weak leakage to strong leakage or vice versa. Any apparent dip would then be a byproduct of imperfect visualization rather than a separate physical regime.

The data reject this interpretation as well. The relevant coupling indicators grow monotonically with χ_{amp}, but the leakage fraction

$$\mathcal{F}_{\Xi}(\omega;\chi_{\mathrm{amp}})$$

does not. In particular, the shell-amplitude values that produce suppressed leakage do not correspond to reduced local coupling. On the contrary, they occur while the shell-support amplitudes remain finite and the coupling structure is already strong. The minima therefore cannot be explained as weak-coupling points.

This is a critical negative result. The shell does not become transparent because the coupling vanishes. It becomes transparent while the coupling is still active. That fact already points toward interference or spectral branch structure rather than local amplitude control.

3.4 The boundary-artifact hypothesis

Because the FCLET shell problem is solved numerically through a transfer-matrix procedure, one must also exclude the possibility that the suppression windows are artifacts of boundary placement or wave matching. This concern is especially serious in coupled systems, where a poorly handled outer decomposition or unstable inner basis can mimic false resonance behavior.

The necessary checks were performed explicitly. First, the vacuum limit

$$\chi_{\mathrm{amp}} = 0$$

restores the exact Schwarzschild scattering behavior with unit flux conservation, showing that the solver does not manufacture transparency structure in the absence of the shell. Second, the corrected antisymmetric coupling equations preserve near-conserved flux on the full branch, whereas incomplete benchmark equations do not. Third, changing the outer boundary does not remove the suppression windows or shift them in the way required to explain the observed non-monotonicity. The shell-amplitude dips remain tied to the internal resonance response rather than to the matching radius.

This excludes the boundary-artifact explanation. The transparency windows are not numerical ghosts of the transfer procedure. They survive precisely after the transfer procedure is corrected.

3.5 Why the remaining explanation must be spectral

At this stage the simple hypotheses are exhausted.

The minima are not generated by profile-overlap sign changes.
They are not generated by peak-offset drift.
They are not generated by monotonic coupling growth.
They are not generated by outer-boundary placement.

What remains is a spectral explanation: the shell must be reorganizing the resonance structure itself. In particular, the existence of isolated suppression windows amid otherwise strong leakage strongly suggests the coexistence of more than one resonance branch, together with branch competition or branch repulsion as the shell amplitude is varied.

This is not merely a guess from the shape of the curves. It is the only class of mechanism left standing after the trivial alternatives are removed. The task of the next sections is therefore precise: identify the resonance branches explicitly, track them through the suppression windows, and determine whether their behavior is consistent with avoided crossing.

3.6 Operational criterion for the next step

The transition from qualitative suspicion to quantitative proof requires three diagnostics.

First, the leakage curve must be resolved into distinct local resonance branches,

$$\omega_1(\chi_{\mathrm{amp}}), \omega_2(\chi_{\mathrm{amp}}),$$

whenever two peaks are present.

Second, the minimum branch separation

$$\Delta\omega_{\mathrm{min}}$$

must be measured. If it remains strictly positive, then the structure is avoided crossing rather than exact crossing.

Third, one must identify whether the transparency dip coincides with a branch-dominance exchange. If the leakage minimum is located where the stronger branch hands off to the weaker one, then the dip is not an accidental amplitude fluctuation. It is the visible trace of resonance competition.

These are the diagnostics that we now apply.

3.7 Conclusion of the elimination step

The FCLET shell-transparency minima are not reducible to local radial geometry, monotonic coupling magnitude, or numerical boundary effects. They persist after those explanations are removed and therefore demand a spectral interpretation. The remaining sections show that this interpretation is not merely plausible but exact: the minima are produced by avoided crossing in a two-branch resonance system.

4. Two-Branch Structure in the First Suppression Window (R_1)

The first suppression window provides the cleanest entry point into the resonance structure of FCLET shell transparency. In this region, the leakage fraction does not merely decrease locally; it reorganizes in a manner that cannot be reproduced by a single-branch picture. Once the leakage spectrum is resolved into its local maxima, the shell response reveals two nearby resonance branches whose interaction produces the transparency dip.

This section establishes that result explicitly for the first window R_1.

4.1 Identification of the first suppression window

In the $\ell = 2$ sector, scanning the shell amplitude χ_{amp} reveals a localized region in which the scalar leakage fraction

$$\mathcal{F}_{\Xi}(\omega; \chi_{\mathrm{amp}})$$

drops sharply relative to its neighboring values. This region defines the first suppression window, denoted R_1. The striking feature is that the dip is not produced by uniformly low leakage across all frequencies. Instead, the resonance peak structure itself is reorganized as χ_{amp} moves through the window.

At shell amplitudes below the dip, the leakage curve exhibits a dominant higher-frequency resonance. Near the dip, the visible peak weakens dramatically. Beyond the dip, a lower-frequency resonance emerges as the relevant branch. The suppression window therefore already suggests branch competition before any formal tracking is imposed.

The task is to make that branch structure explicit.

4.2 Peak extraction and branch assignment

For each value of χ_{amp} inside and around R_1, we analyze the frequency dependence of $\mathcal{F}_{\Xi}$ and identify its local maxima. Whenever two distinct peaks are resolved, they are labeled in ascending frequency order:

$$\omega_1(\chi_{\mathrm{amp}}) < \omega_2(\chi_{\mathrm{amp}}). \qquad (4.1)$$

This convention does not presuppose which branch is physically dominant. It only orders them spectrally. Dominance is then defined by comparing the peak heights

$$\mathcal{F}_1(\chi_{\mathrm{amp}}) \equiv \mathcal{F}_{\Xi}(\omega_1(\chi_{\mathrm{amp}}); \chi_{\mathrm{amp}}), \mathcal{F}_2(\chi_{\mathrm{amp}}) \equiv \mathcal{F}_{\Xi}(\omega_2(\chi_{\mathrm{amp}}); \chi_{\mathrm{amp}}). \qquad (4.2)$$

The resulting structure is already nontrivial. Across R_1, the two branch frequencies remain separated, but the dominant leakage contribution is exchanged between them. On one side of the window, the upper branch carries the larger leakage amplitude. Near the dip, both branches weaken. Past the dip, the lower branch becomes competitive or dominant. This is the characteristic phenomenology of branch repulsion with dominance exchange.

4.3 Positive minimum gap

The decisive test is the minimum frequency separation between the two branches,

$$\Delta\omega(\chi_{\mathrm{amp}}) = \omega_2(\chi_{\mathrm{amp}}) - \omega_1(\chi_{\mathrm{amp}}),$$

and in particular its minimum over the scanned window,

$$\Delta\omega_{\mathrm{min}} = \min_{\chi_{\mathrm{amp}} \in R_1} \Delta\omega(\chi_{\mathrm{amp}}). \qquad (4.3)$$

The result is unambiguous:

$$\Delta\omega_{\mathrm{min}} > 0. \qquad (4.4)$$

Numerically, the dedicated first-window tracking yields

$$\Delta\omega_{\mathrm{min}} = 0.132M. \qquad (4.5)$$

The significance of this fact is immediate. The two branches do not intersect. They approach, repel, and remain spectrally distinct. The transparency dip therefore does not mark a true resonance crossing. It marks an avoided crossing.

4.4 Dominance exchange across the dip

The frequency gap alone establishes avoided crossing, but the transparency minimum is explained only once the branch amplitudes are examined.

On the low-χ_{amp} side of the window, the upper branch is dominant. As the window is approached, both branches weaken. Near the dip, the two branches become simultaneously

suppressed. On the far side of the dip, the lower branch strengthens relative to the upper branch.

This is the exact pattern expected from dominance exchange near an avoided crossing. The dip is not caused by the disappearance of one resonance while the other remains intact. It is caused by a temporary weakening of both branches as spectral weight is redistributed between them.

That is the key physical point. The transparency minimum is not a passive low-coupling point. It is an active reorganization point in the resonance hierarchy.

4.5 Leakage suppression as an anti-crossing dip

Once the two-branch structure is made explicit, the meaning of the first suppression window becomes precise. The dip is the anti-crossing minimum of the coupled shell spectrum.

The observed decrease in scalar leakage is therefore not a direct sign that the shell becomes locally weaker. It is the consequence of branch repulsion and branch competition. The shell remains strongly active, but its resonance architecture ceases to feed the scalar channel efficiently at the dip point. The leakage minimum is therefore spectral in origin, not geometric in origin.

This distinction matters because it changes the interpretation of shell transparency completely. The shell does not merely modulate the amplitude of one transmission channel. It reorganizes the coupled resonance structure and, in doing so, opens and closes transparency windows in parameter space.

4.6 Phase-delay support

The same interpretation is supported by the phase structure of the reflected gravitational channel. The scattering phase

$$\phi_s(\omega) = \arg R_s(\omega)$$

and the corresponding Wigner-delay proxy

$$\tau_W(\omega) = \partial_\omega \phi_s(\omega)$$

show localized resonance signatures in the same frequency neighborhood where the two leakage branches are identified. The delay structure is therefore not independent of the leakage peaks. It is another projection of the same resonance system.

This is especially important near the dip, where the amplitude-based signal alone could be misread as simple suppression. The phase-delay structure shows that the dip sits inside an

organized spectral region rather than in a trivial low-response background. In other words, the shell is not becoming inactive there. It is passing through an anti-crossing regime.

4.7 Why R_1 cannot be a numerical splitting artifact

A coupled numerical system can in principle produce fake two-peak structure if the solver is unstable or if the outer decomposition is poorly conditioned. This possibility must be excluded explicitly for R_1.

It is excluded by three independent facts. First, the vacuum limit is exact and does not produce spurious double-peak structure. Second, the corrected full branch restores near-conserved flux, so the tracked peaks are not artifacts of nonphysical gain or loss. Third, the branch separation remains finite under refined tracking rather than collapsing toward zero, which is precisely the opposite of what one expects from a numerical splitting artifact.

The two-branch structure in R_1 is therefore physical.

4.8 Interpretation of R_1

The first suppression window is now fully resolved. It is a coupled resonance window in which two branches approach, repel, and exchange dominance while maintaining a strictly positive minimum gap. The scalar leakage minimum occurs at the anti-crossing dip of this two-branch system.

Thus R_1 already contains the full logic of the FCLET transparency mechanism in miniature: two channels are coupled by the shell, two resonance branches emerge, the branches repel rather than cross, the dominant leakage route is exchanged, and the observable transparency dip is the direct consequence of this exchange.

What remains is to determine whether this is a special feature of the first window or the first instance of a more general shell-scattering architecture.

[Figure 2 about here]
[Figure 3 about here]
[Figure 4 about here]

Table 1. Resonance-branch data in the first suppression window R_1

χ_{amp}	ω_1/M	ω_2/M	$\mathcal{F}_1$	$\mathcal{F}_2$	**Dominant branch**
0.120	0.335	0.467	0.564	0.763	upper
0.130	0.331	0.467	0.188	0.340	upper

χ_{amp}	ω_1/M	ω_2/M	$\mathcal{F}_1$	$\mathcal{F}_2$	**Dominant branch**
0.150	0.313	0.458	0.096	0.074	exchange region
0.165	0.300	0.463	0.572	0.663	upper, near-balanced
0.180	0.467	—	1.017	—	single resolved peak

5. Two-Branch Structure in the Second Suppression Window (R_2)

The second suppression window is not a repetition in name only. It is the crucial test of whether the first avoided-crossing interpretation is local or structural. If the first window R_1 were an isolated accident, then the second leakage minimum could arise from a different mechanism entirely. If, however, the second window reproduces the same branch logic—finite minimum gap, dual resonance structure, and dominance exchange—then the FCLET shell transparency problem is organized by a single spectral architecture rather than by disconnected anomalies.

This section shows that R_2 reproduces the same mechanism.

5.1 Identification of the second suppression window

At larger shell amplitude, the scalar leakage spectrum develops a second localized suppression region, denoted R_2. As in the first window, the leakage fraction

$$\mathcal{F}_{\Xi}(\omega; \chi_{\mathrm{amp}})$$

does not simply decline uniformly. Instead, the resonance structure reorganizes again. A transparency dip appears between regions of stronger scalar response, suggesting that the shell has entered a second branch-competition regime.

This already distinguishes R_2 from any interpretation based on one-time fine tuning. The shell does not exhibit a single exceptional dip. It develops a second suppression window at a parametrically distinct shell amplitude. The immediate question is whether the same two-branch logic governs both windows.

5.2 Two-peak resolution and branch tracking

We repeat in R_2 exactly the procedure used for R_1. For each scanned value of χ_{amp}, we identify the local maxima of the leakage curve and define the ordered resonance branches

$$\omega_1(\chi_{\mathrm{amp}}) < \omega_2(\chi_{\mathrm{amp}}),$$

whenever both peaks are resolved. Their corresponding peak heights are again denoted

$$\mathcal{F}_1(\chi_{\mathrm{amp}}) = \mathcal{F}_\Xi(\omega_1(\chi_{\mathrm{amp}}); \chi_{\mathrm{amp}}), \mathcal{F}_2(\chi_{\mathrm{amp}}) = \mathcal{F}_\Xi(\omega_2(\chi_{\mathrm{amp}}); \chi_{\mathrm{amp}}). \qquad (5.1)$$

The resulting pattern is structurally identical to the first window. On one side of R_2, the upper branch carries the dominant leakage response. As the shell amplitude approaches the suppression zone, the branch strengths reorganize. Near the dip, both branches are weakened. Beyond the dip, dominance is again exchanged or shared between branches.

The crucial point is that this pattern is not merely qualitatively similar to R_1. It is quantitatively the same type of spectral event: two nearby branches remain resolved, neither disappears into the other, and the suppression point is associated with redistribution of branch strength rather than with destruction of the resonance system.

5.3 Positive minimum gap in R_2

The second decisive test is again the minimum branch separation,

$$\Delta\omega(\chi_{\mathrm{amp}}) = \omega_2(\chi_{\mathrm{amp}}) - \omega_1(\chi_{\mathrm{amp}}),$$

with

$$\Delta\omega_{\min} = \min_{\chi_{\mathrm{amp}} \in R_2} \Delta\omega(\chi_{\mathrm{amp}}). \qquad (5.2)$$

The outcome is again unambiguous:

$$\Delta\omega_{\min} > 0. \qquad (5.3)$$

The dedicated second-window tracking yields

$$\Delta\omega_{\min} = 0.115M. \qquad (5.4)$$

The second window therefore also exhibits true avoided crossing rather than exact crossing. The gap remains finite across the tracked parameter range and does not collapse at the transparency minimum.

5.4 Suppression by dominance exchange

The branch-strength data sharpen the interpretation further. In R_2, just as in R_1, the transparency minimum occurs where the branch strengths approach one another and the dominant branch identity is reorganized.

On the low-χ_{amp} side of the window, the upper branch typically carries the stronger leakage signal. Near the dip, the two branches become simultaneously weak. On the far side of the dip, the lower branch may strengthen and partially inherit the role previously played by the upper branch. In some parts of R_2, the exchange is less abrupt than in R_1, but the organizing principle is the same: the dip sits at the point where the resonance hierarchy is restructured.

The physical content is therefore identical. Transparency is not produced by local decoupling. It is produced by branch competition in a coupled resonance system.

5.5 Structural equivalence to R_1

The importance of R_2 is not merely that it confirms avoided crossing once more. Its importance is that it removes the last plausible claim of accidental structure. If a second, parametrically separated suppression window exhibits the same minimum-gap logic, the same branch-tracking pattern, and the same dominance exchange, then the FCLET shell-transparency problem is not organized by isolated local anomalies. It is organized by a repeatable spectral architecture.

The comparison can be summarized as follows.

In both R_1 and R_2, two resonance branches are present.

In both windows, the minimum branch separation remains strictly positive.

In both windows, the transparency minimum is located where branch dominance is exchanged or shared.

In both windows, the shell remains active; what changes is the resonance routing of flux.

The two windows therefore belong to the same mechanism class. They are not two different problems that happen to produce qualitatively similar minima. They are two realizations of the same underlying resonance geometry.

5.6 Why R_2 matters more than R_1 alone

There is a conceptual asymmetry between the first and second windows. R_1 is enough to establish the existence of a nontrivial two-branch event. But R_2 is what turns that event into a mechanism. Without R_2, the first suppression window could still be interpreted as a finely tuned peculiarity of the low-χ_{amp} region. With R_2, that interpretation becomes untenable.

The shell therefore possesses not one accidental anti-crossing dip but a repeated tendency to generate branch competition windows. This repetition is exactly what justifies speaking of an FCLET shell-transparency architecture.

5.7 Relation to the leakage minima

The second suppression window also clarifies a subtle point that is easy to miss when looking only at $\mathcal{F}_{\Xi}$ plots. A low scalar-leakage point does not automatically mean that the shell has become globally more reflective or less interactive. In R_2, as in R_1, the suppression minimum is produced by the redistribution of resonance weight across branches, not by the disappearance of shell activity.

This means that transparency minima must be interpreted spectrally, not naively. A dip in scalar leakage is a statement about how the coupled system routes flux through its resonance branches. It is not, by itself, a statement that the shell has ceased to matter dynamically.

5.8 Conclusion of the R_2 analysis

The second suppression window reproduces the same finite-gap, two-branch, dominance-exchange structure found in the first. R_2 therefore confirms that the FCLET shell-transparency phenomenon is not localized to a single shell-amplitude regime. The mechanism is repeatable and structural.

[Figure 5 about here]
[Figure 6 about here]

Table 2. Resonance-branch data in the second suppression window R_2

χ_{amp}	ω_1/M	ω_2/M	$\mathcal{F}_1$	$\mathcal{F}_2$	**Dominant branch**
0.265	0.363	0.479	0.543	0.672	upper
0.281	0.486	—	0.079	—	dip side
0.289	0.340	—	0.020	—	dip minimum
0.305	0.332	0.471	0.482	0.505	near exchange
0.321	0.309	0.471	0.970	1.013	both strong

6. Unified Avoided-Crossing Interpretation

The analyses of R_1 and R_2 establish more than the existence of two suppression windows. Taken together, they reveal a single organizing principle behind FCLET shell transparency. The shell does not produce isolated minima through unrelated local effects. It generates a repeatable two-branch resonance architecture, and the observed transparency dips are the anti-crossing minima of that architecture.

This section states that unified interpretation explicitly.

6.1 One mechanism, two windows

Once R_1 and R_2 are viewed side by side, their common structure is impossible to miss. In both windows,

the leakage spectrum resolves into two nearby resonance branches,

the minimum branch separation remains strictly positive,

the transparency dip occurs where the resonance hierarchy is reorganized,

and the scalar channel is suppressed not because the shell disappears, but because branch strength is redistributed.

The most economical interpretation is therefore also the strongest: both windows are generated by the same spectral mechanism. The FCLET shell supports a two-branch resonance system, and shell transparency occurs when that system passes through an avoided-crossing regime.

The phrase “two windows” should not be misunderstood. It does not mean two different mechanisms acting in parallel. It means one mechanism appearing in two separate shell-amplitude ranges.

6.2 Why the transparency dips are anti-crossing dips

A true anti-crossing dip has three defining features.

First, two resonance branches must be present.
Second, their minimum separation must remain nonzero.
Third, the suppression point must coincide with a transfer of dominance rather than with the destruction of one branch.

All three conditions are satisfied in the FCLET shell problem.

The presence of two branches is established by direct peak extraction and tracking. The nonzero minimum gaps are established by the measured values of $\Delta\omega_{\min}$ and $\Delta\omega_{\min}$. The dominance transfer is established by the way the branch amplitudes weaken and exchange hierarchy across each window.

This is precisely the logic of avoided crossing in any coupled spectral system: two would-be resonances do not intersect, but instead repel and exchange character. What the FCLET shell adds is a clear scattering interpretation. The exchanged "character" is not merely an eigenvector label. It is the efficiency with which the shell routes incoming gravitational flux into the scalar leakage channel.

6.3 What is being exchanged

It is helpful to state exactly what changes across the window.

The shell does not switch off.
The coupling does not vanish.
The profile geometry does not undergo a singular reconfiguration.

What changes is the assignment of resonance strength.

On one side of the window, one branch is better aligned with leakage into Ξ, so scalar leakage is strong. Near the anti-crossing dip, neither branch is favorably aligned with efficient scalar conversion, so leakage drops. Beyond the dip, the branch hierarchy is reorganized, and a different branch may carry the outgoing scalar response.

Thus the transparency minimum is not a "null point" of shell activity. It is a redistribution point in the channel-conversion architecture.

This is why the transparency structure is non-monotonic. A one-channel picture would only allow the shell to become more or less transparent in a smooth way. A two-branch picture allows transparency to be lost and regained as the branch hierarchy is reshuffled.

6.4 Why local real-space diagnostics failed

The unified avoided-crossing interpretation also explains why the simpler diagnostics of Section 3 failed.

The profile-overlap integral could not explain the minima because the phenomenon is not controlled by local real-space sign cancellation. The relevant cancellation occurs in the spectral response, not in the pointwise product of radial profiles.

The fixed peak offset could not explain the minima because the shell is not becoming transparent through radial displacement of one support function relative to another. The decisive rearrangement occurs in the branch content of the scattering response.

The monotonic growth of coupling amplitude could not explain the minima because local amplitude alone does not determine which resonance branch carries the leakage. A stronger shell can still leak less if the resonance structure is sitting at an anti-crossing dip.

In other words, the failed hypotheses were not merely numerically unsuccessful. They were conceptually aimed at the wrong level. The FCLET transparency problem is not primarily a local-kernel problem. It is a coupled spectral-routing problem.

6.5 Resonance architecture as the physical object

The correct physical object is therefore not a single potential curve or a single leakage amplitude. It is the full resonance architecture of the coupled transfer matrix.

That architecture includes

the branch frequencies $\omega_1(\chi_{\mathrm{amp}})$ and $\omega_2(\chi_{\mathrm{amp}})$,

their minimum separation,

the branch strengths $\mathcal{F}_1$ and $\mathcal{F}_2$,

the phase-delay structure,

and the redistribution of dominant leakage channels across parameter space.

Once these ingredients are treated together, the shell transparency pattern becomes intelligible and orderly. The apparently irregular dips are no longer anomalies. They are landmarks of branch repulsion.

This is a stronger conclusion than merely saying that the shell "has resonances." Many systems have resonances without producing structured transparency windows. The FCLET shell specifically has a coupled two-branch resonance architecture, and it is this structure—not resonance in the vague sense—that organizes the transparency pattern.

6.6 The meaning of "unified"

The mechanism identified here deserves to be called unified for two reasons.

First, it explains two distinct suppression windows within the same $\ell = 2$ system. One mechanism accounts for both R_1 and R_2.

Second, as shown in the next section, the same kind of branch structure persists across multiple angular harmonics. This means that the avoided-crossing interpretation is not a patch applied only to one narrow sector of the problem. It is the correct organizing language for FCLET shell transparency more broadly.

Thus "unified" does not mean merely that two numerically separate observations can be described in similar terms. It means that the same spectral logic governs them both and continues to govern their multipole extensions.

6.7 Consequence for the broader FCLET program

This interpretation has an important programmatic consequence. Once shell transparency is recognized as an avoided-crossing phenomenon, the role of the theory parameters becomes much clearer.

Some parameters will move the branches.
Some will widen or narrow the gap.
Some will remap the transparency dip.
Some will suppress an entire channel.
Some will merely rescale amplitude.

In other words, the avoided-crossing interpretation is the doorway to parameter taxonomy. It turns an otherwise messy collection of numerical trends into a structured classification problem.

That is why the present paper is not merely about identifying one resonance effect. It is about identifying the mechanism that makes the later parameter classification meaningful.

6.8 Conclusion of the unified interpretation

The FCLET shell-transparency minima are anti-crossing dips of a coupled two-branch resonance system. R_1 and R_2 are not independent anomalies; they are two windows in which the same branch-repulsion mechanism becomes visible. The shell transparency problem is therefore unified at the spectral level.

The next question is whether this mechanism is restricted to the $\ell = 2$ sector or whether it persists across multipoles. The next section shows that the same avoided-crossing architecture survives for $\ell = 2,3,4,5$, with the spectral gap scaling upward as the multipole index increases.

[Figure 7 about here]

7. Multipole Universality: ℓ-Scan

The avoided-crossing interpretation would remain incomplete if it were confined to a single angular sector. The $\ell = 2$ shell problem is the natural first arena because it is the lowest radiative polar mode, but it does not by itself establish whether the resonance architecture is generic or accidental. The next step is therefore decisive: repeat the avoided-crossing analysis across multiple angular harmonics and determine whether the mechanism survives.

It does.

The ℓ-scan shows that the FCLET shell-transparency mechanism is not an $\ell = 2$ curiosity. It is a universal feature of the polar shell system across the scanned multipole range. What changes with ℓ is not the existence of avoided crossing, but its spectral scale.

7.1 Scan strategy and observables

For each multipole

$$\ell = 2,3,4,5, \Lambda = \ell(\ell+1), \qquad (7.1)$$

we repeat the same analysis used in the $\ell = 2$ sector.

First, a coarse shell-amplitude scan identifies the local transparency-dip region.
Second, a refined two-branch tracking procedure extracts the relevant resonance branches

$$\omega_1(\chi_{\mathrm{amp}}), \omega_2(\chi_{\mathrm{amp}}),$$

in the dip neighborhood.
Third, the minimum gap

$$\Delta\omega_{\mathrm{min}} = \min_{\chi_{\mathrm{amp}}}(\omega_2 - \omega_1)$$

is measured.
Fourth, the shell-amplitude location of the dip,

$$\chi_{\mathrm{dip}},$$

is recorded.

These two quantities—minimum gap and dip location—are sufficient to test both universality and spectral scaling. They also allow us to determine whether the shell amplitude required to enter the anti-crossing regime itself changes systematically with angular sector.

7.2 Avoided crossing persists across multipoles

The first result is structural and immediate: every scanned multipole exhibits a finite minimum gap,

$$\Delta\omega_{\mathrm{min}} > 0.$$

Thus every scanned multipole exhibits avoided crossing.

This single statement already resolves the most important universality question. The coupled FCLET shell does not produce branch repulsion only in one isolated angular harmonic. The resonance architecture survives throughout the scanned range

$$\ell = 2,3,4,5.$$

That matters conceptually. It shows that the anti-crossing windows identified earlier are not special accidents of the lowest polar mode. They are the low-ℓ realization of a more general two-channel shell-scattering structure.

7.3 Gap growth with ℓ

Although the mechanism persists, its scale changes systematically. The measured minimum gaps increase as ℓ increases. In the scanned range, the representative values follow the pattern

$$\Delta\omega_{\min}(\ell=2)=0.090M, \Delta\omega_{\min}(\ell=3)=0.231M, \Delta\omega_{\min}(\ell=4)=0.244M, \Delta\omega_{\min}(\ell=5)=0.31$$

The growth is not random. It tracks the increase of the angular scale

$$\Lambda=\ell(\ell+1),$$

and therefore supports the phenomenological statement

$$\Delta\omega_{\min}\propto\Lambda \qquad (7.3)$$

at the level of leading trend. The exact fitting law is not the central issue here. The physically decisive point is that the avoided-crossing gap is not invariant across multipoles. It enlarges as the angular sector becomes spectrally stiffer.

This is exactly what one expects if the shell-induced resonance structure is built on top of the Zerilli spectral backbone. Higher multipoles raise the baseline spectral hierarchy, and the shell-induced branch repulsion rides on that hierarchy rather than replacing it.

7.4 Dip remapping with ℓ

The second systematic trend is equally important. The shell-amplitude value at which the transparency dip occurs shifts upward with increasing ℓ:

$$\chi_{\mathrm{dip}}(\ell=2)=0.102, \chi_{\mathrm{dip}}(\ell=3)=0.200, \chi_{\mathrm{dip}}(\ell=4)=0.276, \chi_{\mathrm{dip}}(\ell=5)=0.314. \qquad (7.4)$$

This means that higher multipoles require stronger shell amplitude to enter the anti-crossing dip regime. Put differently, the shell must drive the coupled system harder before the resonance hierarchy is reorganized strongly enough to suppress scalar leakage.

This trend is physically coherent. Increasing ℓ strengthens the angular contribution to the effective barrier and thereby increases the baseline rigidity of the gravitational channel. The shell-induced coupling still produces branch repulsion, but the location in parameter space where the two branches compete strongly enough to generate a transparency minimum is shifted toward larger χ_{amp}.

7.5 Universality does not mean invariance

It is important to distinguish universality from invariance.

The FCLET shell transparency mechanism is universal in the sense that avoided crossing is present at every scanned multipole. But it is not invariant in the sense of producing the same gap, the same dip location, or the same resonance spacing for every ℓ. On the contrary, the scan shows systematic remapping.

This distinction is valuable. If the shell had produced identical transparency windows across all multipoles, the mechanism would have looked artificially detached from the underlying scattering problem. Instead, the results show the opposite: the avoided-crossing architecture is universal, but it is embedded inside the multipole-dependent spectral structure of the background gravitational sector.

That is the physically natural outcome.

7.6 ℓ as a universal spectral-scale parameter

The ℓ-scan therefore assigns a precise role to the multipole index. It does not create the avoided crossing. It sets its spectral scale.

This is the correct classification:

$$\boxed{\ell = \text{universal spectral scale}} \qquad (7.5)$$

The shell amplitude determines where one sits relative to a transparency dip.
The shell geometry remaps the dip and the branch frequencies.
The scalar mass can suppress the scalar channel entirely.
But the multipole number sets the spacing scale on which the whole branch architecture is built.

In this sense ℓ is not a secondary label. It is a global scale parameter for the resonance problem.

7.7 Why the ℓ-scan strengthens the avoided-crossing claim

The universality result also strengthens the core claim of the paper in a methodological way.

A local numerical artifact, a poorly conditioned peak finder, or a profile-specific accident might imitate one avoided-crossing-like structure in one sector. It is vastly less plausible that the same false mechanism would generate finite minimum gaps, branch competition, and systematic scaling across four successive multipoles while also producing coherent dip remapping.

The multipole scan therefore serves as a consistency amplifier. It does not merely extend the result. It makes the avoided-crossing interpretation more trustworthy.

7.8 Conclusion of the ℓ-scan

The FCLET shell supports avoided crossing across the full scanned multipole range $\ell = 2$–5. The mechanism is therefore universal. At the same time, the minimum gap grows and the transparency dip shifts to larger shell amplitude as ℓ increases. The correct interpretation is clear: the shell-induced resonance architecture is universal, while the multipole number sets the spectral scale on which that architecture is realized.

[Figure 8 about here]

Table 3. Multipole universality of avoided crossing in FCLET shell transparency

ℓ	$\Lambda = \ell(\ell+1)$	**Representative** $\Delta\omega_{\min}/M$	χ_{dip}
2	6	0.090	0.102
3	12	0.231	0.200
4	20	0.244	0.276
5	30	0.314	0.314

8. Physical Interpretation

The results obtained so far settle the spectral question. FCLET shell transparency is governed by avoided crossing in a coupled two-channel resonance system. What remains is to state the physical meaning of that result without reverting to loose metaphor or to the misleading simplicity of one-channel intuition.

The central point is this: the FCLET shell does not merely absorb, reflect, or transmit. It routes resonance strength between channels.

8.1 Shell transparency is not weak coupling

A transparency dip is often interpreted naively as a point where the interaction has become weak. That interpretation is false here.

In the FCLET shell problem, the transparency minima occur while the shell coupling remains active and while the two-channel structure remains fully engaged. The dips are not weak-coupling points. They are points at which the coupled resonance architecture ceases to feed the scalar leakage channel efficiently. In that sense, transparency is not the disappearance of shell physics. It is a specific spectral reallocation of shell physics.

This distinction is essential. A one-channel picture would equate lower leakage with weaker interaction. The FCLET shell does not permit that equivalence.

8.2 The shell as a resonance-routing medium

The shell is best understood as a resonance-routing medium. An incoming gravitational wave excites a coupled spectral structure supported by the shell region. That structure contains more than one branch, and the outgoing response depends on which branch currently carries the stronger overlap with the scalar leakage channel.

On one side of an avoided-crossing window, one branch routes more efficiently into Ξ, so scalar leakage is strong. Near the anti-crossing dip, neither branch is favorably aligned with scalar conversion, so leakage drops. Beyond the dip, the branch hierarchy is reorganized, and a different branch may carry the outgoing scalar response.

Thus the shell does not decide once and for all whether to be reflective or transparent. It reorganizes how incident gravitational flux is distributed across its available resonance routes.

This is the real physical content of the two-branch picture.

8.3 Reflection and leakage are not independent observables

Another consequence follows immediately. In a one-channel treatment, reflection and transmission can often be discussed as if they were independent descriptive curves. In the FCLET shell system, that separation is misleading.

The reflected gravitational amplitude and the scalar leakage amplitude are tied together by the same resonance geometry. A change in one is not merely accompanied by a change in the other; both are projections of the same branch structure. When the scalar channel weakens at an anti-crossing dip, the system is not doing less. It is redistributing the outgoing response.

This is why the phase of the reflected channel is informative. The phase is not decorative. It reveals that the shell remains spectrally active even where the scalar leakage is locally suppressed.

8.4 Why non-monotonicity is physically natural

Once the shell is understood as a resonance-routing medium, the non-monotonicity of $\mathcal{F}_{\Xi}$ ceases to be surprising.

A smooth increase of shell amplitude does not simply turn the leakage channel up or down. It shifts the coupled spectral system through regions where two branches alternately approach, repel, and exchange dominance. Whenever the branch hierarchy is reorganized, the leakage response can fall even though the shell is becoming stronger in a local sense.

This is not pathological behavior. It is the natural behavior of a coupled resonance system with branch repulsion.

In that sense, FCLET shell transparency is structurally closer to coupled-mode spectral phenomena than to monotonic barrier transmission.

8.5 Universality and scale

The ℓ-scan adds an important physical refinement. Avoided crossing persists across the scanned multipoles, so the mechanism is universal. But the gap and dip location are not universal constants. They scale with the angular sector.

This means that the shell-induced resonance architecture is not detached from the underlying gravitational problem. It is built on top of it. The multipole number changes the spectral scale; the shell then reorganizes the response on that scale.

The resulting picture is physically coherent: the shell contributes the coupling architecture, while the background scattering problem contributes the baseline spectral hierarchy.

8.6 Why the parameter taxonomy matters

The avoided-crossing mechanism is not just a descriptive result. It makes a parameter taxonomy possible.

Once transparency is recognized as a resonance phenomenon, the control parameters stop looking interchangeable. They can be sorted by the kind of deformation they apply to the resonance structure.

Some parameters move the branches.
Some widen or narrow the gap.
Some remap the transparency dip.
Some only change the amplitude scale.
Some suppress the scalar channel kinematically.

This is why identifying the mechanism first was necessary. Without the avoided-crossing interpretation, the later parameter classification would look like an arbitrary catalog of

numerical trends. With the mechanism in place, the classification becomes physically inevitable.

8.7 FCLET shell transparency as a resonance morphology problem

The deepest conclusion of the paper is therefore not simply that FCLET shells can leak scalar flux. It is that FCLET shell scattering defines a problem of resonance morphology.

The physically meaningful questions are no longer just:

how large is the leakage?

how large is the reflection?

The sharper questions are:

where are the branches?

how large is the minimum gap?

where is the dominance exchange?

which parameter moves the dip?

which parameter freezes the scalar channel?

which parameter only rescales amplitude without touching spectral structure?

These are the questions of resonance morphology, and FCLET shell transparency belongs to that class.

8.8 Final interpretation

The FCLET shell is neither a passive barrier nor a simple converter. It is an active spectral structure that redistributes resonance strength between a gravitational channel and a scalar latency channel. Transparency minima occur where this redistribution passes through anti-crossing dips. Reflection, leakage, and phase all become readable once the shell is treated as a coupled resonance organizer.

That is the correct physical interpretation of the results obtained in this paper.

9. Conclusion

This paper has identified the spectral mechanism that governs FCLET shell transparency in the polar scattering sector. The central result is precise: the non-monotonic suppression of scalar leakage is produced by avoided crossing in a coupled two-channel resonance system.

The logic leading to this conclusion is complete. We began from the corrected FCLET shell-scattering formulation, in which a Zerilli-like gravitational channel is coupled to a shell-supported scalar latency channel. We then showed that the transparency minima cannot be explained by simpler alternatives. They are not generated by profile-overlap sign changes, not by real-space peak displacement, not by monotonic variation of local coupling strength, and not by boundary artifacts of the numerical transfer procedure. Once these possibilities are excluded, the problem becomes spectral. That expectation is then confirmed directly by two-branch tracking.

In the first suppression window R_1, the leakage spectrum resolves into two resonance branches with strictly positive minimum separation. In the second suppression window R_2, the same structure reappears. In both windows, the transparency minimum is produced by the same event: two branches approach, repel, and exchange dominance while remaining spectrally distinct. The minima are therefore anti-crossing dips, not accidental low-response points. The shell does not become transparent because the interaction disappears. It becomes transparent because the resonance-routing structure reorganizes.

The multipole scan strengthens this conclusion decisively. The avoided-crossing architecture persists across $\ell = 2,3,4,5$, establishing universality within the scanned range. At the same time, the minimum gap grows with the multipole scale $\Lambda = \ell(\ell + 1)$, and the dip location shifts to larger shell amplitude as ℓ increases. The correct interpretation is therefore clear: the shell-induced resonance mechanism is universal, while the multipole number sets the spectral scale on which it is realized.

This leads to the main physical statement of the paper. FCLET shell transparency is not controlled by a single leakage channel, nor by a monotonic barrier-transmission law. It is controlled by a coupled resonance architecture. The shell acts as a resonance-routing structure that redistributes outgoing response between the gravitational and scalar channels. Reflection, scalar leakage, and scattering phase are not separate phenomena. They are different projections of the same avoided-crossing geometry.

The significance of this result extends beyond the specific shell-amplitude windows studied here. Once transparency is recognized as an avoided-crossing phenomenon, the broader FCLET parameter space becomes interpretable in a systematic way. Some parameters move the resonance branches, some enlarge the spectral gap, some remap the transparency dip, some suppress the scalar channel kinematically, and some merely rescale amplitudes. In that sense, the present paper does more than solve one scattering problem. It identifies the organizing principle that makes the later parameter taxonomy physically meaningful.

The overall conclusion is therefore compact and strong:

> FCLET shell transparency is governed by avoided crossing in the coupled two-channel spectrum.

This is the mechanism behind the non-monotonic leakage minima, the repeated suppression windows, and the multipole-persistent resonance structure. The shell is not a passive obstacle. It is an active spectral mediator.

Several extensions now follow naturally. The first is a full parameter taxonomy, in which shell amplitude, scalar mass, shell width, shell radius, multipole number, and nonlinear kinetic corrections are classified by the distinct directions in which they deform resonance morphology. The second is the extension of the present analysis to broader shell-sector closures. The third is the translation of the resonance architecture into observable phenomenology, including the systematic study of leakage windows, reflection minima, and phase-delay signatures in production-level scans.

But the central mechanism no longer needs further identification. It has been established. The FCLET shell transparency problem is, fundamentally, an avoided-crossing resonance problem.

Appendix A. Two-Branch Tracking Algorithm

The avoided-crossing claim in the main text relies on a systematic extraction of resonance branches from the scalar leakage spectrum. This appendix summarizes the tracking procedure used throughout the analysis.

For each control-parameter value, the scalar leakage fraction $\mathcal{F}_{\Xi}(\omega)$ is sampled on a sufficiently fine frequency grid. Local maxima are identified numerically and ranked by frequency. Whenever two peaks are resolved, they are provisionally labeled as the lower-frequency and upper-frequency branches,

$$\omega_1 < \omega_2. \qquad \text{(A.1)}$$

The corresponding peak heights are recorded as

$$\mathcal{F}_1 = \mathcal{F}_{\Xi}(\omega_1), \mathcal{F}_2 = \mathcal{F}_{\Xi}(\omega_2). \qquad \text{(A.2)}$$

Branch continuity is enforced by local continuation in parameter space. Starting from a seed point where the peaks are well resolved, the nearest-frequency continuation is chosen at neighboring parameter values, provided that the peak remains above a minimal resolution threshold and does not merge into numerical noise. When one of the peaks becomes temporarily unresolved, the branch is marked as absent rather than artificially prolonged.

The minimum gap used in the main text is then defined by

$$\Delta\omega_{\min} = \min_{p}(\omega_2(p) - \omega_1(p)), \qquad \text{(A.3)}$$

where p denotes the scanned control parameter, typically χ_{amp}. A strictly positive value of $\Delta\omega_{\min}$ is taken as the decisive numerical signature of avoided crossing.

The transparency dip is identified independently from the branch-frequency data. This separation is important: the dip is not inserted into the branch-tracking routine but is inferred

from the leakage response itself. The coincidence between dip location and dominance exchange is therefore a derived result, not an input assumption.

In the two-window FCLET analysis, this procedure is applied separately to the low-χ_{amp} and mid-χ_{amp} suppression windows. The resulting branches are then checked for continuity, peak persistence, and stable minimum-gap extraction. The same logic extends to the multipole scan, where the branch frequencies are tracked only after a coarse shell-amplitude scan isolates the dip region relevant to that ℓ.

Appendix B. Wigner-Delay Diagnostic

In addition to the amplitude-based branch diagnostics, the analysis uses the reflected phase of the gravitational channel,

$$\phi_s(\omega) = \arg R_s(\omega), \qquad \text{(B.1)}$$

and the associated Wigner-delay proxy,

$$\tau_W(\omega) = \partial_\omega \phi_s(\omega). \qquad \text{(B.2)}$$

The purpose of this quantity is not to define the resonance branches by itself, but to provide an independent spectral consistency check. A localized peak in τ_W indicates that the scattering phase is varying rapidly with frequency, which is the expected behavior near resonance. In the FCLET shell problem, the dominant structures in τ_W align with the branch frequencies extracted from the scalar leakage channel. This supports the interpretation that the transparency dips occur inside a genuine resonance architecture rather than in a trivial low-response background.

Numerically, the derivative $\partial_\omega \phi_s$ is evaluated from the unwrapped phase of R_s. Phase unwrapping is necessary because the raw argument function contains 2π discontinuities that would otherwise generate false spikes in the delay curve. The Wigner-delay plots shown in the paper are therefore based on an unwrapped phase, differentiated over the same frequency grid used for the leakage scan.

The Wigner-delay proxy is especially useful in the dip regions, where the amplitude response alone may look deceptively featureless. A low value of $\mathcal{F}_{\Xi}$ does not imply spectral inactivity. The delay structure shows that the shell remains dynamically engaged even where scalar leakage is locally suppressed.

In the present analysis, the delay structure supports the same conclusion in both R_1 and R_2: the transparency minima sit inside organized resonance regions rather than between unrelated isolated peaks. This is one of the reasons the avoided-crossing interpretation is spectrally stronger than a purely amplitude-based reading of the data.

Appendix C. Numerical Stability and Consistency Checks

Because the FCLET shell problem is a coupled transfer-matrix scattering problem, numerical consistency checks are essential. This appendix summarizes the checks underlying the main-text claims.

C.1 Vacuum consistency

In the vacuum limit,

$$\chi_{\mathrm{amp}} = 0,$$

the shell coupling vanishes and the problem must reduce to standard uncoupled Schwarzschild scattering. This limit is recovered exactly in the implementation. The total flux returns to unity, scalar leakage disappears, and no artificial two-branch structure is produced. This verifies that the numerical solver does not manufacture resonance splitting in the absence of the shell.

C.2 Full-branch flux consistency

The corrected full branch restores near-conserved flux,

$$\mathcal{F}_{\mathrm{tot}} = \mathcal{F}_R + \mathcal{F}_\Xi \approx 1, \qquad \text{(C.1)}$$

across the scanned parameter range. This is a decisive improvement over incomplete benchmark structures, which can exhibit artificial gain or loss. The avoided-crossing analysis reported in the main text is therefore based on the physically reliable branch of the solver.

C.3 Boundary independence

The observed suppression windows are not artifacts of the outer matching radius. Varying the outer boundary does not remove the windows or shift them in the way required to explain the non-monotonic leakage pattern. The minima remain tied to the internal resonance response of the shell rather than to the wave-extraction location.

C.4 Reproducibility of branch extraction

The two-branch structure persists under refinement of the scan grid and under repeated peak extraction. In particular, the positive minimum gap does not collapse toward zero when the parameter scan is refined. This is opposite to the behavior expected from numerical peak-splitting artifacts and supports the physical interpretation of the tracked branches.

C.5 Interpretation of numerical reliability

Taken together, these checks establish that the observed transparency windows are not numerical accidents. They survive vacuum reduction, full-branch flux restoration, boundary variation, and scan refinement. The avoided-crossing interpretation is therefore supported both spectrally and numerically.

Figure Captions

Figure 1. FCLET polar shell scattering as a coupled two-channel resonance problem.
Schematic representation of the FCLET polar shell system showing the gravitational Zerilli-like channel Z, the shell-supported scalar latency channel Ξ, the shell-localized coupling region, and the asymptotic ingoing/outgoing amplitudes used in the transfer-matrix formulation. The essential physical point is that shell transparency is not a one-channel transmission effect but a coupled resonance-routing phenomenon in which outgoing response is redistributed between reflected gravitational flux and scalar leakage.

Figure 2. Scalar leakage fraction $\mathcal{F}_{\Xi}(\omega; \chi_{\mathrm{amp}})$ in the first suppression window R_1.
Frequency-resolved scalar leakage fraction for shell amplitudes spanning the first non-monotonic suppression region. The curves show that the leakage minimum is not produced by a uniform reduction across all frequencies. Instead, the resonance peak structure reorganizes as χ_{amp} varies, indicating that the shell is passing through a localized spectral-rearrangement regime rather than a trivial weak-coupling point.

Figure 3. Two-branch tracking in R_1: $\omega_1(\chi_{\mathrm{amp}})$, $\omega_2(\chi_{\mathrm{amp}})$, and branch dominance exchange.
Tracked resonance branches in the first suppression window. The two branches remain spectrally distinct and exhibit a strictly positive minimum separation,

$$\Delta\omega_{\mathrm{min}} > 0,$$

establishing genuine avoided crossing rather than true mode crossing. The branch-amplitude markers show that the scalar leakage minimum occurs near the point where branch dominance is exchanged, identifying the transparency dip as an anti-crossing dip.

Figure 4. Wigner-delay structure in R_1.
Wigner-delay proxy $\tau_W(\omega) = \partial_\omega \phi_s(\omega)$ across the first suppression window. The delay peaks align with the tracked resonance branches, confirming that the leakage minima occur inside an organized spectral region rather than in a trivial low-response background. The delay structure provides an independent phase-based diagnostic of the same two-branch resonance architecture.

Figure 5. Scalar leakage fraction $\mathcal{F}_{\Xi}(\omega; \chi_{\mathrm{amp}})$ in the second suppression window R_2.
Frequency-resolved scalar leakage fraction across the second non-monotonic suppression region. As in R_1, the shell does not simply weaken or strengthen monotonically. Instead, the resonance morphology reorganizes locally, producing a second transparency dip that is structurally similar to the first window.

Figure 6. Two-branch tracking in R_2: $\omega_1(\chi_{\mathrm{amp}})$, $\omega_2(\chi_{\mathrm{amp}})$, and branch competition.
Tracked resonance branches in the second suppression window. The positive minimum gap,

$$\Delta\omega_{\mathrm{min}} > 0,$$

demonstrates that R_2 is also an avoided-crossing window. The peak-strength evolution shows that the transparency minimum is again associated with branch competition and dominance exchange, confirming that R_2 is not a separate anomaly but the second realization of the same spectral mechanism.

Figure 7. Unified avoided-crossing interpretation of R_1 and R_2.
Combined view of the two suppression windows showing that both arise from the same two-branch resonance architecture. Each window contains a finite-gap branch-repulsion region and a local transparency dip associated with redistribution of branch strength. The figure summarizes the central claim of the paper: FCLET shell transparency is governed by avoided crossing in the coupled two-channel transfer spectrum.

Figure 8. Multipole universality of the avoided-crossing mechanism.
Minimum spectral gap $\Delta\omega_{\min}$ and transparency-dip location χ_{dip} as functions of the multipole index ℓ. Avoided crossing persists across the scanned range $\ell = 2,3,4,5$, establishing universality of the mechanism. At the same time, the minimum gap grows with the multipole scale $\Lambda = \ell(\ell+1)$, while χ_{dip} shifts to larger shell amplitude, showing that ℓ acts as a universal spectral-scale parameter rather than as the origin of the mechanism itself.

Gravitational-Scalar Shell Scattering in FCLET

Corrected Two-Channel Equations, Full-Branch Completion, Flux Restoration, and Physical Scattering Coefficients

Ali Caner Yücel

Gaziantep, Türkiye

Abstract

We develop the foundational scattering paper of the FCLET polar shell program by deriving, validating, and solving the corrected two-channel gravitational-scalar system that governs even-parity shell scattering on a Schwarzschild background. The problem is formulated in terms of a Zerilli-like gravitational master variable Z and a gauge-invariant scalar latency channel Ξ, coupled through shell-supported gradient and algebraic interaction terms. We show that the reduced action enforces an antisymmetric gradient-coupling structure: the C_H term enters the two equations with opposite signs, and the derivative completion $C_H'/2$ is mandatory for a physically consistent flux-conserving system. This corrected structure resolves the instability and flux pathology of incomplete benchmark formulations.

We then construct the full-branch completion of the shell problem by activating the nontrivial $\xi_2 \neq 0$ sector and its induced coefficient functions $\xi_1(r)$, $\xi_2(r)$, and $z_q(r)$. The benchmark branch provides the minimal coupled scaffold and reproduces the vacuum limit exactly, while the full branch restores the missing shell-supported couplings and upgrades the system from a provisional numerical model to a physically closed scattering framework. Using a QR-renormalized transfer-matrix solver, we compute the gravitational reflection coefficient $R_s(\omega)$, the scalar leakage amplitude $T_\Xi(\omega)$, and the associated flux balance. The vacuum limit satisfies exact unit flux conservation, and the full branch restores near-unit flux throughout the shell-active regime, improving the benchmark flux deviation by approximately two orders of magnitude.

The resulting FCLET shell is not a passive barrier but an active conversion layer: over a finite frequency window, incident gravitational flux is partially redirected into the scalar channel, producing a structured response in $|R_s(\omega)|$, $|T_\Xi(\omega)|$, and the scattering phase $\phi_s(\omega)$. This paper establishes the formal and numerical foundation on which the avoided-crossing analysis and the later parameter taxonomy rest. It provides the corrected equations of motion, the full-branch coefficient closure, the conserved-current structure, the transfer-matrix algorithm, and the first physically reliable FCLET shell-scattering observables.

Keywords

FCLET; shell scattering; two-channel system; Zerilli mode; scalar latency channel; corrected EOM; flux restoration; transfer matrix; full branch; gravitational-scalar conversion

1. Introduction

The FCLET shell problem is the first place where the formal structure of the program, the shell-supported scalar sector, and physically measurable wave observables must all coexist inside a single closed calculation. Earlier FCLET developments established the background logic of latency support, shell-localized coupling, and gravitational-scalar interaction. What remained was the construction of a corrected and numerically stable two-channel scattering framework capable of producing physically meaningful reflection and conversion observables without violating the vacuum limit or the radial flux balance.

That problem is solved here.

The polar even-parity shell sector of FCLET is not a one-channel perturbation problem. Once the shell is activated, the gravitational master mode cannot remain dynamically isolated. A second, shell-supported scalar channel is unavoidable. The correct physical system is therefore a coupled problem: a Zerilli-like gravitational channel Z interacting with a gauge-invariant scalar latency channel Ξ. Any treatment that tries to collapse the dynamics to one effective channel obscures the actual conversion process and, more seriously, risks misidentifying the physical source of shell transparency, shell leakage, and shell-induced phase structure.

The first task is formal. One must derive the correct coupled equations of motion from the reduced mixed action. This task is not cosmetic. The sign structure of the coupling terms decides whether the system is physically conservative or spuriously gainful. In particular, the gradient coupling C_H cannot be inserted symmetrically by hand. It must enter antisymmetrically, with opposite signs in the two channel equations. Moreover, the derivative completion $C_H'/2$ is not optional. It is required by the action-level structure of the coupled system and by the existence of the correct radial current. If these terms are omitted or mis-signed, the resulting transfer problem can produce dramatic flux failure even when the numerical integration itself appears stable.

The second task is structural. Even with the corrected two-channel equations, the shell problem remains incomplete until the full branch is activated. The benchmark branch, defined by the $\xi_2 = 0$ restriction, is useful because it isolates the minimal coupled scaffold and allows the corrected EOM structure to be identified cleanly. But it remains only a scaffold. The physical shell sector is not closed until the nontrivial $\xi_2 \neq 0$ contribution is turned on and its induced coefficient functions $\xi_1(r)$, $\xi_2(r)$, and $z_q(r)$ are incorporated. This completion changes the system qualitatively: it restores the missing shell-supported coupling structure, repairs the benchmark flux deficit, and promotes the model from a provisional coupled toy system to a physically meaningful scattering framework.

The third task is numerical. A two-channel shell problem of this kind is stiff. The fundamental matrix develops strong directional growth, the basis vectors become nearly linearly dependent, and naive forward shooting rapidly becomes ill-conditioned. The physically reliable route is a QR-renormalized transfer-matrix propagation in which the basis is periodically re-orthonormalized while preserving the asymptotic scattering data needed for the final outer matching. Only after that stabilization can one speak confidently about physical reflection coefficients $R_s(\omega)$, scalar leakage amplitudes $T_\Xi(\omega)$, or flux restoration.

The formal point and the numerical point are inseparable. A wrong action reduction can produce a numerically stable but physically false solution. Conversely, a correct action reduction can still fail to produce physical observables if the numerical propagation is ill-conditioned. The present paper closes both issues simultaneously. It derives the correct reduced system and solves it in a way that preserves the physical content of the asymptotic scattering data.

The result of carrying out all three tasks is decisive. The vacuum limit is recovered exactly. The corrected full branch restores near-unit flux across the shell-active regime. The shell then reveals itself as a conversion layer rather than as a passive barrier: in a finite frequency window, incident gravitational flux is redistributed into the scalar channel, producing a nontrivial frequency dependence in $|R_s(\omega)|$, $|T_\Xi(\omega)|$, and the scattering phase $\phi_s(\omega)$. These are not merely numerical outputs. They are the first physically reliable FCLET shell-scattering observables.

This paper therefore has a specific role inside the FCLET program. It is the formal and numerical foundation paper. It does not yet take the avoided-crossing structure as its central object; that belongs to the next paper. It does not yet classify the full parameter geometry of shell transparency; that belongs to the taxonomy paper. Instead, it does the necessary foundational work: it derives the corrected coupled system, closes the full branch, restores the flux structure, and establishes the solver that makes later spectral interpretation legitimate.

The logic of the paper is therefore direct. Section 2 defines the background geometry, shell profile, and channel structure. Section 3 performs the gauge-invariant reduction and clarifies the relation between the benchmark and full branches. Section 4 derives the corrected mixed action and the antisymmetric two-channel equations, including the mandatory $C_H'/2$ terms and the conserved radial current. Section 5 constructs the coefficient functions and the full-branch closure. Section 6 establishes the asymptotic scattering decomposition and physical observables. Section 7 presents the QR-renormalized transfer-matrix method. Section 8 validates the benchmark scaffold and exact vacuum reduction. Section 9 shows how the full branch restores the flux balance. Section 10 presents the physical scattering coefficients and shell-induced scalar conversion. Section 11 interprets the result and places it in the FCLET research program. Section 12 concludes.

The central statement of the paper is compact:

FCLET polar shell scattering is a corrected, flux-restored, two-channel conversion problem whose physical observables emerge only on the full branch.

Everything else in the paper is the derivation, stabilization, and demonstration of that claim.

2. Background Geometry and Shell Setup

2.1 Schwarzschild exterior and radial variables

We work on a Schwarzschild exterior background,

$$ds^2 = -f(r)\,dt^2 + f(r)^{-1}dr^2 + r^2 d\Omega^2,$$

with

$$f(r) = 1 - \frac{2M}{r}. \qquad (2.1)$$

Throughout the paper we use geometrized units and treat M as the characteristic scale. The angular sector is organized by

$$\Lambda = \ell(\ell+1). \qquad (2.2)$$

For scattering and asymptotic decomposition it is natural to use the tortoise coordinate,

$$u = r_*, \frac{du}{dr} = \frac{1}{f(r)}. \qquad (2.3)$$

The coordinate u renders the wave asymptotics explicit and permits a clean incoming/outgoing channel separation at large radius.

The inverse transformation is determined implicitly by

$$u = r + 2M\ln\left(\frac{r}{2M} - 1\right), \qquad (2.4)$$

so that near the horizon $r \to 2M^+$, one has $u \to -\infty$, whereas asymptotically $r \to \infty$ implies $u \to +\infty$. This is the standard wave-scattering geometry, but in the present problem it is used in a genuinely coupled two-channel context.

The physical shell sits outside the horizon at a finite radius $r_{\text{shell}} > 2M$. In the numerical implementation used throughout the FCLET shell program, representative benchmark values are of order $r_{\text{shell}} \sim 5M$, with a shell width of order M, but the formal derivations below do not require a fixed numerical value. The shell is therefore a compact interaction region embedded in an otherwise Schwarzschild exterior.

For later convenience we also define

$$f'(r) = \frac{2M}{r^2}. \qquad (2.5)$$

2.2 FCLET shell profile

The shell is generated by a background latency profile $\bar{\chi}(r)$. What matters dynamically is not merely the profile value but the shell-supported derivatives that localize the interaction region. In practice the shell is encoded by a smooth finite-width profile, and the derivative $\bar{\chi}'(r)$, together with the background scalar-potential sector when active, determines where the gravitational and scalar channels are mixed.

A convenient representative profile is a smoothed step or shell-like tanh profile,

$$\bar{\chi}(r) = \frac{\chi_{\text{amp}}}{2}\left[1 - \tanh\left(\frac{r - r_{\text{shell}}}{\text{width}}\right)\right], \qquad (2.6)$$

whose radial derivative is

$$\bar{\chi}'(r) = -\frac{\chi_{\text{amp}}}{2\,\text{width}}\,\text{sech}^2\left(\frac{r - r_{\text{shell}}}{\text{width}}\right). \qquad (2.7)$$

This derivative is sharply localized around $r = r_{\text{shell}}$, so it is $\bar{\chi}'$, not $\bar{\chi}$ alone, that most directly encodes the shell-supported coupling.

When needed, the second derivative is

$$\bar{\chi}''(r) = \frac{\chi_{\text{amp}}}{\text{width}^2}\,\text{sech}^2\left(\frac{r - r_{\text{shell}}}{\text{width}}\right)\tanh\left(\frac{r - r_{\text{shell}}}{\text{width}}\right). \qquad (2.8)$$

The shell is therefore characterized by:

the amplitude χ_{amp},

the position r_{shell},

the width parameter width.

Later sections and companion papers also use:

the scalar mass μ,

the quartic kinetic parameter σ_s,

the potential shift χ_0,

and the inner Robin/quenching parameter κ_c.

The shell is localized but not singular. This matters because the transfer problem is a genuine finite-region coupled scattering problem rather than a delta-shell junction problem. The FCLET shell should be thought of as a finite conversion layer.

2.3 Channel-support logic of the shell

The shell does not affect the two channels symmetrically in a trivial way. Its background profile enters the reduced action through specific shell-supported coefficient functions. The key structural statement is that the shell region is where:

the gradient coupling becomes nonzero,

the algebraic coupling becomes nonzero,

the scalar channel departs from its vacuum-decoupled form,

gravitational-to-scalar conversion occurs.

Thus the shell is not merely a modified potential well. It is a localized interaction architecture.

The shell profile enters the reduced dynamics through functions that will later be assembled into $C_H(r)$, $C_V(r)$, $U_Z(r)$, and $U_\Xi(r)$. These objects are not independent phenomenological profiles. They are generated by the background shell configuration and the FCLET field content after gauge-invariant reduction.

2.4 Physical channels

The polar even-parity sector contains two physically relevant channel variables:

a Zerilli-like gravitational master variable Z,

a gauge-invariant scalar latency channel Ξ.

The shell does not simply perturb the effective potential of the gravitational sector. Instead, it opens a conversion layer in which Z and Ξ are mixed. Outside the shell support, the coupling vanishes asymptotically and the channels decouple. Inside the shell region, the channels exchange flux.

That exchange is the physical core of the FCLET shell problem. Reflection, scalar leakage, and phase delay are not independent one-channel observables. They are different readouts of a localized two-channel conversion system.

2.5 Why a two-channel description is unavoidable

A one-channel reduction can be useful in strict vacuum or in incomplete auxiliary limits, but it is not physically closed once the shell is active. The shell-supported scalar sector carries independent dynamical information and cannot be consistently absorbed into a single corrected potential without loss of flux bookkeeping and without obscuring channel conversion.

The shell therefore forces the correct question: not how one effective master variable scatters from one corrected potential, but how an incoming gravitational channel is redistributed

between a reflected gravitational wave and an outgoing scalar channel after interaction with a finite conversion layer.

That is the description adopted throughout the paper.

2.6 Summary of the geometric shell setup

The FCLET shell problem is a Schwarzschild exterior scattering problem with:

a finite shell at r_{shell},

a smooth background latency profile $\bar{\chi}(r)$,

a localized support function $\bar{\chi}'(r)$,

a Zerilli-like gravitational channel,

and a shell-supported scalar channel.

The geometry is standard, but the shell sector is not. The novelty lies in the coupling architecture.

3. Gauge-Invariant Reduction and Channel Variables

3.1 Zerilli-like gravitational master variable

The gravitational channel is organized around a Zerilli-like even-parity master variable Z. In the vacuum limit, this variable reduces to the standard Schwarzschild polar master channel and reproduces the standard Zerilli equation. This is not merely a formal convenience. The vacuum recovery of the Zerilli structure is a required consistency condition for the FCLET shell program.

In the exterior vacuum problem, the Zerilli channel satisfies

$$Z'' + (\omega^2 - V_Z(r))Z = 0, \qquad (3.1)$$

where the standard Zerilli potential is

$$V_Z(r) = f(r)\,\frac{\Lambda(\Lambda+2)r^3 + 6\Lambda M r^2 + 36M^2 r + 72M^3}{r^3(\Lambda r + 6M)^2}. \qquad (3.2)$$

Any correct FCLET shell reduction must collapse to this equation when the shell coupling is turned off.

The FCLET gravitational master variable Z is therefore chosen so that:

it is gauge-invariant in the reduced shell sector,

it reproduces the Zerilli structure in the vacuum limit,

it couples minimally and correctly to the scalar shell sector.

This fixes the gravitational channel far more tightly than a generic even-parity variable choice would.

3.2 Scalar gauge-invariant channel Ξ

The second channel is the scalar latency degree of freedom Ξ. It is shell-supported in the sense that its physical coupling to the gravitational channel is localized by the shell background. It is also gauge-invariant in the reduced formulation. This is essential because the shell problem is not a coordinate artifact of even-parity perturbation variables; it is a true two-channel scattering problem.

In the simplest asymptotic form, the scalar effective channel is governed by

$$\Xi'' + (\omega^2 - U_\Xi(r))\Xi = \cdots , \qquad (3.3)$$

with

$$U_\Xi(r) \to \frac{\Lambda}{r^2} f(r) + \mu^2 \text{as the shell couplings are removed.} \qquad (3.4)$$

When $\mu = 0$, the scalar channel remains massless asymptotically. When $\mu > 0$, the scalar channel acquires a nontrivial asymptotic wavenumber

$$k_\Xi = \sqrt{\omega^2 - \mu^2}. \qquad (3.5)$$

The scalar channel is not an auxiliary bookkeeping device. It is the outgoing carrier of shell-induced scalar leakage, and its asymptotic amplitude $T_\Xi(\omega)$ is one of the central observables of the paper.

3.3 Reduction logic and auxiliary coefficients

The reduced shell dynamics is not specified solely by the two master variables Z and Ξ. The channel transformation brings with it a set of shell-supported coefficient functions that encode how the original perturbative shell sector closes onto the gauge-invariant basis.

The most important among these are:

$$\xi_1(r), \xi_2(r), z_q(r). \qquad (3.6)$$

These are not arbitrary fitting functions. They arise from the reduction of the shell-supported perturbation system and mediate the passage from the raw shell variables to the final reduced channel equations.

The crucial branch distinction is defined precisely through them.

3.4 Benchmark and full branches

The reduction naturally separates into two structurally distinct branches.

The **benchmark branch** is defined by the restriction

$$\xi_2(r) = 0. \qquad (3.7)$$

This branch is useful because it provides the minimal coupled scaffold in which the corrected equation structure can be identified and the vacuum limit can be validated. It already exhibits shell-induced conversion and therefore serves as a diagnostic starting point.

The **full branch** activates the nontrivial shell-supported sector

$$\xi_2(r) \neq 0, \qquad (3.8)$$

together with its induced coefficients $\xi_1(r)$ and $z_q(r)$. This is the physically closed branch. It repairs the benchmark flux deficit, restores the missing coupling structure, and produces physically reliable scattering coefficients.

The distinction is fundamental. The benchmark branch is not wrong in the sense of being useless; it is incomplete in the sense of not being the final physical shell sector.

3.5 Why the full branch matters

The importance of the full branch is easiest to state operationally: the benchmark branch can reproduce the vacuum limit and reveal the correct sign structure of the coupled equations, but it does not restore the flux balance to the level required for a physically closed scattering system. That restoration occurs only after the $\xi_2 \neq 0$ sector is included.

More explicitly, the benchmark branch captures the existence of two-channel conversion but not the complete shell closure. The full branch completes the effective coupling structure and thereby restores the compatibility between:

the reduced action,

the asymptotic channel decomposition,

the radial current,

and the numerical transfer solution.

This paper therefore uses the benchmark branch as a stepping stone and the full branch as the final physical object.

3.6 Structural role of ξ_2

Although later sections give the effective couplings directly in terms of C_H and C_V, it is useful to state at this point why ξ_2 has such disproportionate importance. The ξ_2 sector is the part of the reduced shell closure that upgrades the channel transformation from a formally suggestive scaffold to a dynamically complete system. It is the difference between partial shell support and full shell support in the reduced effective theory.

This is why the benchmark-to-full transition is not a mere parameter turn-on. It is a closure transition.

3.7 Summary of the reduction step

The gauge-invariant reduction produces:

a gravitational Zerilli-like master channel Z,

a scalar latency channel Ξ,

a family of shell-supported reduction coefficients,

and a structural bifurcation into benchmark and full branches.

The next step is to derive the corrected mixed action and show how the exact two-channel equations emerge from it.

4. Corrected Two-Channel Action and Equations of Motion

4.1 Reduced mixed action

The FCLET shell system is governed by a reduced mixed action in the two channels Z and Ξ. The essential mixed term has the structure

$$S_{\mathrm{mix}} = \frac{1}{2}\int du\,[C_H(u)(Z\Xi' - \Xi Z') - 2C_V(u)Z\Xi]. \qquad (4.1)$$

This form is decisive. The gradient coupling is antisymmetric already at the action level. The algebraic coupling enters separately through $C_V(u)$. The shell dependence is encoded in the coefficient functions.

This action is not a phenomenological ansatz added after the fact. It is the reduced shell action implied by the gauge-invariant FCLET sector once the physically relevant two channels are identified.

To make the full reduced problem explicit, one may write the total quadratic action schematically as

$$S^{(2)} = \frac{1}{2}\int du\,[(Z')^2 - (U_Z - \omega^2)Z^2 + (\Xi')^2 - (U_\Xi - \omega^2)\Xi^2 + C_H(Z\Xi' - \Xi Z') - 2C_V Z\Xi]. \qquad (4.2)$$

This is the compact variational origin of the corrected coupled system.

4.2 Variation with respect to Z

Varying the action with respect to Z, and integrating by parts carefully, gives

$$\delta_Z S^{(2)} = \frac{1}{2}\int du\,\delta Z\,[-2Z'' - 2(U_Z - \omega^2)Z + 2C_H\Xi' + C_H'\Xi - 2C_V\Xi]. \qquad (4.3)$$

Setting the Euler–Lagrange variation to zero yields

$$Z'' + (U_Z - \omega^2)Z - C_H\Xi' - \frac{C_H'}{2}\Xi + C_V\Xi = 0. \qquad (4.4)$$

Equivalently,

$$Z'' + (\omega^2 - U_Z)Z = C_H\Xi' + \left(\frac{C_H'}{2} - C_V\right)\Xi. \qquad (4.5)$$

This is the corrected gravitational-channel equation.

4.3 Variation with respect to Ξ

The variation with respect to Ξ proceeds similarly:

$$\delta_\Xi S^{(2)} = \frac{1}{2}\int du\,\delta\Xi\,[-2\Xi'' - 2(U_\Xi - \omega^2)\Xi - 2C_H Z' - C_H' Z - 2C_V Z]. \qquad (4.6)$$

Thus the scalar equation becomes

$$\Xi'' + (U_\Xi - \omega^2)\Xi + C_H Z' + \frac{C_H'}{2}Z + C_V Z = 0, \qquad (4.7)$$

or

$$\Xi'' + (\omega^2 - U_\Xi)\Xi = -C_H Z' - \left(\frac{C_H'}{2} + C_V\right)Z. \qquad (4.8)$$

This is the corrected scalar-channel equation.

4.4 Correct antisymmetric gradient structure

The coupled system is therefore

$$Z'' + (\omega^2 - U_Z)Z = C_H\,\Xi' + \left(\frac{C_H'}{2} - C_V\right)\Xi, \qquad (4.9)$$

$$\Xi'' + (\omega^2 - U_\Xi)\Xi = -\,C_H\,Z' - \left(\frac{C_H'}{2} + C_V\right)Z. \qquad (4.10)$$

The key point is the sign structure:

- the C_H term appears with opposite signs in the two equations,
- the derivative completion $C_H'/2$ appears with opposite algebraic placement in the two channels.

This structure is the corrected FCLET shell EOM. Earlier provisional equations lacking this exact antisymmetric form fail the flux test and should not be used for physical scattering claims.

4.5 Why the $C_H'/2$ terms are mandatory

The derivative terms are not optional refinements. They are required by the variational structure of the reduced action. Dropping them changes the dynamics and breaks the radial current balance. In numerical tests, this omission produces large and unphysical flux failure.

The physical message is clear: the shell problem is not merely sensitive to the presence of coupling, but to the exact differential structure of that coupling. A wrong mixed derivative term does not slightly perturb the answer. It changes the class of the system.

One can see this already at the action level: the antisymmetric derivative combination $Z\Xi' - \Xi Z'$ necessarily generates both direct gradient mixing and derivative-of-coupling completion. Any attempt to keep one while discarding the other destroys the variational integrity of the reduced system.

4.6 Effective channel potentials

The two channels propagate in real effective potentials $U_Z(u)$ and $U_\Xi(u)$. In the vacuum limit, U_Z reduces to the standard Zerilli potential,

$$U_Z(r) \underset{\chi_{\mathrm{amp}}\to 0}{\to} V_Z(r). \qquad (4.11)$$

The scalar channel U_Ξ carries the shell-sector dependence and, when the scalar mass parameter μ is activated, includes the corresponding mass contribution,

$$U_\Xi(r) = f(r)\frac{\Lambda}{r^2} + \mu^2 + \delta U_\Xi^{\text{shell}}(r). \qquad (4.12)$$

The present paper does not require the later full parameter taxonomy of these potentials. What matters here is that they are real, asymptotically decoupled, and embedded in the corrected two-channel action.

4.7 Conserved radial current

The corrected equations imply the radial current

$$J = \text{Im}\left[Z^*Z' + \Xi^*\Xi' + \frac{C_H}{2}(Z^*\Xi - \Xi^*Z)\right]. \qquad (4.13)$$

Outside the shell, where $C_H \to 0$, this reduces to the standard uncoupled current. This is the current whose asymptotic reduction underwrites the physical flux observables used later.

To see the role of the antisymmetric structure more explicitly, differentiate J and substitute the equations of motion. The terms proportional to C_H and C_H' cancel pairwise only when the corrected sign pattern is used. A symmetric insertion of the gradient coupling would not produce this cancellation. The current would fail to close, and the total scattering flux would no longer have the correct physical interpretation.

The existence of this current is the formal reason the corrected system can support physically meaningful flux accounting.

4.8 First-order transfer-matrix form

For numerical propagation it is convenient to rewrite the second-order system as a first-order matrix problem. Define the state vector

$$\Upsilon = \begin{pmatrix} Z \\ Z' \\ \Xi \\ \Xi' \end{pmatrix}. \qquad (4.14)$$

Then

$$\Upsilon' = \mathbb{M}(u, \omega)\,\Upsilon, \qquad (4.15)$$

with

$$\mathbb{M} = \begin{pmatrix} 0 & 1 & 0 & 0 \\ U_Z - \omega^2 & 0 & \frac{C_H'}{2} - C_V & C_H \\ 0 & 0 & 0 & 1 \\ -\left(\frac{C_H'}{2} + C_V\right) & -C_H & U_\Xi - \omega^2 & 0 \end{pmatrix}. \qquad (4.16)$$

This is the transfer matrix used later in the QR-renormalized propagation. Its precise structure is inherited directly from the variationally correct second-order equations.

4.9 Formal conclusion of the section

At the level of the equations themselves, the shell problem is now fixed. The FCLET shell is described by a corrected two-channel system with:

antisymmetric gradient coupling,

mandatory derivative completion,

real effective potentials,

a conserved radial current,

and an exact first-order transfer representation.

This is the formal core of the paper.

5. Coefficient Functions and Full-Branch Closure

5.1 Structural role of the coefficient sector

The corrected two-channel equations derived in the previous section are universal at the level of form, but their physical content is controlled by the coefficient functions that enter the reduced channel basis. These coefficient functions determine how the shell-supported sector closes onto the pair (Z, Ξ), and therefore decide whether the resulting scattering problem is merely formally suggestive or physically complete.

The central objects are

$$\xi_1(r), \xi_2(r), \xi_3(r), z_q(r), \qquad (5.1)$$

with ξ_3 vanishing on the corrected branch and the physical distinction between benchmark and full branches encoded primarily in whether $\xi_2(r)$ is set to zero or allowed to take its shell-supported value.

The gravitational and scalar channel variables should therefore be understood not as bare perturbative fields, but as reduced fields dressed by shell-supported coefficient functions. This dressing is not optional. It is precisely what allows the reduced action, the radial current, and the asymptotic scattering data to become mutually compatible.

5.2 Benchmark branch coefficients

On the benchmark branch, the reduction is intentionally simplified:

$$\xi_2(r) = 0. \qquad (5.2)$$

This choice preserves the vacuum limit cleanly and provides a minimal coupled scaffold in which the corrected sign structure of the mixed action can be identified. The benchmark branch is therefore valuable for:

validating exact Schwarzschild recovery,

isolating the antisymmetric C_H structure,

and testing the QR-renormalized propagation on the simplest nontrivial shell system.

However, this branch suppresses a physically relevant piece of the shell-supported scalar closure. In practice, that means that the benchmark branch retains the qualitative existence of gravitational-to-scalar conversion, but misses part of the coupling architecture required by the full shell sector. The result is a partial but incomplete flux restoration.

This makes the benchmark branch mathematically useful and physically provisional.

5.3 Full-branch activation and shell-supported closure

The full branch activates the nontrivial scalar-support coefficient,

$$\xi_2(r) \neq 0. \qquad (5.3)$$

Once ξ_2 is nonzero, the reduced shell system induces corresponding nontrivial values of $\xi_1(r)$ and $z_q(r)$, so that the coefficient sector becomes dynamically closed. Schematically, the full branch is defined by the set

$$\{\xi_1(r), \xi_2(r), z_q(r)\}_{\text{full}}, \qquad (5.4)$$

with $\xi_3(r) = 0$ on the corrected branch.

The physical meaning of this closure is simple: the shell-supported scalar sector can no longer be represented consistently by the minimal scaffold alone. The full branch restores the

missing shell-mediated contributions to the reduced effective couplings and therefore closes the physical shell problem.

The benchmark branch is what one obtains when part of the shell-supported scalar feedback is deliberately held at zero. The full branch is what one obtains when that restriction is removed and the shell sector is allowed to close.

5.4 Effective scalar-channel normalization and the role of ξ_2

The coefficient $\xi_2(r)$ is not merely another radial weight. It directly affects the normalization and mixing structure of the scalar channel. In the corrected shell program, this role is mathematically visible through two facts:

- the shell-induced scalar channel cannot be made flux-compatible on the benchmark branch alone,
- the restored branch acquires the correct physical balance only when the ξ_2-supported terms are included.

At an operational level, the full branch should be understood as rebalancing the way the shell-supported scalar degree of freedom contributes to the reduced effective channel basis. That rebalancing is exactly what later appears numerically as flux restoration.

This is why the benchmark-to-full transition is not a cosmetic refinement. It is a normalization-and-closure correction of the reduced shell sector.

5.5 Effective coupling functions $C_H(r)$ and $C_V(r)$

The mixed action of Section 4 is written in terms of two effective coupling functions:

$$C_H(r), C_V(r). \qquad (5.5)$$

These are not arbitrary ansatz functions. They are built from the shell background $\bar{\chi}(r)$, the reduction coefficients, and the effective scalar-sector normalization.

The gradient coupling $C_H(r)$ is shell-supported and vanishes outside the shell region. On the benchmark branch, a representative reduced form is

$$C_H^{\text{bench}}(r) \propto N(r)\,\frac{\Lambda+2}{\Lambda}\,r^2 f(r)^2\,G_\chi\,\bar{\chi}'(r), \qquad (5.6)$$

where $N(r)$ is the reduced gravitational normalization factor and

$$G_\chi \equiv Z_\chi + 2\sigma_s \bar{X} \qquad (5.7)$$

is the effective scalar kinetic factor.

On the full branch, the same structure is corrected by the nontrivial shell-supported closure,

$$C_H^{\mathrm{full}}(r) = C_H^{\mathrm{bench}}(r) + \delta C_H^{(\xi_2)}(r), \qquad (5.8)$$

where $\delta C_H^{(\xi_2)}$ represents the contribution generated by the $\xi_2 \neq 0$ sector. The precise numerical form depends on the chosen FCLET closure functions, but the structural statement is independent of implementation: the full branch modifies the gradient coupling itself.

The algebraic coupling $C_V(r)$ behaves similarly. On the benchmark branch it may be absent or reduced, depending on the chosen active shell sector. On the full branch it becomes

$$C_V^{\mathrm{full}}(r) = C_V^{\mathrm{bench}}(r) + \delta C_V^{(\xi_2)}(r), \qquad (5.9)$$

where again the correction is shell-supported and vanishes asymptotically.

Thus the full branch does not merely change a single coefficient. It alters the shell-supported coupling architecture of the reduced action.

5.6 Reduced normalization factor $N(r)$

The reduced gravitational channel carries a standard normalization factor

$$N(r) = \frac{r^2}{\Lambda r + 6M}. \qquad (5.10)$$

This factor is familiar from the Zerilli sector and is required for dimensional consistency and vacuum compatibility. The shell couplings inherit this factor because the shell system is built on top of the Zerilli-like gravitational master channel rather than replacing it.

In particular, the shell-supported coupling functions inherit combinations such as

$$N(r)\,\frac{\Lambda + 2}{\Lambda}, \qquad (5.11)$$

which appear naturally in the reduced coupling sector. This is one reason why the shell problem cannot be treated as a completely independent scalar scattering problem weakly attached to gravity. Its normalization is already tied to the Zerilli backbone.

5.7 Scalar effective potential and mass activation

The scalar channel potential can be written in the general form

$$U_{\Xi}(r) = f(r)\frac{\Lambda}{r^2} + \mu^2 + \delta U_{\Xi}^{\mathrm{shell}}(r), \qquad (5.12)$$

where:

$f(r)\Lambda/r^2$ is the standard centrifugal-like exterior term,

μ^2 is the scalar mass activation,

$\delta U_{\Xi}^{\mathrm{shell}}(r)$ is the shell-supported correction.

The mass parameter μ does not create the shell coupling by itself. Rather, it modifies the propagation threshold of the scalar channel. When $\omega < \mu$, the scalar channel tends toward freeze-out, and the shell-induced leakage is suppressed. This mass effect belongs properly to the later taxonomy paper, but it is useful to state here because it already enters the full-branch coefficient logic.

5.8 Full-branch closure as a consistency condition

The best way to summarize the coefficient sector is this:

The benchmark branch gives a mathematically controlled two-channel scaffold.

The full branch gives the physically closed shell sector.

The transition from one to the other is controlled by the activation of $\xi_2(r)$ and its induced correction of C_H, C_V, and the scalar-sector normalization.

This means the full branch is not an optional "improvement." It is the consistency completion of the shell reduction.

5.9 Section conclusion

The coefficient sector determines whether the reduced FCLET shell system is merely suggestive or physically complete. The benchmark branch isolates the minimal coupled structure. The full branch restores the missing shell-supported closure. Through that restoration, the effective couplings $C_H(r)$ and $C_V(r)$ become physically complete, and the shell problem acquires the flux behavior required of a genuine scattering system.

This coefficient closure is the bridge between the formal equations of Section 4 and the asymptotic observables of Section 6.

6. Asymptotic Scattering Structure

6.1 Asymptotic decoupling and channel interpretation

Because the shell couplings are localized, the full FCLET shell system decouples asymptotically. This is the crucial property that makes a scattering interpretation possible. Far outside the shell support, one has

$$C_H(r) \to 0, C_V(r) \to 0, \delta U_{\Xi}^{\text{shell}}(r) \to 0, \qquad (6.1)$$

so that the channels reduce to independent asymptotic waves.

In that region, the gravitational channel and scalar channel can each be decomposed into incoming and outgoing pieces. This is what allows a physical definition of reflection and scalar leakage.

6.2 Outer-channel decomposition

In the asymptotic region, the channel solutions take the form

$$Z(u) \sim A_{\text{in}} e^{-i\omega u} + A_{\text{out}} e^{+i\omega u}, \qquad (6.2)$$
$$\Xi(u) \sim B_{\text{in}} e^{-ik_{\Xi} u} + B_{\text{out}} e^{+ik_{\Xi} u}. \qquad (6.3)$$

The scalar wavenumber is

$$k_{\Xi} = \sqrt{\omega^2 - U_{\Xi}(\infty)}. \qquad (6.4)$$

When the scalar potential asymptotes to a pure mass term,

$$U_{\Xi}(\infty) = \mu^2, \qquad (6.5)$$

one has

$$k_{\Xi} = \sqrt{\omega^2 - \mu^2}. \qquad (6.6)$$

The asymptotic decomposition is therefore structurally identical to a two-channel scattering problem in one spatial dimension, but the underlying effective potentials and channel couplings are inherited from the FCLET shell reduction.

6.3 Physical scattering coefficients

For purely gravitational incidence, the incoming data are chosen as

$$A_{\mathrm{in}} = 1, B_{\mathrm{in}} = 0. \qquad (6.7)$$

The outgoing amplitudes then define the physical scattering coefficients

$$R_s(\omega) = A_{\mathrm{out}}, T_{\Xi}(\omega) = B_{\mathrm{out}}. \qquad (6.8)$$

The interpretation is immediate:

$R_s(\omega)$ is the gravitational reflection coefficient,

$T_{\Xi}(\omega)$ is the scalar leakage amplitude.

These coefficients are the first nontrivial physical observables of the shell problem. They answer the basic physical question: after an incoming gravitational wave encounters the FCLET shell, how much of it returns gravitationally, and how much is converted into the scalar latency channel?

6.4 Flux observables

The corresponding flux fractions are defined by

$$\mathcal{F}_R(\omega) = \mid R_s(\omega) \mid^2, \qquad (6.9)$$

$$\mathcal{F}_{\Xi}(\omega) = \frac{k_{\Xi}}{\omega} \mid T_{\Xi}(\omega) \mid^2, \qquad (6.10)$$

and

$$\mathcal{F}_{\mathrm{tot}}(\omega) = \mathcal{F}_R(\omega) + \mathcal{F}_{\Xi}(\omega). \qquad (6.11)$$

The factor k_{Ξ}/ω is required because the two channels do not necessarily carry the same group-velocity normalization. In particular, when $\mu \neq 0$, the scalar channel wavenumber differs from the gravitational frequency. Thus $\mid T_{\Xi} \mid^2$ alone is not the correct scalar flux observable; it must be weighted by the appropriate asymptotic kinematic factor.

6.5 Reflection phase and spectral structure

The reflected gravitational phase is

$$\phi_s(\omega) = \arg R_s(\omega). \qquad (6.12)$$

This quantity is already meaningful at the present formal stage because it records how the shell modifies not only the magnitude but also the phase of the reflected gravitational signal. The frequency derivative of the unwrapped phase,

$$\tau_W(\omega) = \partial_\omega \phi_s(\omega), \qquad (6.13)$$

later becomes the Wigner-delay proxy used to identify resonance structure. But even here, before any spectral taxonomy is imposed, $\phi_s(\omega)$ is already one of the physically measurable outputs of the system.

6.6 Asymptotic current and flux interpretation

The radial current derived in Section 4,

$$J = \mathrm{Im}\left[Z^* Z' + \Xi^* \Xi' + \frac{C_H}{2}(Z^* \Xi - \Xi^* Z)\right], \qquad (6.14)$$

reduces asymptotically to the uncoupled sum of channel currents because $C_H \to 0$. This asymptotic reduction is exactly what justifies the flux observables defined above.

In particular, if the full branch is correctly implemented, the total flux

$$\mathcal{F}_{\mathrm{tot}}(\omega) \qquad (6.15)$$

must approach unity up to numerical error. This is the physical reason why flux restoration is such a decisive test. It does not merely indicate a numerically tidy solution. It indicates compatibility between:

the reduced action,

the channel decomposition,

the asymptotic current,

and the extracted scattering coefficients.

6.7 The shell as a conversion layer

At the level of observables, the shell is most naturally interpreted as a conversion layer. In the vacuum limit, one has purely gravitational reflection with no scalar leakage:

$$T_\Xi(\omega) = 0 \text{when} \chi_{\mathrm{amp}} = 0. \qquad (6.16)$$

Once the shell is activated, a finite part of the incoming gravitational flux is redirected into the scalar channel:

$$T_{\Xi}(\omega) \neq 0 \text{for shell-active frequencies.} \qquad (6.17)$$

The shell therefore does not behave as a passive reflecting barrier. It behaves as a localized region in which channel conversion becomes dynamically possible.

6.8 Section conclusion

The asymptotic scattering structure of FCLET shell scattering is now fixed. The shell problem admits:

a gravitational reflection amplitude $R_s(\omega)$,

a scalar leakage amplitude $T_{\Xi}(\omega)$,

flux observables $\mathcal{F}_R, \mathcal{F}_{\Xi}, \mathcal{F}_{\text{tot}}$,

and a reflected phase $\phi_s(\omega)$.

These quantities are meaningful only because the shell couplings are localized and the corrected reduced system possesses the proper asymptotic decoupling and current structure.

7. Numerical Method: QR-Renormalized Transfer Matrix

7.1 Why the numerical problem is nontrivial

The FCLET shell problem is not difficult because the equations are numerous. It is difficult because the two-channel fundamental matrix is stiff. In a naive outward integration, one basis direction tends to grow strongly relative to the other, and the two basis vectors become nearly linearly dependent. When that happens, the outer matching no longer distinguishes the physical incoming and outgoing components reliably.

Thus the problem is not merely to integrate the ODEs, but to preserve basis independence while doing so.

7.2 First-order state vector

Using the first-order form of Section 4, define

$$\Upsilon = \begin{pmatrix} Z \\ Z' \\ \Xi \\ \Xi' \end{pmatrix}, \qquad (7.1)$$

so that

$$\Upsilon' = \mathbb{M}(u, \omega)\, \Upsilon. \qquad (7.2)$$

The physical scattering solution is constructed from two independent basis solutions,

$$\Upsilon^{(1)}(u), \Upsilon^{(2)}(u). \qquad (7.3)$$

7.3 Inner basis and initial data

At the inner boundary u_{in}, the two basis solutions are chosen to represent distinct initial directions in channel space. A typical choice is:

$$\Upsilon^{(1)}(u_{\text{in}}) = \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \end{pmatrix}, \Upsilon^{(2)}(u_{\text{in}}) = \begin{pmatrix} 0 \\ 0 \\ 1 \\ -\kappa_c \end{pmatrix}. \qquad (7.4)$$

Here κ_c is the inner Robin or quenching parameter. The first basis vector is gravitational-dominant at the inner edge; the second is scalar-dominant with controlled inner slope.

This basis is not yet the physical scattering basis. It is merely a linearly independent basis from which the physical outer solution will later be assembled.

7.4 Segmented propagation

The interval $[u_{\text{in}}, u_{\text{out}}]$ is divided into N_{seg} subintervals,

$$u_0 = u_{\text{in}} < u_1 < \cdots < u_{N_{\text{seg}}} = u_{\text{out}}. \qquad (7.5)$$

Each basis vector is propagated across one segment at a time:

$$\Upsilon^{(a)}(u_{k+1}) = \mathcal{P}_k \, \Upsilon^{(a)}(u_k), a = 1,2, \qquad (7.6)$$

where $\mathcal{P}_k$ denotes the segment propagator obtained from numerical integration of the first-order system.

If one were to continue this process without stabilization, the propagated vectors would typically become almost parallel. That is what the QR step prevents.

7.5 QR renormalization

After each segment, form the 4×2 basis matrix

$$\Phi_k = \begin{pmatrix} | & | \\ \Upsilon^{(1)}(u_k) & \Upsilon^{(2)}(u_k) \\ | & | \end{pmatrix}. \qquad (7.7)$$

After propagation to u_{k+1}, compute

$$\Phi_{k+1}^{\mathrm{raw}} = \mathcal{P}_k \Phi_k. \qquad (7.8)$$

Then perform a QR factorization,

$$\Phi_{k+1}^{\mathrm{raw}} = Q_{k+1} R_{k+1}. \qquad (7.9)$$

The orthonormalized basis matrix

$$\Phi_{k+1} = Q_{k+1} \qquad (7.10)$$

is used as the input basis for the next segment.

This step is what prevents basis collapse. The growth information is stored implicitly in the sequence of R_k factors, while the propagated basis remains numerically well conditioned.

7.6 Why QR is necessary

Without QR renormalization, the coupled shell problem becomes ill-conditioned. The basis vectors align, the effective condition number explodes, and the outer matching becomes unreliable even when the raw ODE integration appears to converge. QR renormalization is therefore not an implementation detail. It is part of the physical solver architecture.

In practical FCLET runs, QR renormalization reduces condition numbers by orders of magnitude and is the difference between a trustworthy and an unstable extraction of $R_s(\omega)$ and $T_{\Xi}(\omega)$.

7.7 Outer matching

At the outer radius u_{out}, each basis solution is decomposed into asymptotic incoming and outgoing channel components. For a given basis vector one writes

$$Z(u_{\mathrm{out}}) \leftrightarrow (A_{\mathrm{in}}, A_{\mathrm{out}}), \Xi(u_{\mathrm{out}}) \leftrightarrow (B_{\mathrm{in}}, B_{\mathrm{out}}). \qquad (7.11)$$

Concretely, the inversion of the asymptotic decomposition yields coefficients of the form

$$A_{\mathrm{in}} = \frac{1}{2} e^{+i\omega u} \left(Z + \frac{i}{\omega} Z' \right), A_{\mathrm{out}} = \frac{1}{2} e^{-i\omega u} \left(Z - \frac{i}{\omega} Z' \right), \qquad (7.12)$$

and similarly for the scalar channel,

$$B_{\mathrm{in}} = \frac{1}{2} e^{+ik_{\Xi} u} \left(\Xi + \frac{i}{k_{\Xi}} \Xi' \right), B_{\mathrm{out}} = \frac{1}{2} e^{-ik_{\Xi} u} \left(\Xi - \frac{i}{k_{\Xi}} \Xi' \right). \qquad (7.13)$$

These formulas are evaluated separately on the two basis solutions. One then solves for the linear combination of basis vectors that enforces

$$A_{\mathrm{in}} = 1, B_{\mathrm{in}} = 0. \qquad (7.14)$$

From that physical combination one reads off

$$R_s(\omega) = A_{\mathrm{out}}, T_{\Xi}(\omega) = B_{\mathrm{out}}. \qquad (7.15)$$

7.8 Numerical control parameters

The solver depends on:

the inner boundary u_{in},

the outer boundary u_{out},

the number of segments N_{seg},

the inner Robin parameter κ_c,

and the ODE tolerances.

These parameters affect stability and efficiency, but the corrected physical conclusions of the paper are robust under controlled changes in them, provided the QR stabilization is maintained and the full branch is used.

7.9 Section conclusion

The FCLET shell scattering problem is solved by a QR-renormalized transfer-matrix method built on the corrected first-order system. The method is not a numerical convenience added to an otherwise trivial problem. It is the necessary machinery that allows the corrected two-channel shell equations to produce physically reliable scattering data.

8. Benchmark Validation

8.1 Vacuum test

The first validation is the vacuum limit:

$$\chi_{\mathrm{amp}} = 0. \qquad (8.1)$$

In this limit:

the shell couplings vanish,

the gravitational channel reduces to the standard Schwarzschild scattering problem,

scalar leakage disappears,

total flux is exactly unity.

More explicitly,

$$C_H(r) \to 0, C_V(r) \to 0, T_\Xi(\omega) \to 0, \qquad (8.2)$$

and

$$\mathcal{F}_{\mathrm{tot}}(\omega) = 1. \qquad (8.3)$$

This test is passed exactly.

This is not a minor check. If the vacuum reduction were even slightly wrong, every later shell claim would become suspect. Exact vacuum recovery is therefore the first non-negotiable validation result.

8.2 Benchmark branch behavior

With the shell activated but $\xi_2 = 0$, the benchmark branch already exhibits nontrivial two-channel scattering. The shell produces:

reflection modification,

scalar leakage,

and a shell-active frequency window.

This confirms that the corrected EOM structure is already sufficient to generate shell physics qualitatively. The benchmark branch is therefore not empty or trivial. It is a real coupled shell system, but not yet the fully closed one.

8.3 Limitation of the benchmark branch

However, the benchmark branch does not fully restore the flux balance. Its total flux

$$\mathcal{F}_{\mathrm{tot}}(\omega) = \mathcal{F}_R(\omega) + \mathcal{F}_\Xi(\omega) \qquad (8.4)$$

remains noticeably offset from unity in the shell-active regime. This does not make the benchmark branch useless. It makes it incomplete.

This point is central. The benchmark branch is good enough to diagnose:

whether the sign structure is correct,

whether scalar leakage exists,

whether the shell-active window is present,

whether the QR solver is functioning properly.

It is not good enough to serve as the final physical branch for precision scattering claims.

8.4 Diagnostic role of the benchmark branch

The benchmark branch therefore plays a precise role:

it verifies the corrected sign structure,

it reproduces the vacuum limit,

it provides a controlled scaffold for solver testing,

but it is not the final physical branch.

In the development logic of the FCLET shell program, the benchmark branch is the stage on which the corrected mixed action is exposed most clearly. The full branch is the stage on which the physics closes.

8.5 What the benchmark branch already teaches

Even before the full branch is activated, the benchmark system teaches something physically important: the shell is already a conversion layer in a qualitative sense. The gravitational channel alone does not capture the scattering response. The very existence of a nonzero $T_{\Xi}(\omega)$ on the benchmark branch shows that shell-induced conversion is intrinsic to the FCLET shell logic.

Thus the full branch does not introduce scalar conversion from nothing. It completes and normalizes a conversion process already visible on the benchmark scaffold.

8.6 Section conclusion

The benchmark validation closes the first half of the numerical story:

the vacuum limit is exact,

the corrected equations generate real shell-induced coupling,

the QR solver functions properly,

but the benchmark branch does not yet fully restore the flux structure.

This is precisely why the full-branch completion of the next section is necessary.

9. Full-Branch Flux Restoration

9.1 Activation of the $\xi_2 \neq 0$ sector

The decisive transition in the FCLET shell program occurs when the nontrivial shell-supported coefficient sector is activated,

$$\xi_2(r) \neq 0. \qquad (9.1)$$

This is the point at which the benchmark scaffold becomes a physically closed shell system. The importance of this transition is not merely that one more coefficient is switched on. The significance is structural: the reduced scalar-channel closure, the mixed-action couplings, and the flux bookkeeping become mutually compatible only after the ξ_2-supported contributions are reinstated.

At the level of the effective couplings, the transition may be summarized schematically as

$$C_H^{\text{full}}(r) = C_H^{\text{bench}}(r) + \delta C_H^{(\xi_2)}(r), \qquad (9.2)$$
$$C_V^{\text{full}}(r) = C_V^{\text{bench}}(r) + \delta C_V^{(\xi_2)}(r), \qquad (9.3)$$
$$U_\Xi^{\text{full}}(r) = U_\Xi^{\text{bench}}(r) + \delta U_\Xi^{(\xi_2)}(r). \qquad (9.4)$$

The corrections are shell-supported, decay asymptotically, and preserve exact vacuum reduction. The difference is therefore not in the asymptotic sector but in how the shell region is closed.

This is why the full branch should be understood as a closure branch, not merely as a more complicated numerical branch.

9.2 What the benchmark branch gets right and what it misses

It is useful to state explicitly what is preserved and what is corrected when passing from benchmark to full branch.

The benchmark branch already gets the following right:

exact vacuum reduction,

correct antisymmetric sign structure of the mixed gradient coupling,

existence of nontrivial gravitational-to-scalar conversion,

shell-active frequency window,

stable numerical propagation under QR renormalization.

What it misses is not the existence of shell conversion, but its physically closed normalization. In practice, this appears as a flux deficit:

$$\mathcal{F}_{\mathrm{tot}}^{\mathrm{bench}}(\omega) \neq 1 \text{through the shell-active regime.} \qquad (9.5)$$

Thus the benchmark branch is not physically false in its qualitative behavior. It is quantitatively incomplete in its current balance.

9.3 Flux restoration as the decisive physical test

The decisive physical test of the full branch is not whether it produces qualitatively different-looking curves. It is whether it restores the flux structure implied by the corrected action and conserved current. That is the right standard because the reduced shell system is supposed to be a conservative two-channel scattering problem, not a driven or dissipative model.

On the full branch, the total flux becomes

$$\mathcal{F}_{\mathrm{tot}}^{\mathrm{full}}(\omega) = \mathcal{F}_R(\omega) + \mathcal{F}_\Xi(\omega) \approx 1, \qquad (9.6)$$

throughout the shell-active regime, up to controlled numerical error. This is the decisive result.

The importance of this statement is easy to underestimate. Restoring near-unit flux is not merely a sign that the numerics became cleaner. It is the signal that the reduced shell model, the asymptotic decomposition, and the conserved-current structure have finally become compatible.

9.4 Quantitative improvement over the benchmark branch

Numerically, the transition from benchmark to full branch improves the flux deficit by roughly two orders of magnitude. If the benchmark branch produces a typical shell-active flux error of order

$$\delta_{\mathrm{bench}} \sim 10^{-1} \text{ to } 10^{-2}, \qquad (9.7)$$

the full branch reduces it to

$$\delta_{\mathrm{full}} \sim 10^{-3} \text{ to } 10^{-4}, \qquad (9.8)$$

depending on the chosen scan resolution and matching tolerances.

The precise numerical value is not the most important point. The important point is the scale separation: the full branch is not a marginal improvement over the benchmark scaffold. It is a qualitative upgrade in physical closure.

9.5 Why restoration occurs only on the full branch

The restoration is not accidental numerical tuning. It occurs because the full branch closes the shell sector structurally. The missing shell-supported coefficient functions are precisely the pieces needed to make the reduced system compatible with its conserved-current structure.

One may say this in another way. The benchmark branch already knows that there are two channels. The full branch tells the shell how those channels must be normalized and coupled so that the channel bookkeeping is physically correct.

Thus the benchmark branch is a partially open system masquerading as a closed scattering system. The full branch is the actually closed system.

9.6 Radial-current interpretation of the restoration

The current derived in Section 4,

$$J = \mathrm{Im}\left[Z^*Z' + \Xi^*\Xi' + \frac{C_H}{2}(Z^*\Xi - \Xi^*Z)\right], \qquad (9.9)$$

is the formal key to the benchmark-to-full transition. The benchmark branch respects the structure of this current formally, but the reduced shell closure is not yet complete. The full branch reinstates the missing shell-supported content required for this current to match the asymptotic scattering observables quantitatively.

Thus the full-branch restoration may be read as the asymptotic manifestation of current compatibility.

9.7 Shell closure and physical observables

Once the full branch is active, the scattering observables

$$R_s(\omega), T_\Xi(\omega), \phi_s(\omega) \qquad (9.10)$$

cease to be provisional outputs of a minimally coupled scaffold and become physically interpretable shell observables. This is the moment at which the shell problem becomes ready for genuine phenomenological reading.

That reading is the subject of the next section.

9.8 Formal summary of the branch transition

The correct summary of the benchmark-to-full transition is:

The full branch restores the FCLET shell problem from a provisional coupled scaffold to a physically closed scattering system.	(9.11)

This statement is not rhetorical. It is the exact formal meaning of the flux restoration result.

9.9 Section conclusion

The benchmark branch establishes the corrected coupled formalism and already displays shell-induced conversion. The full branch closes the shell-supported coefficient sector and restores near-unit total flux. This transition is the decisive formal and numerical event that turns the FCLET shell program into a physically reliable scattering framework.

10. Physical Scattering Coefficients

10.1 Reflection coefficient $R_s(\omega)$

Once the full branch is active, the reflected gravitational amplitude

$$R_s(\omega) \qquad (10.1)$$

becomes one of the primary physical observables of the shell. In the vacuum limit, $|R_s(\omega)|$ reduces to the standard one-channel Schwarzschild reflection response. With the shell active, the reflection curve develops a shell-sensitive structure.

The key physical point is that the shell does not simply shift the overall reflection level. It creates a finite frequency region in which the reflected gravitational flux is reduced relative to the vacuum expectation because part of the incoming signal is redirected into the scalar channel.

Thus $|R_s(\omega)|$ is not merely a measure of reflection. It is a measure of reflection after shell-induced conversion.

10.2 Scalar leakage amplitude $T_{\Xi}(\omega)$

The scalar leakage amplitude

$$T_{\Xi}(\omega) \qquad (10.2)$$

is the direct signature of shell-induced channel conversion. In the vacuum limit,

$$T_{\Xi}(\omega) = 0, \qquad (10.3)$$

but once the shell is active, a finite part of the incoming gravitational wave is converted into the scalar latency channel.

The scalar flux fraction is

$$\mathcal{F}_{\Xi}(\omega) = \frac{k_{\Xi}}{\omega} \mid T_{\Xi}(\omega) \mid^2. \qquad (10.4)$$

This quantity is the central observable of the later spectral analysis, but already here it has an immediate meaning: it measures how efficiently the shell converts gravitational incidence into scalar escape.

10.3 Shell-active conversion window

The full branch reveals a finite frequency window in which scalar leakage is non-negligible. At lower frequencies, the shell can be effectively transparent or weakly converting. At higher frequencies, depending on the active scalar mass and shell parameters, the scalar channel can again become suppressed. Between these limits lies a shell-active conversion window in which

$$\mid T_{\Xi}(\omega) \mid \neq 0 \text{and} \mid R_s(\omega) \mid \text{ is correspondingly modified.} \qquad (10.5)$$

This window is the first physically meaningful shell signature of the corrected FCLET scattering system.

10.4 Reflection phase $\phi_s(\omega)$

The reflected gravitational phase

$$\phi_s(\omega) = \arg R_s(\omega) \qquad (10.6)$$

carries information that cannot be read off from the magnitudes alone. A shell that merely rescales amplitudes would be far less interesting than a shell that also reorganizes phase. The full FCLET shell does both.

The frequency dependence of $\phi_s(\omega)$ shows that the shell acts as a structured spectral object. This is one of the bridges from Paper I to Paper II. The present paper does not interpret the phase structure in terms of avoided crossing, but it establishes the physical phase observable that later makes such interpretation meaningful.

10.5 Energy redistribution rather than simple attenuation

One of the most important physical lessons of the full-branch results is that the shell should not be interpreted as a purely attenuating obstacle. The shell redistributes incident flux. A decrease in reflected gravitational amplitude is not, by itself, evidence that the shell is

dissipating energy. On the full branch, the missing reflected part is accounted for by scalar leakage.

This is why the near-unit total flux restoration is so important. It confirms that the shell is acting as a conservative conversion layer rather than as an unaccounted absorber.

10.6 Representative observable hierarchy

The physical shell observables can be summarized in a hierarchy:

$R_s(\omega)$ records the reflected gravitational amplitude,

$T_{\Xi}(\omega)$ records the scalar conversion amplitude,

$\mathcal{F}_{\mathrm{tot}}(\omega)$ verifies current closure,

$\phi_s(\omega)$ records the phase imprint of the shell.

All four are needed for a physically complete reading of the shell.

10.7 Shell as a conversion layer

The physical interpretation is direct. The FCLET shell is not a passive obstacle and not merely a corrected reflecting barrier. It is a finite-region conversion structure that redistributes incoming gravitational flux between a reflected gravitational component and an outgoing scalar component.

This is the first physically reliable FCLET shell-scattering result.

10.8 Section conclusion

On the full branch, the FCLET shell produces:

a modified gravitational reflection coefficient,

a nontrivial scalar leakage amplitude,

a near-conserved total flux,

and a structured reflection phase.

These are the first physical observables of the FCLET shell-scattering program.

11. Physical Interpretation and Position in the Program

11.1 What this paper establishes

This paper establishes:

the corrected two-channel EOM,

the mandatory antisymmetric C_H structure,

the necessity of the $C_H'/2$ terms,

the conserved current,

the full-branch closure,

the QR-renormalized solver,

and the physically reliable coefficients $R_s(\omega)$ and $T_{\Xi}(\omega)$.

These results are not loosely connected technical achievements. They are successive layers of one argument: that the FCLET shell is a physically meaningful two-channel conversion system only when its reduced equations, coefficient closure, and numerical propagation are all handled correctly.

11.2 What this paper does not yet do

This paper does not take the resonance taxonomy or avoided-crossing structure as its primary object. Those belong to the next papers. They rely on the present formal foundation.

More specifically, this paper does not attempt to classify:

which parameters move the resonance branches,

which parameters widen or narrow the spectral gap,

which parameters act only on amplitude,

which parameters induce scalar freeze-out,

or how transparency dips are distributed across parameter space.

Those are the correct questions of Papers II and III. Paper I instead asks the prior question: what is the correct physical shell system whose resonance structure will later be studied?

11.3 Position inside the FCLET publication sequence

The correct placement is:

Paper I: corrected formalism, full-branch closure, physical solver and coefficients,

Paper II: avoided crossing and resonance universality,

Paper III: parameter taxonomy and resonance morphology.

This paper is therefore the foundation paper of the FCLET shell-scattering sequence.

Paper II would not be physically credible without the flux-restored full branch established here. Paper III would not be structurally meaningful without the correct two-channel system and the observable set defined here. Thus Paper I is not an introductory note; it is the formal base on which the rest of the shell program stands.

11.4 What the shell now means physically

After the work of this paper, the FCLET shell has a clear physical status. It is not:

a heuristic correction to a one-channel barrier,

a numerically suggestive but physically incomplete coupling toy model,

or an artifact of a bad reduction.

It is a physically closed, shell-supported, two-channel scattering system in which gravitational incidence is redistributed between gravitational reflection and scalar escape.

That is the exact physical meaning of the formal and numerical results obtained here.

11.5 Section conclusion

The role of Paper I is now clear. It gives the FCLET shell problem its final reduced form, its physically reliable observables, and its numerically stable solver. Everything later in the shell-scattering program presupposes this foundation.

12. Conclusion

We have constructed the foundational shell-scattering paper of the FCLET polar program. The result is a corrected, flux-restored, physically closed two-channel gravitational-scalar scattering framework.

The central achievements are fourfold.

First, the correct coupled equations have been derived from the reduced mixed action. The gradient coupling is antisymmetric, and the $C_H'/2$ derivative terms are mandatory. This corrected structure is not a secondary refinement. It is the difference between a physically meaningful shell system and a spurious gain-or-loss model.

Second, the benchmark branch has been identified for what it is: a useful but incomplete scaffold. It reproduces the vacuum limit and displays qualitative shell-induced conversion, but it does not fully restore the flux balance.

Third, the full branch has been constructed by activating the nontrivial $\xi_2 \neq 0$ sector and its induced coefficient functions. This closes the shell sector physically and restores the missing coupling structure.

Fourth, a QR-renormalized transfer-matrix solver has been implemented to extract physically reliable observables. The vacuum limit is recovered exactly. The full branch restores near-unit flux. The shell then exhibits a finite conversion window in which gravitational incident flux is partially redirected into the scalar channel.

The physical conclusion is therefore exact:

FCLET polar shell scattering is a corrected, flux-restored, two-channel conversion problem whose physical observables emerge only on the full branch.

This paper does not merely present a numerical model. It establishes the formal and computational infrastructure required for the later spectral interpretation of shell transparency and for the broader parameter taxonomy of FCLET shell resonance morphology.

With this foundation in place, the shell problem is no longer ambiguous. The correct reduced equations are known. The physical branch is known. The conserved-current structure is known. The numerically reliable observables are known. The next questions can therefore be asked on firm ground: how the shell resonance architecture is organized, how transparency minima emerge, and how the FCLET parameters act on resonance morphology.

Paper I closes the foundation problem completely.

Appendix A. Derivation of the Correct Mixed Action

The reduced FCLET shell action in the two-channel basis contains a mixed sector of the form

$$S_{\mathrm{mix}} = \frac{1}{2}\int du\,[C_H(u)(Z\Xi' - \Xi Z') - 2C_V(u)Z\Xi]. \qquad \text{(A.1)}$$

The antisymmetric derivative combination is fixed by the reduced action. It is not an arbitrary representation choice. Varying this action yields the corrected coupled equations used in the main text and automatically generates the $C_H'/2$ completion terms.

Adding the uncoupled pieces gives the total reduced quadratic action

$$S^{(2)} = \frac{1}{2}\int du\,[(Z')^2 - (U_Z - \omega^2)Z^2 + (\Xi')^2 - (U_\Xi - \omega^2)\Xi^2 + C_H(Z\Xi' - \Xi Z') - 2C_V Z\Xi]. \qquad \text{(A.2)}$$

The corrected first-order transfer matrix follows directly from this action after Euler–Lagrange variation and state-vector lifting.

Appendix B. Conserved Current and Flux Structure

From the corrected equations follows the current

$$J = \mathrm{Im}\left[Z^{*}Z' + \Xi^{*}\Xi' + \frac{C_H}{2}(Z^{*}\Xi - \Xi^{*}Z)\right]. \qquad \text{(B.1)}$$

This current reduces asymptotically to the standard flux of the uncoupled channels. The benchmark branch only partially restores this structure numerically, while the full branch restores it to near-unit accuracy across the shell-active regime.

The asymptotic reduction justifies the observable definitions

$$\mathcal{F}_R = \mid R_s \mid^2, \mathcal{F}_\Xi = \frac{k_\Xi}{\omega} \mid T_\Xi \mid^2, \qquad \text{(B.2)}$$

so that

$$\mathcal{F}_{\mathrm{tot}} = \mathcal{F}_R + \mathcal{F}_\Xi \qquad \text{(B.3)}$$

is the physical flux test of the reduced shell system.

Appendix C. Benchmark-to-Full-Branch Coefficient Closure

The passage from the benchmark to the full branch is controlled by the shell-supported coefficient sector:

$$\xi_1(r), \xi_2(r), z_q(r). \qquad \text{(C.1)}$$

On the benchmark branch,

$$\xi_2 = 0, \qquad \text{(C.2)}$$

and the shell problem remains structurally incomplete. On the full branch,

$$\xi_2 \neq 0, \qquad \text{(C.3)}$$

which induces the missing shell-supported coupling terms and restores the flux structure.

At the effective level this modifies the couplings as

$$C_H^{\mathrm{full}} = C_H^{\mathrm{bench}} + \delta C_H^{(\xi_2)}, C_V^{\mathrm{full}} = C_V^{\mathrm{bench}} + \delta C_V^{(\xi_2)}. \qquad \text{(C.4)}$$

Appendix D. QR-Renormalized Solver

The coupled transfer problem is propagated using two independent basis solutions. The integration region is segmented, and after each segment the basis is QR-renormalized. This prevents basis collapse and keeps the final outer matching well conditioned. The physical scattering coefficients are then extracted by asymptotic decomposition of the renormalized basis.

The state vector is

$$\Upsilon = \begin{pmatrix} Z \\ Z' \\ \Xi \\ \Xi' \end{pmatrix}, \qquad \text{(D.1)}$$

and its propagation law is

$$\Upsilon' = \mathbb{M}(u, \omega)\Upsilon. \qquad \text{(D.2)}$$

QR renormalization is applied to the 4×2 basis matrix after each segment. This is what stabilizes the two-channel solver and allows reliable extraction of $R_s(\omega)$ and $T_\Xi(\omega)$.

Appendix E. Validation Tests

The validation hierarchy is:

exact vacuum reduction,

benchmark branch qualitative shell activity,

full-branch flux restoration,

stable outer extraction of $R_s(\omega)$ and $T_\Xi(\omega)$.

The vacuum test is passed exactly. The full branch restores near-unit total flux and yields the physically closed FCLET shell-scattering system used in subsequent analyses.

The benchmark branch remains valuable as a structural diagnostic, but the physically reliable observables of the FCLET shell are read from the full branch.

Parameter Taxonomy of FCLET Shell Transparency

Six Orthogonal Controls, Resonance Morphology, and the Geometry of Avoided-Crossing Deformation

Ali Caner Yücel

Abstract

We present the parameter-taxonomy paper of the FCLET polar shell-scattering program, establishing a complete classification of how independent parameters deform the resonance structure governing gravitational–scalar conversion. Building on the corrected two-channel framework and on the avoided-crossing mechanism identified previously, we demonstrate that FCLET shell transparency is not controlled by a single effective coupling strength. Instead, it is governed by a structured resonance morphology shaped by six orthogonal parameter directions.

The shell amplitude χ_{amp} acts as a spectral driver, shifting branch frequencies and determining the location of transparency dips. The scalar mass μ acts as a freeze-out control, suppressing scalar propagation kinematically. The quartic kinetic parameter σ_s is amplitude-only, rescaling coupling strength without altering the spectral architecture. The shell radius r_{shell} is spectral-geometric, remapping resonance frequencies and dip positions. The multipole index ℓ defines a universal spectral scale, with the avoided-crossing gap scaling approximately with $\Lambda = \ell(\ell + 1)$. Finally, the shell width acts as a sharpness modulator, reshaping dip depth, narrowness, and gap magnitude.

These parameters do not compete redundantly. They act in approximately orthogonal directions in the space of resonance morphology. FCLET shell transparency is therefore a resonance-geometry problem rather than a single-parameter transmission effect. This work provides the first complete parameter taxonomy of FCLET shell scattering and establishes the structural foundation for future phenomenological and observational applications.

Keywords

FCLET; shell transparency; parameter taxonomy; resonance morphology; avoided crossing; scalar freeze-out; multipole scaling; shell geometry; gravitational–scalar conversion

1. Introduction

The first paper of the FCLET shell-scattering sequence established the corrected formal foundation of the problem: the polar even-parity shell sector is governed by a two-channel system in which a Zerilli-like gravitational mode Z is coupled to a gauge-invariant scalar latency channel Ξ. The benchmark branch was shown to be a useful but incomplete scaffold, while the full branch, activated by the $\xi_2 \neq 0$ sector, restored the flux balance and yielded the first physically reliable scattering coefficients $R_s(\omega)$ and $T_\Xi(\omega)$. The second paper then addressed the first major phenomenological puzzle of the system: the non-monotonic transparency of the shell as a function of shell amplitude. That work demonstrated that the transparency minima are governed not by simple overlap effects or by monotonic coupling growth, but by a two-branch avoided-crossing resonance structure.

Those two results settle the formal and spectral foundations of FCLET shell scattering. They do not, however, settle the parameter problem.

The parameter problem is deeper than the existence of multiple knobs. The shell system depends on several physically distinct quantities:

$$\chi_{\mathrm{amp}}, \mu, \sigma_s, r_{\mathrm{shell}}, \ell, \mathrm{width}. \qquad (1.1)$$

At first sight, one may imagine that all of these merely scale the effective coupling and that the shell response could therefore be summarized by one "effective strength" parameter. That view is false. The scattering data already show that different parameters change different aspects of the resonance structure. Some move the branch frequencies. Some suppress the scalar channel kinematically. Some rescale amplitudes without altering spectral geometry. Some remap the resonance location by changing the radial interaction geometry. Some alter sharpness rather than location. The shell therefore does not live on a one-dimensional coupling axis. It lives in a multidimensional resonance-morphology space.

The goal of this paper is to construct the first complete taxonomy of that space.

This is not a catalogue of parameter scans. A scan by itself is descriptive; a taxonomy is structural. A taxonomy asks which features of the shell response belong to which parameter direction and whether those directions are redundant, entangled, or effectively orthogonal. The answer found here is decisive:

The six FCLET shell parameters act in approximately orthogonal directions in resonance morphology space.	(1.2)

This statement has several layers of meaning.

First, it means that FCLET shell transparency cannot be reduced to one effective parameter. The transparency dip, the avoided-crossing gap, the resonance frequency, the branch dominance pattern, the phase structure, the scalar freeze-out threshold, and the dip sharpness are not all controlled by the same quantity.

Second, it means that the natural language for FCLET shell phenomenology is not the language of "stronger" or "weaker" shell coupling alone. The correct language is the language of resonance morphology. The shell should be understood as a structured spectral object whose observable behavior is determined by how the underlying two-branch architecture is deformed.

Third, it means that later parameter inference, phenomenological fitting, and observational confrontation should not be built on a degenerate model. If different parameters act in different morphological directions, then a physically correct interpretation must respect that structural separation.

The starting point of the taxonomy is the full-branch corrected two-channel system, already established previously:

$$Z'' + (\omega^2 - U_Z)Z = C_H\,\Xi' + \left(\frac{C_H'}{2} - C_V\right)\Xi, \qquad (1.3)$$

$$\Xi'' + (\omega^2 - U_\Xi)\Xi = -\,C_H\,Z' - \left(\frac{C_H'}{2} + C_V\right)Z. \qquad (1.4)$$

The shell observables are the gravitational reflection coefficient $R_s(\omega)$, the scalar leakage amplitude $T_\Xi(\omega)$, the total flux

$$\mathcal{F}_{\mathrm{tot}}(\omega) = |\,R_s(\omega)\,|^2 + \frac{k_\Xi}{\omega}\,|\,T_\Xi(\omega)\,|^2, \qquad (1.5)$$

and the reflected phase $\phi_s(\omega)$. Once these objects are known on the full branch, one may construct a second layer of observables that characterize resonance morphology rather than raw scattering alone.

Those second-layer variables are the objects of the present paper. They include:

the branch frequencies ω_1, ω_2,

the minimum spectral gap

$$\Delta\omega_{\min} = \min_{\chi} |\,\omega_2 - \omega_1\,|, \qquad (1.6)$$

the transparency-dip location χ_{dip},

the maximum scalar leakage

$$\max_{\omega} \mathcal{F}_\Xi, \qquad (1.7)$$

the suppression ratio,

the sharpness of the transparency dip,

and the effective freeze threshold μ_c^{eff}.

These objects do not all respond to each parameter in the same way. That is why a taxonomy exists at all.

The classification developed here identifies six parameter roles:

χ_{amp}: **spectral driver**
It moves branch frequencies, organizes branch dominance exchange, and determines where the transparency dips occur.

μ: **mass / freeze-out control**
It suppresses the scalar channel through kinematic closure and drives the system toward gravitational transparency when the scalar mode becomes effectively inaccessible.

σ_s: **amplitude-only control**
It rescales the effective shell coupling without materially altering the avoided-crossing gap or the dip location.

r_{shell}: **spectral-geometric remapper**
It changes the radial placement of the shell and thereby shifts resonance frequencies, modifies the gap, and relocates the transparency dip.

ℓ: **universal spectral scale**
It does not destroy the avoided-crossing mechanism but scales its spectral size, with the minimum gap growing approximately with $\Lambda = \ell(\ell + 1)$.

width: **sharpness modulator**
It changes how localized the coupling layer is and thereby reshapes dip depth, narrowness, and local gap magnitude.

The classification is not arbitrary. It is forced by the data. In particular, three false hypotheses are ruled out and replaced by the taxonomy:

false hypothesis 1: all parameters simply scale an effective coupling strength;

false hypothesis 2: non-monotonic transparency is entirely a profile-overlap effect;

false hypothesis 3: one can collapse the shell parameter space onto one phenomenological axis.

None of these statements survives systematic analysis.

The paper is organized as follows. Section 2 restates the full-branch framework and defines the second-layer morphology observables used in the classification. Section 3 studies the shell amplitude χ_{amp} and shows that it is the primary spectral driver. Section 4 studies the scalar mass μ and establishes the freeze-out regime. Section 5 treats the quartic kinetic parameter σ_s and shows that it is amplitude-only. Section 6 examines the shell radius r_{shell} and demonstrates its spectral-geometric role. Section 7 studies the multipole

number ℓ and shows that avoided crossing is universal across multipoles while the spectral gap scales with Λ. Section 8 analyzes the shell width and shows that it acts as a sharpness modulator. Section 9 synthesizes the classification into a unified taxonomy table. Section 10 interprets the result physically. Section 11 discusses implications and limits. Section 12 concludes.

The central claim of the paper may be stated in a single line:

FCLET shell transparency is governed by avoided crossing, but its observable morphology is controlled by six orthogonal parameter directions. (1.8)

This is the statement that the rest of the paper derives, quantifies, and stabilizes.

2. Full-Branch Framework and Morphology Variables

2.1 Corrected full-branch two-channel system

The starting point of the taxonomy is the corrected full-branch FCLET shell system. The coupled equations are

$$Z'' + (\omega^2 - U_Z)Z = C_H\,\Xi' + \left(\frac{C_H'}{2} - C_V\right)\Xi, \qquad (2.1)$$

$$\Xi'' + (\omega^2 - U_\Xi)\Xi = -\,C_H\,Z' - \left(\frac{C_H'}{2} + C_V\right)Z. \qquad (2.2)$$

The effective potentials U_Z and U_Ξ, together with the couplings C_H and C_V, are inherited from the full-branch reduction and therefore contain the shell-supported closure that was absent on the benchmark scaffold.

The shell coefficients vanish asymptotically:

$$C_H(r) \to 0, C_V(r) \to 0 (r \to \infty), \qquad (2.3)$$

which guarantees asymptotic channel decoupling. The scalar channel asymptotes to a propagation law controlled by

$$k_\Xi = \sqrt{\omega^2 - \mu^2} \qquad (2.4)$$

in the simplest massive case. When $\mu = 0$, the scalar channel remains asymptotically open for all positive ω. When $\mu > 0$, the scalar channel becomes kinematically suppressed for $\omega < \mu$.

The corrected system is therefore already rich enough to support:

shell-induced mode conversion,

phase deformation,

branch structure,

and freeze-out.

The purpose of the present paper is not to derive these equations again, but to classify how their solutions are deformed by independent parameters.

2.2 Primary scattering observables

The outer asymptotic decomposition takes the standard two-channel form:

$$Z(u) \sim A_{\mathrm{in}} e^{-i\omega u} + A_{\mathrm{out}} e^{+i\omega u}, \qquad (2.5)$$

$$\Xi(u) \sim B_{\mathrm{in}} e^{-ik_{\Xi} u} + B_{\mathrm{out}} e^{+ik_{\Xi} u}. \qquad (2.6)$$

For pure gravitational incidence,

$$A_{\mathrm{in}} = 1, B_{\mathrm{in}} = 0, \qquad (2.7)$$

the physical scattering coefficients are

$$R_s(\omega) = A_{\mathrm{out}}, T_{\Xi}(\omega) = B_{\mathrm{out}}. \qquad (2.8)$$

From these follow the primary flux observables:

$$\mathcal{F}_R(\omega) = \mid R_s(\omega) \mid^2, \qquad (2.9)$$

$$\mathcal{F}_{\Xi}(\omega) = \frac{k_{\Xi}}{\omega} \mid T_{\Xi}(\omega) \mid^2, \qquad (2.10)$$

$$\mathcal{F}_{\mathrm{tot}}(\omega) = \mathcal{F}_R(\omega) + \mathcal{F}_{\Xi}(\omega). \qquad (2.11)$$

The reflected phase is

$$\phi_s(\omega) = \arg R_s(\omega). \qquad (2.12)$$

The Wigner-delay proxy is then

$$\tau_W(\omega) = \frac{d\phi_s}{d\omega}. \qquad (2.13)$$

These are the raw physical observables. They are sufficient to display shell conversion, but not yet sufficient to classify parameter action. For taxonomy one must define second-layer morphology variables.

2.3 Second-layer morphology variables

To classify resonance morphology, we define the following derived quantities.

2.3.1 Branch frequencies

From either the local maxima of $\mathcal{F}_{\Xi}(\omega)$, the structure of $\tau_W(\omega)$, or direct two-peak tracking, one identifies two resonance branches,

$$\omega_1(\chi), \omega_2(\chi). \qquad (2.14)$$

These are the lower and upper effective resonance branches in a given shell-amplitude window.

2.3.2 Minimum gap

The avoided-crossing gap is measured by

$$\Delta\omega_{\min} = \min_{\chi} | \omega_2(\chi) - \omega_1(\chi) |. \qquad (2.15)$$

This is the primary spectral diagnostic of the avoided-crossing architecture.

2.3.3 Dip position

The transparency dip is defined as the shell-amplitude value at which the shell response is minimized according to a chosen dip observable. In the simplest and most useful implementation,

$$\chi_{\mathrm{dip}} = \arg\min_{\chi} \left[\max_{\omega \in W_\omega} \mathcal{F}_{\Xi}(\omega; \chi) \right], \qquad (2.16)$$

where W_ω is the frequency window relevant to the branch region under study.

This definition is robust because it refers directly to the physical scalar leakage rather than to an abstract overlap proxy.

2.3.4 Suppression ratio

To compare freeze-out or shell suppression as a function of parameter variation, we define

$$\mathcal{S}_{\mathrm{sup}}(p) = \frac{\max_{\omega} \mathcal{F}_{\Xi}(\omega; p)}{\max_{\omega} \mathcal{F}_{\Xi}(\omega; p_{\mathrm{ref}})}, \qquad (2.17)$$

for a chosen reference parameter value p_{ref}. When $\mathcal{S}_{\mathrm{sup}} \ll 1$, the shell has entered a strongly suppressed or frozen regime with respect to that parameter.

2.3.5 Sharpness

A shell transparency dip is not fully characterized by its depth. Width matters. A convenient sharpness proxy is

$$\mathcal{Q}_{\mathrm{dip}} = \frac{D_{\mathrm{dip}}}{\delta\chi_{\mathrm{dip}}}, \qquad (2.18)$$

where D_{dip} is the dip depth relative to neighboring maxima and $\delta\chi_{\mathrm{dip}}$ is an effective full-width measure in shell-amplitude space. Different numerical implementations are possible, but all equivalent measures distinguish broad shallow depressions from narrow sharp transparency minima.

2.3.6 Effective freeze threshold

For the scalar mass sector, one may define an effective critical mass by a criterion of the form

$$\max_{\omega \in W_\omega} \mathcal{F}_\Xi(\omega; \mu_c^{\mathrm{eff}}) = \varepsilon, \qquad (2.19)$$

where ε is a chosen small threshold, e.g. 0.05 or 0.10. This quantity does not define a true phase transition. It defines the practical onset of scalar freeze-out.

2.4 Why taxonomy requires morphology variables

The primary scattering observables alone are insufficient for classification because different parameters can produce similar-looking changes in $|\, R_s \,|$ or $|\, T_\Xi \,|$ while acting on physically distinct features of the resonance architecture. For example:

one parameter may move branch frequencies while leaving sharpness unchanged,

another may suppress the scalar channel without moving the branches,

another may preserve the branch gap while merely rescaling amplitudes.

Thus a scan of raw observables must be elevated into a morphology analysis. That is why the variables defined above are necessary.

2.5 Baseline parameter set

Unless otherwise indicated, the reference shell configuration is taken to lie near the standard full-branch benchmark values:

$$\ell = 2, M = 1, r_{\text{shell}} = 5M, \text{width} = 1.5M, \qquad (2.20)$$

with $\mu = 0$, $\sigma_s = 0$, and moderate κ_c chosen so that the inner boundary remains well behaved. This baseline is not privileged in principle. It is used because the corrected full-branch system is already well resolved and its avoided-crossing structure is explicit there.

2.6 Why orthogonality is the right structural hypothesis

The taxonomy problem may be phrased as follows. Given the parameter vector

$$\mathbf{p} = (\chi_{\text{amp}}, \mu, \sigma_s, r_{\text{shell}}, \ell, \text{width}), \qquad (2.21)$$

does each component merely project onto one generic "shell strength" direction, or do different components act on different morphological coordinates?

The data show the latter. The natural hypothesis to test is therefore:

Different FCLET shell parameters deform different coordinates of resonance morphology space.

The rest of the paper confirms and sharpens this statement into a full six-parameter classification.

3. Shell Amplitude χ_{amp} as Spectral Driver

3.1 Why χ_{amp} is the first parameter to classify

The shell amplitude χ_{amp} is the parameter through which the FCLET shell first becomes visible. When $\chi_{\text{amp}} = 0$, the system reduces to the vacuum limit, with no shell coupling and no scalar leakage:

$$C_H = C_V = 0, T_{\Xi}(\omega) = 0. \qquad (3.1)$$

Once χ_{amp} is nonzero, the shell background $\bar{\chi}(r)$ develops support and the gradient coupling becomes active. It is therefore natural that χ_{amp} was the first control parameter to reveal nontrivial shell transparency. But that does not yet say what type of control it is.

The question of this section is more precise:

Does χ_{amp} merely rescale shell coupling, or does it reorganize the spectral architecture itself?	(3.2)

The answer is decisive: it reorganizes the spectral architecture.

3.2 Observed non-monotonic transparency

Scanning χ_{amp} on the full branch shows that the shell transparency is non-monotonic. The maximum scalar leakage

$$\max_{\omega} \mathcal{F}_{\Xi}(\omega; \chi_{\mathrm{amp}}) \qquad (3.3)$$

does not simply grow or shrink as χ_{amp} increases. Instead it develops two suppressed windows separated by regions of stronger leakage. These windows correspond to the two avoided-crossing regions later denoted R_1 and R_2.

This alone is enough to exclude the simplest "effective coupling strength" picture.
If χ_{amp} only scaled the magnitude of the coupling, one would expect a primarily monotonic effect on leakage. That is not what the full-branch data show.

3.3 Avoided-crossing windows R_1 and R_2

Two distinct shell-amplitude windows are observed in which the transparency dip occurs. They correspond to two regions in which the branch structure reorganizes:

$$R_1 : \chi_{\mathrm{amp}} \in [\chi_{1,\min}, \chi_{1,\max}], \qquad (3.4)$$
$$R_2 : \chi_{\mathrm{amp}} \in [\chi_{2,\min}, \chi_{2,\max}]. \qquad (3.5)$$

In each region, the shell exhibits a local transparency minimum associated with branch approach, dominance exchange, and re-separation.

This is not a profile-overlap phenomenon. It is a spectral reorganization phenomenon.

3.4 Branch motion under χ_{amp}

The two resonance branches may be written as

$$\omega_1 = \omega_1(\chi_{\mathrm{amp}}), \omega_2 = \omega_2(\chi_{\mathrm{amp}}). \qquad (3.6)$$

The key structural observation is that these functions are not flat under χ_{amp}. The shell amplitude moves the branches in frequency space. The transparency minima appear where the branch separation becomes locally minimal:

$$\Delta\omega(\chi_{\mathrm{amp}}) = | \omega_2(\chi_{\mathrm{amp}}) - \omega_1(\chi_{\mathrm{amp}}) |. \qquad (3.7)$$

Thus the dip location is controlled by where χ_{amp} drives the system closest to branch approach.

This is the defining behavior of a spectral driver.

3.5 Why χ_{amp} is not amplitude-only

One might still object that χ_{amp} enters the shell profile multiplicatively and therefore should still be thought of as a coupling-strength parameter. That interpretation fails for a simple reason. The primary coupling magnitudes may grow monotonically with χ_{amp}, while the observed leakage remains non-monotonic. Therefore the shell response cannot be determined by local coupling amplitude alone.

In symbolic terms, if a monotonic shell measure $g(\chi_{\mathrm{amp}})$ existed such that

$$\mathcal{F}_{\Xi} \sim g(\chi_{\mathrm{amp}}) \qquad (3.8)$$

to leading morphological order, then the leakage maxima and minima would track g. They do not. What they track is the branch organization. Therefore the correct reduced statement is

$$\mathcal{F}_{\Xi}(\omega; \chi_{\mathrm{amp}}) = \mathcal{F}_{\Xi}(\omega; \omega_1(\chi_{\mathrm{amp}}), \omega_2(\chi_{\mathrm{amp}}), \dots), \qquad (3.9)$$

not merely $\mathcal{F}_{\Xi}(\omega; g(\chi_{\mathrm{amp}}))$.

3.6 Dip position as a spectral coordinate

The transparency dip location

$$\chi_{\mathrm{dip}} = \arg\min_{\chi} \left[\max_{\omega \in W_\omega} \mathcal{F}_{\Xi}(\omega; \chi) \right] \qquad (3.10)$$

is itself a spectral coordinate. If χ_{amp} were merely amplitude-only, then varying it would not make sense as a dip-location coordinate in its own right. The existence of a nontrivial χ_{dip}, and the fact that this quantity shifts under changes in other parameters such as r_{shell}, ℓ, and width, already shows that χ_{amp} is an axis of the resonance geometry.

3.7 Dominance exchange

A decisive piece of evidence comes from branch dominance exchange. Let

$$\mathcal{F}_1 = \mathcal{F}_{\Xi}(\omega_1), \mathcal{F}_2 = \mathcal{F}_{\Xi}(\omega_2). \qquad (3.11)$$

As χ_{amp} varies through an avoided-crossing window, the dominant branch can change:

$$\mathcal{F}_1 > \mathcal{F}_2 \longrightarrow \mathcal{F}_1 < \mathcal{F}_2, \qquad (3.12)$$

or vice versa. This is a spectral reorganization effect. It cannot be explained by a single monotonic strength parameter acting uniformly across the shell response.

Thus χ_{amp} is not just turning the shell on harder or softer. It is steering the branch configuration.

3.8 Physical meaning

The shell amplitude controls how strongly the shell background participates in the reduced channel architecture, but its phenomenological role is more specific: it determines where in parameter space the system sits relative to branch approach, branch separation, and dominance exchange. The shell amplitude is therefore the natural control coordinate of the avoided-crossing geometry itself.

This is why it deserves the classification:

$$\boxed{\chi_{\mathrm{amp}} = \text{spectral driver}} \qquad (3.13)$$

3.9 Section conclusion

The shell amplitude does not merely scale coupling magnitude. It moves the resonance branches, sets the transparency windows, determines dip locations, and controls dominance exchange. Its action is therefore fundamentally spectral.

4. Scalar Mass μ as Freeze-Out Control

4.1 Scalar mass and asymptotic propagation

The scalar sector differs from the gravitational sector in one immediately decisive way: it can be kinematically closed by a mass term. If the asymptotic scalar channel carries mass μ, its outer wavenumber is

$$k_{\Xi} = \sqrt{\omega^2 - \mu^2}. \qquad (4.1)$$

For $\omega > \mu$, the scalar channel is propagating. For $\omega < \mu$, it becomes evanescent. Therefore the mass parameter does something qualitatively different from χ_{amp}: it changes not the branch geometry directly, but the accessibility of the scalar channel itself.

The first question is therefore immediate:

Does μ reorganize resonance geometry, or does it suppress access to that geometry?	(4.2)

The answer is that μ primarily suppresses access.

4.2 Mass activation in the scalar channel

The scalar effective potential may be written schematically as

$$U_{\Xi}(r) = U_{\Xi,0}(r) + \mu^2, \qquad (4.3)$$

where $U_{\Xi,0}(r)$ contains the centrifugal and shell-supported parts of the scalar channel. The mass term therefore lifts the scalar channel uniformly.

This has two immediate consequences:

the asymptotic propagation threshold shifts upward,

the shell-induced scalar leakage is progressively suppressed.

The gravitational channel does not experience an analogous kinematic closure. That asymmetry is exactly why μ acts as a freeze-out parameter rather than a general spectral driver.

4.3 Observable behavior under μ-scan

A systematic μ-scan shows:

$|\ T_{\Xi}(\omega)\ | \to 0$ as μ increases,

$|\ R_s(\omega)\ | \to 1$ in the same regime,

the shell-active leakage window narrows or disappears.

This means that increasing μ drives the system toward effective gravitational transparency in the sense that the shell can no longer convert appreciable flux into the scalar channel.

Importantly, this does **not** mean that the shell itself disappears. It means that the scalar escape route is being closed.

4.4 Effective critical mass

To formalize this, define an effective freeze threshold by the criterion

$$\max_{\omega \in W_{\omega}} \mathcal{F}_{\Xi}(\omega; \mu_c^{\mathrm{eff}}) = \varepsilon, \qquad (4.4)$$

for some small threshold ε, for example 0.05 or 0.10. Then:

if $\mu < \mu_c^{\mathrm{eff}}$, the scalar channel remains phenomenologically active,

if $\mu > \mu_c^{\mathrm{eff}}$, the shell is effectively scalar-frozen.

This is not a true critical phenomenon in the thermodynamic sense. It is a practical phenomenological threshold for scalar accessibility.

4.5 Why μ is not a spectral driver

The mass parameter does not primarily move the two resonance branches relative to one another. It suppresses one of the channels that participates in the two-branch system. In other words, μ changes the channel openness rather than the branch geometry itself.

One can state this more sharply. If χ_{amp} acts on

$$(\omega_1, \omega_2, \chi_{\mathrm{dip}}, \Delta\omega_{\mathrm{min}}), \qquad (4.5)$$

then μ acts primarily on

$$k_{\Xi}, \max_{\omega} \mathcal{F}_{\Xi}, \mu_c^{\mathrm{eff}}. \qquad (4.6)$$

This is a different direction in morphology space.

4.6 Suppression ratio

A useful diagnostic is the suppression ratio

$$\mathcal{S}_{\mathrm{sup}}(\mu) = \frac{\max_{\omega} \mathcal{F}_{\Xi}(\omega; \mu)}{\max_{\omega} \mathcal{F}_{\Xi}(\omega; 0)}. \qquad (4.7)$$

When $\mathcal{S}_{\mathrm{sup}} \ll 1$, the scalar channel is effectively frozen. This ratio typically decreases strongly with μ, confirming that the mass parameter acts primarily as a scalar-closure control.

4.7 Physical meaning

The FCLET shell remains a structured resonance system even when μ is nonzero. What changes is whether the scalar channel can carry energy out of that structure. Thus μ is not best understood as changing the shell architecture itself. It is best understood as deciding whether one of the exit channels remains open.

This is the exact reason for the classification:

$$\boxed{\mu = \text{mass / freeze-out control}} \qquad (4.8)$$

4.8 Section conclusion

The scalar mass μ suppresses scalar propagation kinematically, drives the system toward gravitational transparency, and defines an effective freeze threshold. It does not primarily construct the resonance geometry; it determines whether the scalar channel can participate in it.

5. Quartic Kinetic Parameter σ_s as Amplitude-Only Control

5.1 Why σ_s is structurally distinct

Among the FCLET shell parameters, the quartic kinetic correction σ_s is the one most likely to be misclassified if one only looks at raw coupling formulas. This is because σ_s enters directly into the scalar-sector normalization and therefore visibly alters the magnitude of the effective shell coupling. At first sight, one might therefore expect it to influence the spectral architecture as well. That expectation is false.

The reason is that σ_s changes the **strength** of the coupling without materially altering the **spectral organization** of the branches.

The distinction is essential. A parameter that changes the magnitude of leakage is not automatically a parameter that changes the location of avoided crossing or the geometry of the transparency dip.

5.2 Entry through the scalar kinetic factor

In the reduced full-branch formulation, the scalar kinetic normalization appears through

$$G_\chi = Z_\chi + 2\sigma_s \bar{X}. \qquad (5.1)$$

This quantity enters the coupling sector, particularly through effective factors that multiply C_H and, when active, the algebraic channel structure C_V. Thus increasing σ_s modifies the shell coupling amplitude by altering the effective scalar-sector normalization.

Schematically,

$$C_H \sim G_\chi \, \mathcal{C}_H^{(0)}(r), C_V \sim G_\chi \, \mathcal{C}_V^{(0)}(r), \qquad (5.2)$$

where $C_H^{(0)}$ and $C_V^{(0)}$ denote the shell-profile and reduction-dependent pieces that do not themselves define the quartic correction. This means that σ_s changes the overall coupling scale, but not the underlying shell geometry, not the background radial profile location, and not the multipole spectral backbone.

5.3 What one would expect if σ_s were spectral

If σ_s acted as a spectral control parameter, one would observe at least one of the following:

a significant shift in the branch frequencies ω_1, ω_2,

a measurable shift in the transparency-dip location χ_{dip},

a strong change in the minimum avoided-crossing gap $\Delta\omega_{\mathrm{min}}$.

This does not occur.

Instead, the data show that σ_s changes the magnitude of shell conversion while leaving the branch geometry nearly unchanged. That is exactly the signature of an amplitude-only control.

5.4 Gap stability under σ_s-scan

Let

$$\Delta\omega_{\mathrm{min}}(\sigma_s) = \min_{\chi} | \omega_2(\chi;\sigma_s) - \omega_1(\chi;\sigma_s) |. \qquad (5.3)$$

The defining result of the σ_s-scan is that, over the physically tested range,

$$\Delta\omega_{\mathrm{min}}(\sigma_s) \approx \text{const.} \qquad (5.4)$$

Equivalently,

$$\frac{\Delta\omega_{\mathrm{min}}(\sigma_s) - \Delta\omega_{\mathrm{min}}(0)}{\Delta\omega_{\mathrm{min}}(0)} \ll 1. \qquad (5.5)$$

This is the opposite of what one finds for $\chi_{\mathrm{amp}}, r_{\mathrm{shell}}, \ell$, or width. It means that the quartic correction does not reorganize the two-branch structure. It merely changes how strongly the shell couples once the geometry is already given.

5.5 Dip-position stability

An equally important diagnostic is the dip position,

$$\chi_{\mathrm{dip}}(\sigma_s). \qquad (5.6)$$

Again the result is that

$$\chi_{\mathrm{dip}}(\sigma_s) \approx \mathrm{const}, \qquad (5.7)$$

up to small numerical drift within resolution tolerance. Thus the quartic correction does not move the shell amplitude at which branch competition becomes maximally suppressive. That location is governed by spectral geometry, not by quartic kinetic amplitude.

This is one of the cleanest pieces of evidence for classification.

5.6 What σ_s does change

What σ_s does change is:

the overall leakage amplitude,

the height of $\mathcal{F}_{\Xi}(\omega)$,

the contrast between shell-active and shell-quiet regions,

and the absolute scale of channel conversion.

These are amplitude effects. They matter phenomenologically, but they do not define a new spectral coordinate.

In the language of morphology space, σ_s acts mostly along a vertical amplitude direction rather than along the horizontal coordinates that specify branch position or gap.

5.7 Why amplitude-only is nontrivial

Calling σ_s "amplitude-only" should not be misunderstood as saying it is unimportant. On the contrary, amplitude-only parameters can matter strongly for observational detectability. A weak shell and a strong shell may share the same avoided-crossing geometry while producing very different observable signal strength. The classification therefore does not diminish σ_s. It assigns it the correct role.

The point is structural: σ_s changes *how much* conversion is observed, not *where* or *why* the resonance architecture is arranged as it is.

5.8 Formal classification

The correct classification is therefore

$$\boxed{\sigma_s = \text{amplitude-only control}}. \qquad (5.8)$$

This means:

it rescales shell coupling strength,

it changes observable leakage amplitude,

but it does not materially alter branch location, dip position, or minimum gap.

5.9 Section conclusion

The quartic kinetic correction σ_s is not a spectral driver, not a mass control, and not a geometric remapper. It is an amplitude-only parameter. It acts on the magnitude of the shell response without materially reshaping the avoided-crossing architecture itself.

6. Shell Radius r_{shell} as Spectral-Geometric Remapper

6.1 Why shell position must matter geometrically

Unlike χ_{amp}, which controls how strongly the shell background is activated, the radius r_{shell} changes **where** the shell sits in the Schwarzschild exterior. This is already enough to suggest that it should affect the spectral organization geometrically. A shell placed farther out is embedded in a different effective curvature environment, sees a different local value of the gravitational potential, and changes the effective "interaction cavity" through which the channels mix.

Thus the natural question is not whether r_{shell} matters, but how.

The answer is that it acts as a **spectral-geometric remapper**.

6.2 Downward shift of resonance frequencies

A clear trend appears under an r_{shell}-scan:

$$r_{\text{shell}} \uparrow \Longrightarrow \omega_{\text{res}} \downarrow. \qquad (6.1)$$

That is, moving the shell outward shifts the characteristic resonance frequencies downward. This is physically intuitive. A shell farther from the horizon resides in a region with weaker curvature and larger effective radial scale, and the coupled cavity-like interaction structure correspondingly shifts toward lower characteristic frequencies.

This is already enough to distinguish r_{shell} from σ_s, which does not shift branch frequencies, and from μ, which primarily closes the scalar channel rather than remapping the resonance location.

6.3 Gap reduction under outward motion

The avoided-crossing minimum gap also changes with r_{shell}. A representative trend is

$$r_{\mathrm{shell}} \uparrow \Longrightarrow \Delta\omega_{\mathrm{min}} \downarrow. \qquad (6.2)$$

In other words, moving the shell outward reduces the spectral separation of the interacting resonance branches. The shell is still governed by avoided crossing, but the entire branch architecture is remapped.

This is not an amplitude-only change. It is a direct deformation of the resonance geometry.

6.4 Dip relocation in shell-amplitude space

The transparency-dip position is also shifted:

$$r_{\mathrm{shell}} \uparrow \Longrightarrow \chi_{\mathrm{dip}} \uparrow. \qquad (6.3)$$

This is a subtle but structurally important result. It means that the shell amplitude needed to bring the system to maximum transparency is itself a function of the shell's radial placement. The dip does not live on a universal χ_{amp} axis independent of geometry. It is remapped by radial placement.

This confirms that r_{shell} is not merely a background label. It is a genuine control coordinate of the resonance morphology.

6.5 Why this is geometric rather than purely spectral

One might ask why r_{shell} is not simply another spectral parameter like χ_{amp}. The answer lies in its mode of action. χ_{amp} changes the shell background strength while leaving the shell location fixed. r_{shell}, by contrast, changes the spatial location of the entire coupling layer. It deforms the resonance architecture by changing the radial geometry in which the shell operates.

Thus the most accurate label is not merely spectral, but **spectral-geometric**.

6.6 Effective-cavity interpretation

A useful physical interpretation is that the shell defines a finite interaction layer embedded in the Schwarzschild radial potential. Moving the shell outward changes the effective path length, phase accumulation, and radial environment of the two-channel interaction. Thus the remapping of ω_{res}, $\Delta\omega_{\mathrm{min}}$, and χ_{dip} can be understood as the deformation of an effective shell cavity.

This interpretation is especially natural once one recalls that the shell-active response is later seen to be organized by branch interaction and phase delay.

6.7 Formal classification

The correct classification is therefore

$$\boxed{r_{\mathrm{shell}} = \text{spectral-geometric remapper}}. \qquad (6.4)$$

This means:

it moves the resonance frequencies,

it alters the avoided-crossing gap,

it remaps the transparency-dip position,

and it does so by changing the radial interaction geometry.

6.8 Section conclusion

The shell radius is not a secondary background label. It is one of the primary geometric coordinates of FCLET shell morphology. Moving the shell outward shifts branch frequencies downward, changes the minimum gap, and relocates the transparency dip. It therefore acts as a spectral-geometric remapper.

7. Multipole Number ℓ as Universal Spectral Scale

7.1 Why ℓ deserves separate classification

The angular harmonic number ℓ is not a shell parameter in the same sense as χ_{amp} or r_{shell}, but it is a physical control parameter of the scattering problem. It determines the angular sector in which the shell is probed and enters the effective potentials through

$$\Lambda = \ell(\ell + 1). \qquad (7.1)$$

Since the Zerilli sector and scalar centrifugal structure both depend on Λ, it is natural to ask whether the avoided-crossing architecture found at $\ell = 2$ is an accident of the quadrupole channel or a universal feature of the FCLET shell system.

The result is clear: avoided crossing persists across multipoles.

7.2 Universality of avoided crossing

For all tested multipoles $\ell = 2,3,4,5$, the shell continues to exhibit the same fundamental two-branch structure:

branch approach,

nonzero minimum gap,

branch re-separation,

transparency dip associated with dominance reorganization.

Thus the mechanism itself is universal. The shell does not lose its avoided-crossing character when one moves to higher multipoles. What changes is the spectral scale on which that mechanism operates.

7.3 Gap growth with ℓ

A systematic ℓ-scan reveals that the avoided-crossing gap grows with multipole order. A compact way to express the trend is

$$\Delta\omega_{\min} \propto \Lambda = \ell(\ell + 1), \qquad (7.2)$$

at least approximately over the scanned range.

This is one of the strongest classification results in the entire taxonomy. It shows that ℓ does not generate a new mechanism. It scales the existing mechanism.

In morphology-space language, ℓ is a scale direction rather than a branch-selection or geometry-remapping direction.

7.4 Dip position versus ℓ

The dip location also shifts with multipole order:

$$\chi_{\text{dip}} \uparrow \text{as} \ell \uparrow. \qquad (7.3)$$

This means that higher multipoles require larger shell amplitude to reach the same degree of transparency suppression. Physically, this is natural: higher multipoles carry stronger angular

structure and therefore require stronger shell activation to reach comparable branch competition.

Thus ℓ affects both scale and dip threshold, but its most fundamental action remains the scaling of the spectral architecture.

7.5 Universality versus invariance

It is important to distinguish universality from invariance.

Universality means the same fundamental mechanism persists across ℓ.

Invariance would mean that the numerical values of the gap, dip, and branch locations remain unchanged across ℓ.

The FCLET shell system shows universality, not invariance. The mechanism is stable; the scale is not. This is exactly why the correct label is **universal spectral scale**.

7.6 Why ℓ is not merely another geometric parameter

Although ℓ enters the potentials, its role is different from r_{shell}. The shell radius changes the radial geometry of the coupling layer. The multipole number changes the angular spectral scale of the entire problem. Thus ℓ does not remap the shell geometrically. It rescales the spectral backbone on which the shell operates.

This is a distinct morphological direction.

7.7 Formal classification

The correct classification is therefore

$$\boxed{\ell = \text{universal spectral scale}}. \qquad (7.4)$$

This means:

avoided crossing persists across multipoles,

the branch gap scales with Λ,

the dip location shifts upward with ℓ,

and the mechanism remains the same while its spectral scale changes.

7.8 Section conclusion

The FCLET shell transparency mechanism is not quadrupole-specific. It is universal across the tested multipoles. The role of ℓ is to set the spectral scale of the avoided-crossing architecture, making it the universal spectral-scale parameter of the taxonomy.

8. Shell Width as Sharpness Modulator

8.1 Why width is not just another geometric parameter

The shell width controls how spatially localized the coupling layer is. At first glance one might therefore group it together with r_{shell} as another purely geometric parameter. That would miss its most distinctive effect. While r_{shell} primarily remaps where the shell sits, width primarily controls how sharply or diffusely the shell acts.

Thus width is not best classified as a remapper. It is best classified as a **sharpness modulator**.

8.2 Narrow versus broad shell logic

A narrow shell has a highly localized derivative support:

$$|\,\bar{\chi}'(r)\,| \text{ more concentrated around } r_{\mathrm{shell}}, \qquad (8.1)$$

whereas a broad shell spreads the coupling support over a larger radial region. This has several immediate spectral consequences:

the effective interaction layer may become sharper or more diffuse,

the branch approach may become narrower or broader in control-parameter space,

the transparency dip can deepen, broaden, or relocate.

Thus width changes not only the shell support but the **shape** of the resonance response.

8.3 Gap variation under width scan

One of the main results of the width scan is that the minimum gap changes significantly under width variation:

$$\Delta\omega_{\min}(\text{width}) \approx/\text{const.} \qquad (8.2)$$

In representative FCLET scans, the gap can vary by order tens of percent or more across the tested width range. This already distinguishes width sharply from σ_s, which leaves the gap nearly unchanged.

However, unlike r_{shell}, width does not simply shift the entire resonance architecture in one direction. Its action is more morphological: it changes the narrowness and local contrast of the dip.

8.4 Dip relocation and dip shape

The transparency-dip location

$$\chi_{\text{dip}}(\text{width}) \qquad (8.3)$$

also shifts under width variation. But the more distinctive result is that the dip's **shape** changes strongly:

narrow shells can produce sharper, more localized minima,

broader shells can produce wider or more irregular suppression regions.

Thus width modifies both the spectral gap and the morphology of the dip itself.

8.5 Sharpness measure

To formalize this, define a sharpness proxy

$$\mathcal{Q}_{\text{dip}} = \frac{D_{\text{dip}}}{\delta\chi_{\text{dip}}}, \qquad (8.4)$$

where D_{dip} measures the dip depth and $\delta\chi_{\text{dip}}$ measures the width of the dip in shell-amplitude space. Then width acts strongly on $\mathcal{Q}_{\text{dip}}$:

$$\mathcal{Q}_{\text{dip}}(\text{width})\text{changes substantially across the scan.} \qquad (8.5)$$

This is the defining signature of a sharpness modulator.

8.6 Why width is not just amplitude-only

A purely amplitude-only parameter would not strongly change the gap or the dip shape. Width does both. Therefore it is not reducible to amplitude scaling. Likewise, width does not act like χ_{amp}, which primarily moves branches, nor like μ, which closes the scalar channel kinematically.

Width acts most strongly on the local form of the transparency structure.

8.7 Physical interpretation

The shell width controls how abruptly the shell turns on and off in space. A narrow shell behaves like a sharply localized interaction layer. A broader shell behaves like a distributed conversion region. Since the avoided-crossing architecture depends on phase accumulation and effective coupling localization, the width naturally deforms the *shape* of the branch competition rather than merely its gross location.

This is why width is better understood as a morphology parameter than as a simple geometric position parameter.

8.8 Formal classification

The correct classification is therefore

$$\boxed{\text{width} = \text{sharpness modulator}}. \qquad (8.6)$$

This means:

it changes the depth and narrowness of transparency dips,

it modifies the minimum gap significantly,

it remaps dip position,

and its most distinctive action is on resonance sharpness.

8.9 Section conclusion

The shell width does not primarily move the shell in space, rescale its strength, or freeze the scalar channel. It changes how sharply the shell resonance architecture is expressed. It is therefore the sharpness modulator of FCLET shell transparency.

9. Unified Parameter Taxonomy

9.1 Why a unified taxonomy is necessary

The previous sections established that each FCLET shell parameter deforms a different aspect of the resonance structure. The next task is to synthesize these results into one classification scheme. This synthesis is not cosmetic. Without it, the shell program would remain a collection of disconnected scan results. With it, the shell response becomes structurally intelligible.

The decisive point is that the shell observables live in a multidimensional morphology space. The branches, the gap, the dip location, the dip sharpness, the scalar freeze threshold, and the

overall leakage amplitude are not all controlled by the same coordinate. Each parameter acts preferentially on one subset of these observables.

Thus the correct question is not: “Which parameter is the most important?”
The correct question is: “Which parameter controls which morphological direction?”

That question now has a complete answer.

9.2 The six classes

The six-parameter classification developed in this paper is:

χ_{amp} — spectral driver

μ — mass / freeze-out control

σ_s — amplitude-only control

r_{shell} — spectral-geometric remapper

ℓ — universal spectral scale

width — sharpness modulator

Each of these labels is justified by a distinct body of evidence, and each refers to a distinct deformation pattern of the resonance architecture.

9.3 Final taxonomy table

The classification can be summarized in compact form as follows.

Parameter	Class	Primary effect	Gap effect	Dip effect	Physical role
χ_{amp}	Spectral driver	Moves branches and controls avoided-crossing windows	strong	strong	organizes branch motion and dominance exchange
μ	Mass / freeze-out	Suppresses scalar channel kinematically	indirect	indirect	closes scalar propagation access
σ_s	Amplitude-only	Rescales shell coupling strength	weak / none	weak / none	changes magnitude of conversion only

Parameter	Class	Primary effect	Gap effect	Dip effect	Physical role
r_{shell}	Spectral-geometric remapper	Shifts resonance frequencies and shell geometry	strong	strong	remaps branch structure radially
ℓ	Universal spectral scale	Sets overall scale of avoided crossing	strong	moderate	rescales spectral architecture with Λ
width	Sharpness modulator	Changes dip depth, narrowness, and local morphology	strong	strong	controls localization of shell coupling

This table is the core structural result of the paper.

9.4 Orthogonality statement

The main conceptual synthesis is the following:

The six FCLET shell parameters do not compete redundantly; they act in orthogonal directions in resonance morphology space. (9.1)

This does not mean exact mathematical orthogonality in the linear-algebraic sense. It means functional orthogonality in phenomenological space:

one parameter mainly moves branches,

another mainly freezes a channel,

another mainly rescales amplitude,

another mainly remaps the shell geometry,

another mainly sets the spectral scale,

another mainly sharpens or broadens the morphology.

Thus the shell parameter space is structured rather than degenerate.

9.5 Why the one-parameter picture fails

The taxonomy immediately rules out any attempt to collapse FCLET shell transparency onto one effective shell-strength parameter. Such a collapse would imply that all observables—gap,

dip position, sharpness, freeze-out, and amplitude—are generated by different projections of the same underlying axis. The classification shows this is false.

A one-parameter picture fails because:

μ can suppress leakage without moving the avoided-crossing structure in the same way as χ_{amp},

σ_s can change signal amplitude without shifting the gap,

r_{shell} can remap resonance position even if amplitude remains comparable,

width can sharpen the dip without acting like either μ or σ_s,

ℓ can scale the whole architecture without eliminating the mechanism.

These are qualitatively different actions.

9.6 Taxonomy as resonance-geometry map

The best interpretation of the unified classification is that it defines a resonance-geometry map. Each parameter corresponds to a direction in the deformation space of the shell resonance architecture. In this language:

χ_{amp} is the main coordinate of branch steering,

μ is the channel-access coordinate,

σ_s is the amplitude axis,

r_{shell} is the radial-geometric coordinate,

ℓ is the scale axis,

and width is the localization/shape axis.

Thus the FCLET shell problem is naturally described not by one transparency curve, but by a structured geometry of coupled-resonance deformation.

9.7 Practical meaning of the taxonomy

The taxonomy matters for three reasons.

First, it organizes theory. It tells us which parameters are structurally comparable and which are not.

Second, it organizes phenomenology. A detected change in leakage amplitude should not automatically be interpreted as a change in shell geometry, and a shift in dip location should not automatically be interpreted as a change in quartic coupling. The classification protects against such misreadings.

Third, it organizes later inference. Any future attempt to infer FCLET shell properties from scattering data must respect the fact that different observables are controlled by different morphological directions.

9.8 Section conclusion

The FCLET shell parameter space is not an unstructured collection of knobs. It is a six-direction morphology space in which each parameter plays a distinct role. The resulting taxonomy is the central output of the paper.

10. Physical Interpretation

10.1 Why transparency is the wrong primitive concept

The word “transparency” is useful descriptively, but it is not the deepest language for the FCLET shell problem. If taken literally, it suggests a one-channel transmission picture in which the shell is more or less opaque depending on one effective strength. The taxonomy established here shows that this picture is inadequate.

The primitive physical object is not transparency. It is **resonance morphology**.

What we call shell transparency is one visible consequence of how a coupled two-branch resonance structure is deformed by the shell parameters.

10.2 The shell as a resonance-geometry system

The FCLET shell should therefore be understood as a resonance-geometry system. The shell is not just a place where interaction occurs. It is a localized spectral architecture whose observable behavior depends on:

where the resonance branches sit,

how widely they are separated,

how sharply they compete,

whether the scalar channel is open,

what scale the multipole sector imposes,

and how localized the coupling layer is.

This is why different parameters can change the shell response in sharply different ways even when they all “belong to the same shell.”

10.3 Gravitational–scalar conversion as geometry-dependent routing

The shell converts part of the incoming gravitational signal into scalar leakage. But this conversion is not controlled by one coupling coefficient alone. It is controlled by the geometry of the two-channel resonance system. That is why:

a larger χ_{amp} does not necessarily mean stronger leakage,

a wider shell does not necessarily mean a broader resonance in the same way that moving the shell outward does,

a larger quartic correction does not necessarily mean a shifted avoided crossing,

and a larger mass can suppress leakage without destroying the resonance mechanism itself.

These are all different modes of routing control in the shell architecture.

10.4 Why avoided crossing remains central

The taxonomy does not replace the avoided-crossing mechanism. It presupposes it. Avoided crossing remains the universal structural mechanism behind the transparency minima. What the taxonomy does is explain how different parameters deform that same mechanism.

Thus the correct layered interpretation is:

Paper I: what the shell system is, formally and numerically.

Paper II: what mechanism governs the transparency dips.

Paper III: how the resonance architecture is deformed by each parameter.

This layering is not arbitrary. It is the natural architecture of the research program.

10.5 Orthogonality as physical interpretability

The orthogonality statement has a deeper meaning than mere classification elegance. It means the FCLET shell parameter space is interpretable. If all parameters acted in mutually degenerate ways, the shell would be phenomenologically opaque even if the mathematics were correct. Because the parameters act in different morphological directions, the shell remains interpretable.

This is a major structural advantage of the FCLET shell framework. It means the model is not only rich but organized.

10.6 Resonance morphology as the right language for future work

The correct language for all future shell phenomenology is therefore the language of resonance morphology:

branch motion,

gap deformation,

dip remapping,

sharpness modulation,

scalar-channel freeze-out,

and multipole scaling.

This language is strictly richer and more precise than simply speaking of stronger or weaker transparency. It is also the language required for any later attempt at inverse inference or observational matching.

10.7 Section conclusion

The FCLET shell is best understood not as a one-parameter filter but as a structured resonance-geometry system. Transparency is one observable consequence of that geometry. The taxonomy developed in this paper is therefore not an accessory classification. It is the correct physical interpretation of how shell parameters act.

11. Discussion

11.1 Relation to Paper I

Paper I established the corrected two-channel full-branch shell system, the mandatory antisymmetric coupling structure, the conserved current, and the physically reliable observables $R_s(\omega)$, $T_{\Xi}(\omega)$, and $\phi_s(\omega)$. Without that formal closure, no trustworthy taxonomy would have been possible. The classification given here is therefore inseparable from the flux-restored full-branch framework.

11.2 Relation to Paper II

Paper II identified the fundamental transparency mechanism: avoided crossing in the coupled two-branch resonance structure. The present paper does not replace that result. It assumes it and extends it. What was previously established as the mechanism is now treated as the object whose deformation is to be classified.

Thus Paper II answered “why do the dips occur?”
Paper III answers “how do the parameters deform the dip mechanism?”

11.3 Why taxonomy matters before observation

At first sight, one might think that observational confrontation should come before taxonomy. In fact the opposite is true here. Without taxonomy, one would not know which observables constrain which parameters. Any attempted fit would collapse different morphological directions into one undifferentiated shell-strength parameter and would therefore risk systematic misinterpretation.

The taxonomy is therefore a prerequisite for meaningful observational work.

11.4 Scope and limits of the current analysis

The present paper remains within the parameter and model ranges already explored by the full-branch FCLET shell program. Several natural extensions remain:

broader scan ranges in $(\chi_{\mathrm{amp}}, \mu, \sigma_s, r_{\mathrm{shell}}, \ell, \mathrm{width})$,

more refined local tracking of branch structure in extreme corners of parameter space,

rotating backgrounds,

odd-parity sector generalization,

higher-mode coupling,

and direct observational-template construction.

These are important next steps, but they do not weaken the present result. The central taxonomy already holds in the scanned regime and is structurally clear.

11.5 Theoretical significance

Theoretically, the main significance of the taxonomy is that it shows the shell problem is neither over-parameterized nor degenerate. The parameters do not collapse into one effective coupling, and they also do not act chaotically. They organize into distinct morphological classes. This is exactly the sort of structure one wants in a physically meaningful shell model.

11.6 Phenomenological significance

Phenomenologically, the taxonomy provides a map from parameter change to observable deformation:

branch motion,

scalar suppression,

amplitude scaling,

radial remapping,

scale change,

and sharpness change.

This makes later phenomenological interpretation far more robust than if one only had raw scan plots.

11.7 Section conclusion

The parameter taxonomy established here is not merely descriptive. It is the structural bridge between the formal shell system and any later phenomenological or observational use of the FCLET shell program.

12. Conclusion

We have completed the parameter-taxonomy paper of the FCLET shell-scattering program. Building on the corrected full-branch two-channel system and on the avoided-crossing mechanism established previously, we have shown that FCLET shell transparency is not governed by a single effective coupling parameter. It is governed by a structured resonance morphology shaped by six distinct parameter directions.

The main classification result is:

FCLET shell transparency is governed by avoided crossing, but its observable morphology is controlled by six orthogonal parameter directions. (12.1)

Those directions are:

χ_{amp}: spectral driver,

μ: mass / freeze-out control,

σ_s: amplitude-only control,

r_{shell}: spectral-geometric remapper,

ℓ: universal spectral scale,

width: sharpness modulator.

Each parameter deforms a different aspect of the shell resonance architecture. This means the shell cannot be reduced to a one-parameter transparency model. It is a structured resonance-geometry problem.

This is the central physical message of the paper. The shell is not a passive filter, not a simple absorber, and not a monotonic converter. It is a localized two-channel resonance system whose morphology changes in distinct ways under distinct parameter variations.

The consequence is both theoretical and practical. Theoretically, the FCLET shell program now has a complete internal structure:

formal closure,

mechanism identification,

and parameter taxonomy.

Practically, later observational and phenomenological work now has the correct language in which to proceed. Parameters can be constrained by the morphological directions they control rather than by a crude one-parameter shell-strength proxy.

The present paper therefore closes a major stage of the FCLET shell program. The corrected shell system is known. The avoided-crossing mechanism is known. The deformation map of the resonance architecture is now known as well.

Paper III completes the resonance-morphology foundation of FCLET shell transparency.

Appendix A. Baseline Parameters and Numerical Conventions

The reference shell configuration used throughout the full-branch FCLET shell program is centered on a Schwarzschild exterior with

$$M = 1 \qquad \text{(A.1)}$$

in geometrized units. Unless otherwise specified, the baseline choice is

$$\ell = 2, r_{\text{shell}} = 5M, \text{width} = 1.5M, \mu = 0, \sigma_s = 0. \qquad \text{(A.2)}$$

The shell amplitude χ_{amp} is the primary scan coordinate in the avoided-crossing studies, while the remaining parameters are varied one at a time for taxonomy construction.

The transfer system is propagated between an inner radius $r_{\text{in}} > 2M$ and an outer radius $r_{\text{out}} \gg r_{\text{shell}}$, using QR-renormalized segmented propagation to avoid basis collapse. Frequency scans are performed over the shell-active window and extended as needed to determine maxima, gaps, and suppression thresholds.

Appendix B. Definitions of Morphology Diagnostics

The central morphology diagnostics used in this paper are:

Branch frequencies

$$\omega_1, \omega_2 \qquad \text{(B.1)}$$

Minimum gap

$$\Delta\omega_{\min} = \min_{\chi} \mid \omega_2 - \omega_1 \mid \qquad \text{(B.2)}$$

Dip location

$$\chi_{\mathrm{dip}} = \arg\min_{\chi} \left[\max_{\omega \in W_\omega} \mathcal{F}_\Xi(\omega; \chi) \right] \qquad \text{(B.3)}$$

Suppression ratio

$$\mathcal{S}_{\mathrm{sup}}(p) = \frac{\max_{\omega} \mathcal{F}_\Xi(\omega; p)}{\max_{\omega} \mathcal{F}_\Xi(\omega; p_{\mathrm{ref}})} \qquad \text{(B.4)}$$

Sharpness proxy

$$\mathcal{Q}_{\mathrm{dip}} = \frac{D_{\mathrm{dip}}}{\delta\chi_{\mathrm{dip}}} \qquad \text{(B.5)}$$

Effective freeze threshold

$$\max_{\omega \in W_\omega} \mathcal{F}_\Xi(\omega; \mu_c^{\mathrm{eff}}) = \varepsilon. \qquad \text{(B.6)}$$

These quantities together define the resonance morphology space used for classification.

Appendix C. Supplemental Scan Logic

Each scan is performed by varying one parameter while holding the others at baseline values. The logic is therefore one of structural attribution rather than global multidimensional fitting. This choice is deliberate: the purpose of the paper is classification, not full high-dimensional inference.

The main scan families are:

χ_{amp}-scan for branch motion and transparency dips,

μ-scan for freeze-out,

σ_s-scan for amplitude-only behavior,

r_{shell}-scan for geometric remapping,

ℓ-scan for universality and scale,

width scan for sharpness modulation.

These scans are sufficient to isolate the leading morphological role of each parameter.

Appendix D. Stability and Robustness Checks

The parameter classifications reported here are robust under:

moderate changes in outer boundary,

resolution refinement,

segmented propagation refinement,

and condition-number monitoring under QR renormalization.

In particular:

the avoided-crossing architecture persists,

the qualitative taxonomy assignments remain unchanged,

and the distinctions between spectral, amplitude-only, freeze-out, scale, and sharpness roles are stable.

Thus the taxonomy is not a numerical artifact of one particular scan configuration.

Covariant Saturation Surface, Stationary Rotating Background Latency Dynamics, Teukolsky–GSN Projection, Superradiant Stability, and Spin-Dependent Spectral Observables in the Finite-Capacity Latency–Erasure Theory

Ali Caner Yücel

Abstract

We extend the finite-capacity latency–erasure theory to rotating compact remnants by constructing the Kerr-sector shell theory in a mathematically controlled form. Earlier FCLET work completed the non-rotating strong-field branch: the saturation-shell onset was fixed internally, the shell location and echo-delay scale were derived, odd-parity perturbations were constructed, and the shell reflectivity spectrum was obtained through numerical spectroscopy. What remained open was the astrophysically decisive step. Gravitational-wave remnants are rotating compact objects, and any shell sector confined to Schwarzschild backgrounds remains structurally disconnected from the observational ringdown problem.

In this paper we build the Kerr extension of the FCLET shell theory through four coupled tasks. First, the Schwarzschild shell radius is generalized to a covariant saturation surface, yielding an axisymmetric shell profile. The threshold condition is re-derived on the rotating background from the local burden-balance structure itself rather than imported by analogy, and its leading universality is shown to admit controlled spin-dependent corrections. Second, the latency field is extended from a purely radial Schwarzschild profile to a stationary axisymmetric rotating-background field through a lapse–shift–drag decomposition. In the Kerr sector, the FCLET burden couples not only to the lapse structure but also to the frame-dragging channel, so that the effective background deformation acts simultaneously on lapse, shift, and shell geometry. Third, the linearized metric–latency system is projected to the Teukolsky/Generalized Sasaki–Nakamura channel. The FCLET modification is decomposed into three distinct sectors—background deformation, effective source structure, and shell boundary data—and each sector is carried through separately in the perturbation problem. Exact separability is treated as a special admissible branch rather than assumed generically, while the non-separable regime is handled through a controlled slow-rotation branch with perturbative angular mixing. Fourth, the physical admissibility of the rotating shell sector is constrained by superradiant consistency and ergoregion stability. The paper identifies the stability corridor in which shell reflectivity, frame-dragging deformation, and cavity amplification remain compatible with a spectroscopically viable Kerr-sector solution.

The main outputs are the detector-facing FCLET spectral observables in the rotating sector: the quasi-normal mode shift $\delta\omega_{\ell mn}(a)$, the geometric and mode-projected echo-delay families, the excitation branching coefficients $\mathcal{B}_{\ell mn}(a)$, and the ringdown damping correction

derived from the full complex mode spectrum. These quantities supply the mathematical infrastructure required for the injection–recovery program of the next stage and for event-level confrontation with rotating compact-remnant data. The Schwarzschild shell sector is recovered in the $a \to 0$ limit, the standard Kerr–Teukolsky system is recovered in the $\chi \to 0$ limit, and the admissible Kerr FCLET branch is isolated explicitly from the non-separable or superradiantly unstable regime. The result is not a rotating extension by analogy, but the first controlled Kerr-sector perturbative foundation of the FCLET shell program.

In addition, the paper reports the first stabilized numerical benchmark of the Schwarzschild FCLET shell spectrum: a two-segment continuation analysis in the (ϵ, Λ_s) plane produces explicit, publication-grade real-frequency shifts of approximately $+2.6\%$ and $+0.23\%$ for the $(\ell, n) = (2,0)$ and $(3, 0)$ fundamental modes, establishing the numerical zero-spin anchor for the rotating spectral program.

Keywords: Kerr compact objects; FCLET shell theory; covariant saturation surface; rotating latency background; frame dragging; Teukolsky formalism; generalized Sasaki–Nakamura transformation; superradiant stability; quasi-normal modes; echo delay; excitation hierarchy; strong-field spectroscopy

1. Introduction and Strategic Context

The finite-capacity latency–erasure theory has already established a non-rotating strong-field shell sector. In that sector, compact gravitational collapse does not terminate in a featureless classical horizon. Instead, the local informational burden approaches a finite-capacity threshold, the latency field sharply increases, and the interior approach to horizon formation is replaced by a saturation-shell regime. That regime was not introduced phenomenologically. It emerged from the internal logic of the finite-capacity program: bounded processing capacity, overwrite-driven burden accumulation, and the dynamical conversion of burden into local latency.

That achievement completed the Schwarzschild branch of the strong-field program. It did not complete the observational strong-field program.

The decisive observational boundary is rotation. Astrophysical compact remnants formed in dynamical mergers are not Schwarzschild objects. They are rotating remnants, and the ringdown problem is therefore a Kerr-sector problem. A shell theory restricted to non-rotating backgrounds remains mathematically incomplete at the precise point where gravitational-wave spectroscopy becomes decisive. That incompleteness is not cosmetic. It is structural. The ringdown spectrum, mode excitation hierarchy, late-time scattering channels, and any echo-like timing structure all depend directly on the rotating geometry. A strong-field theory that aims to confront post-merger data must therefore construct its shell sector on a rotating background and must do so in the native perturbative language of that background.

That is the purpose of the present paper.

The aim here is not merely to add spin to an existing non-rotating shell picture. Such a move would be mathematically inadequate. Rotation changes the geometry in a way that directly entangles time flow and angular flow through the frame-dragging channel. The shell can no longer be treated as a single radius r_s. The latency field can no longer be treated as a purely radial scalar profile $\chi(r)$. The perturbation problem can no longer be reduced by naive analogy to a Schwarzschild-style single-channel radial equation. Each of these failures is decisive. Each must be repaired at the level of structure, not rhetoric.

The Kerr extension of the FCLET shell theory therefore requires four foundational advances.

First, the saturation threshold must be rewritten as a covariant condition on a rotating background. In Schwarzschild geometry, the shell onset was represented by a single critical radius. In Kerr geometry, the correct object is a saturation surface defined by

$$\mathcal{F}(r, \theta; a) = 0,$$

with a spin-dependent and angle-dependent profile

$$r_s(\theta; a).$$

The shell is therefore a surface, not a point in the radial coordinate.

Second, the latency field must be promoted from a radial profile to a stationary axisymmetric burden field. In Kerr geometry, the burden is not encoded only in local redshift. It is also encoded in frame dragging. The rotating FCLET sector must therefore deform lapse, shift, and shell geometry together. A purely radial $\chi(r)$ is not only incomplete. It is inconsistent with rotating burden closure.

Third, the shell sector must be projected into the correct perturbative language. For Kerr backgrounds, that language is the Teukolsky sector and its generalized Sasaki–Nakamura reformulation. The FCLET correction must therefore be expressed not as a vague deformation of the spectrum, but as a mathematically controlled contribution to three distinct structures:

background deformation,effective source structure,shell boundary data.

Only then does the shell program enter the rotating perturbation problem in a form that can support later numerical and observational confrontation.

Fourth, the rotating shell sector must be constrained by physical admissibility. The coexistence of rotation and partial reflectivity creates an immediate superradiant stability problem. Not every rotating shell is viable. The physically relevant sector is the one that survives explicit restriction by superradiant consistency, ergoregion stability, and controlled angular-mode mixing.

The present paper executes these four tasks.

The result is a Kerr-sector perturbative foundation for the FCLET shell program. It does not yet perform injection–recovery analyses and does not yet carry out event-level confrontation. Those are subsequent steps. What it does provide is the indispensable mathematical infrastructure without which those later steps would remain formally unjustified. This paper therefore marks the transition from the Schwarzschild shell program to the observationally relevant Kerr shell program.

2. The Schwarzschild Shell Program and the Kerr Observational Boundary

The non-rotating shell program established three core results.

The first result was the internal fixation of shell onset. The shell was not introduced by external boundary stipulation. It emerged from the burden dynamics themselves. The local informational load fraction approached a critical threshold, the accessible residual capacity collapsed, and the effective latency response diverged in a controlled manner before the classical horizon limit was reached. In operational form, this produced a shell onset condition tied to a critical burden fraction, rather than to an arbitrary inserted membrane.

The second result was the perturbative establishment of shell spectroscopy on the non-rotating background. In that regime, the FCLET shell acted as a partially reflecting strong-field structure. The odd-parity sector admitted a well-defined perturbation problem, and the resulting reflection/transmission structure generated a calculable spectral response. This converted the shell concept from a conceptual strong-field statement into a dynamical and spectroscopic one.

The third result was the emergence of detector-facing non-rotating observables. The shell location determined the cavity scale, the cavity scale controlled the echo timing, and the reflectivity profile controlled how strongly the shell sector fed back into the ringdown channel. The shell thus became a predictive object rather than a merely ontological one.

These results completed the Schwarzschild strong-field branch.

But the observational boundary sits beyond Schwarzschild. The post-merger remnant in compact-binary coalescence is generically rotating. Rotation is not a small correction appended to an otherwise completed shell theory. It changes the basic structure of the problem in four ways.

First, the geometry is no longer spherically symmetric. The shell onset condition therefore cannot remain a single-radius statement. Even the background definition of the shell must be reconstructed.

Second, the field responsible for the burden response can no longer be a radial scalar profile alone. The rotating geometry mixes temporal and azimuthal flow through $g_{t\phi}$. Any burden field that ignores this coupling misses the central kinematic feature of the background.

Third, the perturbation problem is no longer naturally expressed in a Schwarzschild-type one-dimensional radial-potential language. In the Kerr problem, the correct perturbative sector is

built from the Teukolsky formalism and its generalized Sasaki–Nakamura reduction. The FCLET correction must therefore be translated into that language.

Fourth, rotation introduces superradiant structure. A partially reflecting surface in a rotating spacetime creates the possibility of cavity amplification. Therefore the shell cannot be declared viable merely because it exists geometrically. It must also be shown to reside in a dynamically admissible regime.

The boundary between the completed Schwarzschild program and the present Kerr extension is therefore sharp.

The Schwarzschild shell program answered the question: Can a finite-capacity theory generate a strong-field shell and give it a perturbative spectrum?

The present Kerr paper answers the next question: Can that shell be defined, perturbed, and spectroscopically constrained on the rotating background that is relevant for gravitational-wave remnants?

This transition also clarifies the role of the present article within the broader FCLET program. It is not an observational paper in the narrow sense. It does not yet fit templates to data. Instead, it determines the mathematical observables that later observational work will carry forward. In that sense, the present paper is the rotating strong-field closure paper: the article that makes later data confrontation formally legitimate.

3. Kerr Background and FCLET Burden Structure

3.1 Boyer–Lindquist coordinates and FCLET field equations

We begin from the Kerr geometry in Boyer–Lindquist coordinates (t, r, θ, ϕ), with mass parameter M and specific angular momentum a. Define

$$\Delta = r^2 - 2Mr + a^2$$

and

$$\Sigma = r^2 + a^2\cos^2\theta.$$

The Kerr line element is

$$ds^2 = -\left(1-\frac{2Mr}{\Sigma}\right)dt^2 - \frac{4Mar\sin^2\theta}{\Sigma}\,dt\,d\phi + \frac{\Sigma}{\Delta}dr^2 + \Sigma\,d\theta^2 + \frac{\sin^2\theta}{\Sigma}[(r^2+a^2)^2 - a^2\Delta\sin^2\theta]d\phi^2.$$

For the rotating FCLET sector, the natural starting point is the decomposition

$$g_{\mu\nu} = \bar{g}^{\mathrm{Kerr}}_{\mu\nu} + \delta g^{\mathrm{FCLET}}_{\mu\nu},$$

with

$$\delta g_{\mu\nu}^{\mathrm{FCLET}} = \delta g_{\mu\nu}^{(\chi)} + \delta g_{\mu\nu}^{(\Gamma_{\mathrm{ov}})} + \delta g_{\mu\nu}^{(I)},$$

and

$$\chi = \bar{\chi}(r,\theta) + \delta\chi.$$

The finite-capacity sector is described by a latency field χ together with a burden variable I that measures the fraction of locally accessible informational capacity that is already occupied by effective load. The strong-field sector is controlled by the approach of I to a critical value I_{crit}. The latency field is the dynamical mediator of this approach.

A minimal rotating FCLET action can be written schematically as

$$S_{\mathrm{FCLET}} = \int d^4x \sqrt{-g}\left[\frac{R}{16\pi G} - \frac{1}{2}K(\chi)(\nabla\chi)^2 - V(\chi) - \mathcal{U}(I,\chi,\Gamma_{\mathrm{ov}})\right],$$

where $K(\chi)$ is the kinetic structure of the latency field, $V(\chi)$ is its self-potential, and $\mathcal{U}$ is the coupling term that links local burden to latency growth. The precise microphysical completion of $\mathcal{U}$ may vary across branches of the theory, but the strong-field shell program depends only on three universal features:

- I increases monotonically with local strong-field burden,
- the low-burden regime reproduces the weak-field branch,
- a finite-capacity saturation regime emerges when the accessible residual capacity becomes comparable to the occupied burden.

The field equations obtained from this action may be written schematically as

$$G_{\mu\nu} = 8\pi G\left(T_{\mu\nu}^{(\chi)} + T_{\mu\nu}^{(\mathrm{ov})} + T_{\mu\nu}^{(I)}\right),$$

together with the latency equation

$$\nabla_\mu(K(\chi)\nabla^\mu\chi) - \frac{1}{2}K_{,\chi}(\nabla\chi)^2 - V_{,\chi} = \mathcal{S}_I.$$

On a rotating background, the essential change is not merely that $\chi \neq \chi(r)$. The essential change is that the background admits a nontrivial shift vector and therefore a nontrivial frame-dragging channel. The latency field must therefore enter the rotating background in a way that can deform not only the lapse structure but also the effective dragging structure and the shell-surface geometry. That is the decisive difference from the Schwarzschild branch.

3.2 Burden variable on a rotating background

In the non-rotating branch, the local burden fraction was effectively radial because the background itself was radially symmetric. In Kerr geometry, that is no longer true. The local accessible capacity and the local burden source both inherit axial structure. Consequently, the correct burden variable is

$$I = I(r, \theta; a),$$

not $I(r)$, and certainly not $I = \text{const}$.

At the structural level, I is the ratio

$$I(r, \theta; a) = \frac{\rho_{\text{bur}}(r, \theta; a)}{\rho_{\text{cap}}(r, \theta; a)},$$

where ρ_{bur} denotes the effective local burden density and ρ_{cap} denotes the locally accessible capacity density. In the rotating sector, ρ_{bur} receives contributions from multiple sources. A generic decomposition is

$$\rho_{\text{bur}} = \rho_{\text{m}} + \rho_{\chi} + \rho_{\text{rot}} + \rho_{\text{mem}} + \rho_{\text{ov}},$$

where ρ_{m} is the matter-associated component, ρ_{χ} is the latency-gradient burden, ρ_{rot} is the rotation-induced burden arising from frame-dragging and angular-flow structure, ρ_{mem} is the finite-memory contribution, and ρ_{ov} is the overwrite/erasure component.

The key point is not the detailed partition. The key point is that the rotating background forces angular differentiation among these contributions. The equatorial and polar sectors are no longer burden-equivalent. The redshift profile, frame-dragging strength, and effective accessible capacity differ with θ. Consequently, the shell onset condition must inherit a genuine angular structure.

For later use, it is convenient to expand the burden variable in even powers of the dimensionless spin parameter a/M:

$$I(r, \theta; a) = I_0(r) + \left(\frac{a}{M}\right)^2 I_2(r, \theta) + O(a^4).$$

However, once the burden variable is interpreted as a scalar threshold quantity attached to a stationary axisymmetric background, the physically relevant shell-threshold branch will prove even under $a \to -a$ at leading order. This means that the shell-threshold structure and shell-location deformation begin effectively at a^2 in the scalar sector, while odd-in-a information appears in dragging-sensitive observables and mode-dependent perturbative channels. This distinction is central and will be made explicit below.

The burden variable therefore carries two layers of spin dependence. The first is the scalar deformation of the shell-generating load profile, which begins at even spin order. The second is the directional and mode-sensitive dragging structure, which enters the perturbative observables through the full rotating dynamics.

3.3 Why $\chi(r)$ is insufficient: frame dragging, axial structure, and stationary closure

A purely radial latency field,

$$\chi = \chi(r),$$

is consistent with Schwarzschild symmetry. It is not consistent with the burden-closure problem on a rotating background.

The reason is direct. In Kerr geometry, the background itself distinguishes angular sectors through Σ, Δ, and $g_{t\phi}$. The frame-dragging channel vanishes on the symmetry axis and is maximal in the equatorial sector. Any burden response that couples to the rotating background must therefore inherit this anisotropy. If the shell-generating field were purely radial, then the burden-to-latency mapping would fail to represent the angular differentiation of the rotating accessible-capacity structure. The result would be a mismatch between the scalar sector and the dragging sector: the field would attempt to describe a rotating saturation problem with a non-rotating burden response.

This is not a small quantitative error. It is a structural inconsistency.

The correct closure class is therefore stationary and axisymmetric:

$$\bar{\chi} = \bar{\chi}(r, \theta; a).$$

Because the scalar shell sector is even under orientation reversal at leading threshold order, the natural small-spin expansion is

$$\bar{\chi}(r, \theta; a) = \chi_0(r) + \left(\frac{a}{M}\right)^2 \chi_2(r, \theta) + O(a^4),$$

with the first anisotropic contribution typically decomposed into Legendre sectors,

$$\chi_2(r, \theta) = \chi_{20}(r) + \chi_{22}(r) P_2(\cos\theta).$$

This structure expresses a basic fact: the rotating shell is not generated by adding a small azimuthal correction to a radial Schwarzschild latency field. It is generated by solving a stationary axisymmetric closure problem in which the shell geometry and the latency profile deform together.

In practical terms, a purely radial $\chi(r)$ fails for three reasons.

First, it cannot support an angle-dependent saturation surface because the field sourcing the surface lacks the angular structure needed to generate it.

Second, it cannot consistently deform the shift sector. Since the shift is sensitive to frame dragging, any FCLET deformation of the dragging channel must be sensitive to the same angular structure that distinguishes equatorial and polar burden accumulation.

Third, it cannot furnish a correct perturbative reduction. Once the shell boundary itself is angle-dependent, the perturbation problem necessarily knows about that angular structure. A radial-only background field would therefore produce an inconsistent boundary reduction.

The correct background FCLET shell solution is therefore the pair

$$\left(\bar{g}_{\mu\nu}(r,\theta;a),\, \bar{\chi}(r,\theta;a)\right)$$

solved jointly in the stationary axisymmetric sector.

This point is foundational. The Kerr extension does not begin by perturbing a radial shell. It begins by replacing the radial shell concept with a rotating saturation-surface concept.

4. Covariant Saturation Surface on the Kerr Background

4.1 From a shell radius to a shell surface

In the Schwarzschild branch of the FCLET shell program, the strong-field saturation threshold was represented by a shell radius r_s. That representation is exact only because the underlying background is spherically symmetric. Once the background is Kerr, the shell can no longer be described by a single radial coordinate. The threshold object must instead be promoted to a covariant saturation surface,

$$\mathcal{F}(r,\theta;a) = 0,$$

with associated geometric profile

$$r_s(\theta;a).$$

This replacement is not cosmetic. It is the first structural mark of the rotating strong-field regime. The shell is no longer a uniform radial wall. It is an axisymmetric threshold surface whose geometry is determined by the angular dependence of the burden variable and the rotating accessible-capacity structure.

4.2 Threshold condition and local burden balance

Let the shell onset be defined by the saturation condition

$$I(r,\theta;a) = I_{\mathrm{crit}}(a,\theta),$$

or equivalently by the vanishing of a shell functional

$$\mathcal{F}(r,\theta;a) \equiv I(r,\theta;a) - I_{\mathrm{crit}}(a,\theta).$$

At the structural level, the threshold remains anchored to the same finite-capacity balance principle as in the non-rotating branch. The leading scalar threshold is therefore not free to drift arbitrarily with spin. It must reduce continuously to the Schwarzschild shell condition in the $a \to 0$ limit. This means that the spin dependence of the threshold surface is organized, not arbitrary.

For the scalar shell-generating branch, symmetry requires that the leading deformation begin at even order in the spin parameter. The natural expansion is

$$r_s(\theta;a) = r_s^{(0)} + \left(\frac{a}{M}\right)^2 r_s^{(2)}(\theta) + O(a^4),$$

with

$$r_s^{(2)}(\theta) = r_{20} + r_{22}P_2(\cos\theta)$$

as the leading axisymmetric deformation. The first term shifts the overall shell position, while the second encodes polar–equatorial shape deformation.

4.3 Effective burden sources on the saturation surface

The shell surface is sourced by the same burden sectors that define the rotating FCLET background, but now evaluated at threshold. Write

$$I(r,\theta;a) = \frac{\rho_{\mathrm{m}} + \rho_{\chi} + \rho_{\mathrm{rot}} + \rho_{\mathrm{mem}} + \rho_{\mathrm{ov}}}{\rho_{\mathrm{cap}}},$$

so that the surface equation takes the form

$$\frac{\rho_{\mathrm{m}} + \rho_{\chi} + \rho_{\mathrm{rot}} + \rho_{\mathrm{mem}} + \rho_{\mathrm{ov}}}{\rho_{\mathrm{cap}}} - I_{\mathrm{crit}} = 0.$$

The crucial rotating correction is ρ_{rot}, which encodes the burden associated with frame dragging and stationary angular transport. This term vanishes in Schwarzschild geometry and therefore has no analogue in the non-rotating shell radius derivation. It is precisely this term that drives the leading angular deformation of the shell in the Kerr sector.

4.4 Geometric interpretation

The saturation surface should be understood as the locus on which the local effective continuation load saturates the accessible capacity budget. Because the accessible budget itself is deformed by the rotating geometry, the shell surface generally differs between equatorial and polar sectors. In qualitative terms, one expects the shell to be displaced differently in the angular sectors where frame dragging is strongest and weakest.

This means that the shell is not a rigid membrane inserted into Kerr spacetime. It is a dynamical threshold geometry generated by the rotating burden law itself.

4.5 Small-spin threshold equation

For later perturbative use, it is convenient to write the threshold equation explicitly to second order in spin:

$$\mathcal{F}(r,\theta;a) = \mathcal{F}_0(r) + \left(\frac{a}{M}\right)^2 \mathcal{F}_2(r,\theta) + O(a^4).$$

If $r_s^{(0)}$ solves

$$\mathcal{F}_0(r_s^{(0)}) = 0,$$

then the leading rotating shell deformation satisfies

$$r_s^{(2)}(\theta) = -\frac{\mathcal{F}_2(r_s^{(0)},\theta)}{\partial_r \mathcal{F}_0(r_s^{(0)})}.$$

This equation is structurally important. It shows that the rotating shell geometry is not postulated. It is derived from the perturbative deformation of the same saturation functional that generated the Schwarzschild shell.

4.6 Surface regularity and admissibility

Not every formal solution of $\mathcal{F} = 0$ defines a physically admissible shell surface. The admissible branch must satisfy at least the following conditions:

smooth axisymmetric closure,

no self-intersection,

continuity to the Schwarzschild surface as $a \to 0$,

compatibility with the later perturbative boundary formulation.

These requirements eliminate pathological branches in which the shell geometry may exist algebraically but cannot support a meaningful perturbation problem.

4.7 Covariant-shell theorem

The first theorem of the Kerr FCLET shell extension is therefore geometric.

Theorem 4.1 (Covariant Saturation-Surface Theorem).
On a rotating background, the FCLET shell is defined not by a single radius but by a covariant axisymmetric saturation surface

$$\mathcal{F}(r, \theta; a) = 0,$$

whose leading scalar deformation relative to Schwarzschild begins at even order in the spin parameter. The Kerr shell is therefore a derived threshold geometry rather than an inserted rotating membrane.

5. Stationary Rotating Background Latency Dynamics

5.1 Lapse–shift–drag decomposition

Once the shell becomes a surface rather than a radius, the latency field must be upgraded accordingly. In the rotating sector, the correct FCLET background language is not redshift-only but lapse–shift–drag.

Write the stationary axisymmetric metric in $3 + 1$ form:

$$ds^2 = -\alpha^2 dt^2 + \gamma_{ij}(dx^i + \beta^i dt)(dx^j + \beta^j dt),$$

where α is the lapse, β^i is the shift, and γ_{ij} is the spatial metric. In Kerr geometry, the shift contains the frame-dragging channel through the azimuthal component

$$\beta^\phi \neq 0.$$

The FCLET background must therefore be expressed as a coupled deformation

$$\alpha \to \alpha_{\mathrm{Kerr}} + \delta\alpha_{\mathrm{FCLET}}, \beta^\phi \to \beta^\phi_{\mathrm{Kerr}} + \delta\beta^\phi_{\mathrm{FCLET}}, \gamma_{ij} \to \gamma_{ij}^{\mathrm{Kerr}} + \delta\gamma_{ij}^{\mathrm{FCLET}},$$

driven by the latency field and its burden source.

5.2 Stationary axisymmetric latency field

The correct background latency configuration is

$$\bar{\chi} = \bar{\chi}(r, \theta; a),$$

with small-spin expansion

$$\bar{\chi}(r, \theta; a) = \chi_0(r) + \left(\frac{a}{M}\right)^2 \chi_2(r, \theta) + O(a^4).$$

The absence of an odd-in-a term in the scalar threshold sector reflects the fact that the shell-generating scalar burden is insensitive to orientation reversal at leading order. However, odd-in-a information reappears in dragging-sensitive observables and in mode-dependent perturbation structure. The background scalar field and the detector-facing observables therefore do not organize their spin dependence in the same way.

5.3 Effective FCLET background equations

The rotating background FCLET equations may be expressed schematically as a coupled stationary system:

$$\begin{aligned}
&\mathcal{E}_\alpha[\alpha, \beta^\phi, \gamma_{ij}, \chi] = 0, \\
&\mathcal{E}_\beta[\alpha, \beta^\phi, \gamma_{ij}, \chi] = 0, \\
&\mathcal{E}_\gamma[\alpha, \beta^\phi, \gamma_{ij}, \chi] = 0, \\
&\mathcal{E}_\chi[\alpha, \beta^\phi, \gamma_{ij}, \chi; I, \Gamma_{\mathrm{ov}}] = 0.
\end{aligned}$$

In practical use, the background is treated perturbatively around Kerr:

$$\alpha = \alpha_0 + \delta\alpha, \beta^\phi = \beta_0^\phi + \delta\beta^\phi, \chi = \chi_0 + \delta\chi,$$

and the field equations are linearized or quasi-linearized in the FCLET sector.

What matters structurally is not the exact coefficient set here, but the three-channel deformation principle:

lapse deformation,

shift deformation,

shell-surface deformation

must be solved together.

5.4 Why redshift-only deformation fails

A redshift-only rotating FCLET ansatz would deform α but leave β^{ϕ} structurally untouched. That would immediately fail for two reasons.

First, it would ignore the burden associated with rotational transport.
Second, it would fail to provide a consistent background for perturbations in which azimuthal dragging directly enters the mode structure.

The rotating shell therefore lives in a background that is not only deeper or shallower in the redshift sense, but differently organized in the dragging sense.

5.5 Background-drag coupling

The FCLET dragging correction may be represented schematically as

$$\delta\beta^{\phi}_{\mathrm{FCLET}} = \mathcal{D}_{\phi}[\bar{\chi}, I, \Gamma_{\mathrm{ov}}],$$

where $\mathcal{D}_{\phi}$ is the dragging response functional of the theory. This functional need not be known in closed microphysical form for the present paper. The paper needs only the following facts:

it vanishes in the FCLET-off limit,

it vanishes in the non-rotating limit,

it contributes to the perturbative mode structure in the rotating shell sector.

That is enough to carry it consistently into the Teukolsky/GSN projection.

5.6 Rotating-background theorem

Theorem 5.1 (Stationary Rotating Latency Theorem).
The Kerr-sector FCLET shell cannot be supported by a purely radial latency profile. The correct background is a stationary axisymmetric latency configuration that deforms lapse, shift, and shell geometry simultaneously. Rotation therefore enters the FCLET shell program through a genuine lapse–shift–drag background rather than through a redshift-only generalization of the Schwarzschild branch.

6. Projection to the Teukolsky–GSN Channel

6.1 Why the Kerr shell problem must be projected into Teukolsky language

The rotating shell problem becomes observationally meaningful only when it is expressed in the perturbative language native to Kerr geometry. That language is not the Regge–

Wheeler/Zerilli system. It is the Teukolsky formalism and its generalized Sasaki–Nakamura reduction.

The central perturbative task is therefore to identify how the FCLET shell sector enters the rotating wave equation.

6.2 Three-part FCLET decomposition

The FCLET correction to the Kerr perturbation problem must be decomposed into three parts:

$$\delta\mathcal{O}_{\mathrm{FCLET}} = \delta\mathcal{O}_{\mathrm{bg}} + \delta\mathcal{O}_{\mathrm{src}} + \delta\mathcal{O}_{\mathrm{bdry}}.$$

Here:

$\delta\mathcal{O}_{\mathrm{bg}}$ is the background deformation contribution,

$\delta\mathcal{O}_{\mathrm{src}}$ is the effective source contribution from the latency sector,

$\delta\mathcal{O}_{\mathrm{bdry}}$ is the shell boundary contribution.

This decomposition is indispensable. Without it, one cannot distinguish a change in the bulk wave operator from a change in the shell matching condition.

6.3 Modified Teukolsky equation

Let Ψ_s denote the spin-s Teukolsky variable. The FCLET-modified Kerr perturbation problem may be written schematically as

$$\left(\mathcal{T}_{\mathrm{Kerr}}+\delta\mathcal{T}_{\mathrm{bg}}+\delta\mathcal{T}_{\mathrm{src}}\right)\Psi_s = 0$$

in the bulk, with shell boundary data imposed separately.

In the exact separable branch, the operator can still be written in a separated radial-angular form, and the FCLET corrections appear as perturbative deformations of the radial and angular operators.

In the generic branch, exact separability fails, and the correct treatment is a slow-rotation, weak-mixing expansion.

6.4 Generalized Sasaki–Nakamura projection

For detector-facing spectral work, the most useful reduction is to a generalized Sasaki–Nakamura variable X, satisfying a radial equation of the form

$$\frac{d^2X}{dr_*^2} + [\omega^2 - V_{\mathrm{GSN}}(r; a, \omega, \ell, m) - \delta V_{\mathrm{FCLET}}(r, \theta; a, \omega, \ell, m)]X = 0,$$

subject to modified shell boundary conditions.

The FCLET potential correction itself splits:

$$\delta V_{\mathrm{FCLET}} = \delta V_{\mathrm{bg}} + \delta V_{\mathrm{src}} + \delta V_{\mathrm{mix}},$$

where the first term arises from the deformed stationary background, the second from the effective source structure of the latency sector, and the third from non-separable angular mixing in the perturbative branch.

6.5 Shell boundary operator in GSN language

The shell sector is represented by a boundary operator

$$\mathbb{B}_{\mathrm{shell}}(a, \omega, \ell, m),$$

which relates the ingoing and outgoing amplitudes of the GSN variable at the rotating saturation surface. In the exact separable branch, $\mathbb{B}_{\mathrm{shell}}$ is diagonal in the modal indices. In the slow-rotation mixed branch, it acquires controlled off-diagonal structure:

$$\mathbb{B}_{\mathrm{shell}} = \mathbb{B}^{(0)} + \left(\frac{a}{M}\right)\mathbb{B}^{(1)} + \left(\frac{a}{M}\right)^2 \mathbb{B}^{(2)} + \cdots .$$

This boundary matrix is one of the main objects exported to the next paper. It is the mathematical route by which Kerr FCLET shell structure enters detector-facing spectroscopy.

6.6 Exact separability versus perturbative mixing

The paper must distinguish two cases sharply.

Case I: separable-admissible branch.
Here the FCLET deformation is mild enough that the rotating perturbation problem remains effectively separable. This is the cleanest analytic branch.

Case II: perturbative-mixing branch.
Here exact separability is broken, but angular mixing remains weak enough to be controlled perturbatively:

$$\varepsilon_{\mathrm{mix}} \ll 1.$$

This second branch is likely the generic physical branch. It does not enjoy exact algebraic simplification, but it remains observationally usable.

6.7 Teukolsky–GSN projection theorem

Theorem 6.1 (Teukolsky–GSN Projection Theorem).
The Kerr-sector FCLET shell problem becomes perturbatively meaningful only after the rotating latency deformation is decomposed into background, source, and shell-boundary sectors and projected into the Teukolsky/GSN channel. Exact separability is a special admissible branch; the generic usable branch is a controlled slow-rotation perturbative-mixing regime.

7. Superradiant Stability, Ergoregion Control, and the Admissibility Corridor

7.1 Why a rotating shell is not automatically viable

A rotating shell plus partial reflectivity is not automatically an admissible strong-field object. Once the background rotates, reflected modes can interact with the superradiant channel. This creates the possibility of cavity amplification and instability.

A Kerr shell theory that ignores this problem is not observationally viable.

7.2 Superradiant consistency condition

Let ω be the mode frequency and $\Omega_s(\theta)$ the effective shell rotation profile. A necessary superradiant stability requirement is that the effective reflection/amplification cycle remain bounded. In schematic form:

$$| \mathcal{R}_{\mathrm{shell}}\, \mathcal{A}_{\mathrm{sr}} | < 1,$$

where $\mathcal{A}_{\mathrm{sr}}$ is the superradiant amplification factor.

This inequality does not forbid all reflectivity. It forbids the branch in which the shell plus rotation creates an unstable cavity.

7.3 Ergoregion stability

A related but distinct admissibility condition concerns the ergoregion. A shell surface that lies in the wrong relation to the rotating effective geometry may support ergoregion instabilities even when the simple superradiant channel appears perturbatively mild.

The admissible shell sector must therefore satisfy both:

superradiant consistency,

ergoregion stability.

7.4 Mode-mixing admissibility

The perturbative branch also requires that angular mode mixing remain controlled:

$$\varepsilon_{\mathrm{mix}} \ll 1.$$

If the FCLET deformation drives strong uncontrolled mixing between angular sectors, the perturbative spectroscopy program loses mathematical reliability. This is not a weak inconvenience. It is an exclusion condition for the present article's controlled rotating branch.

7.5 Admissibility map

The effective parameter vector of the Kerr shell sector may be written schematically as

$$\Lambda_{\mathrm{Kerr-shell}} = \left\{a/M,\ \chi_2,\ r_s^{(2)},\ \mathcal{R}_{\ell mn},\ \varepsilon_{\mathrm{mix}},\ \mathcal{A}_{\mathrm{sr}}\right\}.$$

The admissibility map partitions this space into four classes:

Class I: separable-admissible

$$\varepsilon_{\mathrm{mix}} \approx 0, \mid \mathcal{R}_{\mathrm{shell}}\mathcal{A}_{\mathrm{sr}} \mid < 1.$$

Class II: perturbative-admissible

$$\varepsilon_{\mathrm{mix}} \ll 1, \mid \mathcal{R}_{\mathrm{shell}}\mathcal{A}_{\mathrm{sr}} \mid < 1.$$

Class III: perturbative-unstable

$$\varepsilon_{\mathrm{mix}} \ll 1, \mid \mathcal{R}_{\mathrm{shell}}\mathcal{A}_{\mathrm{sr}} \mid \geq 1.$$

Class IV: excluded

$$\varepsilon_{\mathrm{mix}} \ll /1 \mathrm{orboundary\ mixing\ uncontrolled.}$$

This map is not optional bookkeeping. It is the criterion by which the Kerr FCLET shell program is restricted to its observationally usable branch.

7.6 Exported detector-facing quantities

The final outputs exported from the admissible rotating branch are:

$$\delta\omega_{\ell mn}(a),$$
$$\Delta t_{\mathrm{echo}}(a,\theta),$$
$$\mathcal{B}_{\ell mn}(a),$$
$$\delta\tau_{\ell mn}(a).$$

These are the detector-facing spectral observables that Article 84 will use for injection–recovery and Article 85 will use for LVK confrontation.

7.7 Admissibility theorem

Theorem 7.1 (Rotating-Shell Admissibility Theorem).
The Kerr FCLET shell sector is observationally meaningful only inside the branch in which separability is exact or perturbatively controlled, and in which partial shell reflectivity remains consistent with superradiant and ergoregion stability. The admissible rotating shell program is therefore a restricted corridor, not the full formal rotating parameter space.

8. Slow-Rotation Expansion and Schwarzschild Recovery

8.1 Expansion hierarchy

The slow-rotation expansion is not decorative. It defines the regime in which the Kerr FCLET shell program may be treated as analytically controlled.

Expand all central quantities as

$$\tilde{\chi}(r,\theta;a) = \chi_0(r) + \left(\frac{a}{M}\right)^2 \chi_2(r,\theta) + O(a^4),$$
$$r_s(\theta;a) = r_s^{(0)} + \left(\frac{a}{M}\right)^2 r_s^{(2)}(\theta) + O(a^4),$$
$$\mathbb{B}_{\mathrm{shell}}(a) = \mathbb{B}^{(0)} + \left(\frac{a}{M}\right)\mathbb{B}^{(1)} + \left(\frac{a}{M}\right)^2 \mathbb{B}^{(2)} + \cdots .$$

This hierarchy makes it possible to organize both recovery and admissibility in a controlled way.

8.2 Recovery of the Schwarzschild shell sector

The first mandatory recovery check is the $a \to 0$ limit. In this limit:

the shell surface must collapse to the Schwarzschild shell radius,

the stationary axisymmetric latency field must collapse to the radial Schwarzschild profile,

the rotating boundary operator must collapse to the Schwarzschild shell impedance,

the perturbation problem must collapse to the non-rotating FCLET shell problem.

Symbolically,

$$r_s(\theta; a) \to r_s^{(0)}, \bar{\chi}(r, \theta; a) \to \chi_0(r), \mathbb{B}_{\text{shell}}(a) \to \mathbb{B}_{\text{Schw}}.$$

This recovery is more than a consistency check. It ensures that the Kerr program is an extension of the already constructed Schwarzschild shell theory rather than an independent rotating ansatz.

8.3 Recovery of standard Kerr–Teukolsky/GSN

The second mandatory recovery check is the GR limit. When the FCLET deformation is switched off,

$$\chi \to 0, \Gamma_{\text{ov}} \to 0, I \to 0,$$

the rotating FCLET shell problem must reduce to the ordinary Kerr perturbation problem.

This requires

$$\delta\mathcal{T}_{\text{bg}} \to 0, \delta\mathcal{T}_{\text{src}} \to 0, \mathbb{B}_{\text{shell}} \to \mathbb{B}_{\text{Kerr-horizon}},$$

so that the GSN equation becomes the standard Kerr/Sasaki–Nakamura equation and the inner boundary reduces to the classical ingoing-horizon condition.

Thus the GR recovery is not merely "bulk operator becomes Kerr." It is the statement that the physically relevant strong-field inner boundary also returns to the classical Kerr absorption channel when the FCLET sector is removed.

8.4 Recovery of the shell boundary operator

Because the shell problem is defined by a surface operator rather than by a radius alone, operator recovery must be checked explicitly. The boundary matrix

$$\mathbb{B}_{\text{shell}}(a)$$

must reduce to the non-rotating shell impedance in the combined limit of vanishing spin-induced anisotropy:

$$\mathbb{B}_{\mathrm{shell}}(a) \to \mathbb{B}_{\mathrm{Schw}}(a \to 0).$$

This matters because it is possible for the bulk operator to recover correctly while the boundary structure does not. That would yield false recovery at the level of the spectral problem. The Kerr FCLET sector is therefore acceptable only if both bulk and boundary recoveries hold simultaneously.

8.5 Analytic control and numerical validity window

The slow-rotation expansion is the domain of analytic control. Let the three principal control parameters be:

$$\varepsilon_a \equiv a/M, \varepsilon_{\mathrm{mix}}, \varepsilon_{\mathrm{sr}} \equiv \mid \mathcal{R}_{\mathrm{shell}} \mathcal{A}_{\mathrm{sr}} \mid.$$

Then the analytically controlled slow-rotation Kerr FCLET branch is the domain in which

$$\varepsilon_a \ll 1, \varepsilon_{\mathrm{mix}} \ll 1, \varepsilon_{\mathrm{sr}} < 1.$$

This defines the validity window

$$\mathcal{W}_{\mathrm{valid}}.$$

Inside this window, perturbative spectroscopy is mathematically legitimate. Outside it, one enters either the non-separable strong-mixing regime or the superradiantly unstable regime.

The recovery limit established in §8.2–§8.4 is analytic: the $a \to 0$ limit reduces the rotating FCLET shell problem to its Schwarzschild counterpart at the level of the field equations, the boundary operator, and the Leaver-type spectral condition. It does not by itself demonstrate that the Schwarzschild limit is numerically accessible in the FCLET shell sector — that is, that the complex QNM roots of the Schwarzschild FCLET system can be explicitly tracked in parameter space and that the resulting spectral shifts are numerically stable. That demonstration is carried out in §8.6, which presents the first stabilized benchmark of the Schwarzschild FCLET shell spectrum. The benchmark serves simultaneously as the numerical verification of the $a \to 0$ recovery and as the first concrete observational-scale output of the shell perturbation program.

8.6 Schwarzschild Numerical Benchmark: First Stabilized Real-Sector Shell Spectrum

We report the first stabilized numerical benchmark of the Schwarzschild FCLET shell spectrum in the minimal axial thin-shell sector. The goal is to determine whether the FCLET shell boundary condition produces explicit, numerically trackable complex quasinormal-mode shifts relative to the Schwarzschild Leaver spectrum, and whether these shifts remain stable

under controlled parameter-space tracking. The present benchmark therefore serves a dual function within Article 83: it is the numerical verification of the $a \to 0$ recovery limit established in §8.2 and §8.4, and it is the first concrete spectral output of the FCLET shell perturbation program in a regime where the reference spectrum is independently known.

The numerical setup uses the Regge–Wheeler equation in the axial sector with a shell placed at

$$r_s = 2M(1+\epsilon),$$

together with the minimal FCLET thin-shell reflectivity law

$$R_s(\omega) = \frac{\Lambda_s}{2i\omega - \Lambda_s}.$$

The benchmark is performed in geometrized units with $M = 1$. The shell spectrum is defined by direct complex root finding relative to the Schwarzschild reference modes, which are taken from the Leaver table of Berti, Cardoso, and Starinets and verified against the qnm package when available. The solver implements a continuation path in the (ϵ, Λ_s) plane in which ϵ is opened first at very small Λ_s, and Λ_s is then ramped at fixed final ϵ. This two-segment ordering prevents diagonal branch slips in the complex spectrum.

A key result of the benchmark is methodological before it is phenomenological. Independent grid scans showed large apparent jumps in the $(\ell, n) = (2,0)$ branch. Under continuation, these jumps disappear. The same spectral branch can be followed continuously through the (ϵ, Λ_s) plane, and the continuation driver reports residual, relative-jump, and end-of-ramp spread diagnostics directly in the output. In the present implementation, the continuation path is built as an ϵ-ramp followed by a Λ_s-ramp, with adaptive step-halving when a proposed jump exceeds the allowed relative threshold. This turns the Schwarzschild FCLET benchmark from a raw root-finding experiment into a controlled spectral-tracking problem.

The mode shifts are reported using two separate fractional quantities. The real frequency shift is defined as

$$\delta\mathrm{Re}/\mathrm{Re} \equiv \frac{\mathrm{Re}(\omega_{\mathrm{shell}}) - \mathrm{Re}(\omega_{\mathrm{Schw}})}{|\,\mathrm{Re}(\omega_{\mathrm{Schw}})\,|},$$

and the damping-rate shift as

$$\delta\mathrm{Im}/|\,\mathrm{Im}\,| \equiv \frac{\mathrm{Im}(\omega_{\mathrm{shell}}) - \mathrm{Im}(\omega_{\mathrm{Schw}})}{|\,\mathrm{Im}(\omega_{\mathrm{Schw}})\,|}.$$

This convention is used because it directly communicates the physical content of the shift to a reader comparing the FCLET shell result against the Schwarzschild spectrum.

For the fundamental $(\ell, n) = (2,0)$ mode at $\epsilon = 0.10$, the real frequency is shifted upward by approximately $+2.6\%$ relative to the Schwarzschild value, while the imaginary part — which sets the damping timescale — is shifted by approximately -83.5%. The imaginary shift is large in percentage terms because the FCLET shell compact object is not a black hole: the shell replaces the classical horizon with a finite-capacity saturation layer, and the effective damping of perturbation modes is controlled by the shell reflectivity rather than by horizon absorption. Because the Schwarzschild reference mode is damped primarily by horizon absorption, replacing the horizon with a partially reflecting saturation shell suppresses the net damping rate and therefore produces a large fractional shift in the imaginary sector even when the real-frequency shift remains only a few percent. The shell acts as a partially reflecting boundary that returns some outgoing radiation, reducing the net energy loss rate and thus lengthening the mode lifetime relative to the Schwarzschild case.

For the $(\ell, n) = (3,0)$ mode at $\epsilon = 0.10$, the real shift is smaller, approximately $+0.23\%$, while the damping-rate shift remains in the -83.9% range. The continuation-stabilized spread in the real part across the Λ_s-ramp is 0.034% for $(2, 0)$ and 0.020% for $(3, 0)$, both within the real-sector stabilization threshold of 0.20%. The real-part benchmark is therefore publication-grade in the real sector at $r_{\mathrm{out}} = 300M$ under full continuation.

A second result is structural rather than merely numerical. The FCLET thin-shell law is close to, but not identical with, a constant-R surrogate. The value $\epsilon = 0.010$ is used in the direct FCLET-versus-constant-R comparison rather than the main benchmark value $\epsilon = 0.10$ because the comparison is designed to isolate the effect of the reflectivity law at small shell offset, where the FCLET and constant-R models differ most clearly in relative terms; the same qualitative distinction holds at $\epsilon = 0.10$ but with a smaller relative separation. At matched amplitude, the FCLET thin-shell model produces a real-part shift 0.06%–0.09% smaller in magnitude than the constant-R surrogate, with the difference monotonic and directional across the full Λ_s range. This is the first frequency-dependence-specific FCLET numerical signature.

At the present stage, the real-part frequency shift is publication-grade in the real sector at $r_{\mathrm{out}} = 300M$ under full continuation for both modes: continuation establishes numerical stability, residuals are at the 10^{-13} level, and the spread across parameter space is within the 0.20% threshold. The damping-rate shift is internally consistent along the continuation path but remains sensitive to the outer matching radius. Figure 8.1 is therefore a preliminary diagnostic of outer-radius sensitivity rather than a final convergence proof. A final imaginary-sector convergence test requires $O(1/r_{\mathrm{out}})$ asymptotic corrections or a more faithful ingoing-wave formulation, plus a full continuation re-run at each r_{out} value. The stabilized real-sector benchmark is sufficient for a first publication-level Schwarzschild shell result, while the imaginary sector now defines a separate numerical program rather than an unresolved detail.

9. Spin-Dependent Spectral Observables

The Schwarzschild benchmark of §8.6 establishes the numerical starting point for the rotating spectral program. At $a = 0$, the FCLET shell produces stabilized real-frequency shifts of approximately $+2.6\%$ for $(\ell, n) = (2,0)$ and approximately $+0.23\%$ for $(3, 0)$ relative to the Schwarzschild Leaver spectrum, with sub-0.04% spread across the coupling parameter space. These are the reference values against which the spin-dependent deformations developed in this section must be compared. The Kerr shifts $\delta\omega_{\ell mn}(a)$ carry the $a = 0$ benchmark values as their zero-spin anchor; they must reproduce those values in the $a \to 0$ limit consistently with the analytic recovery demonstrated in §8.2. The present section therefore begins not from an abstract spectral decomposition, but from a numerically anchored Schwarzschild baseline.

9.1 Quasi-normal mode shift $\delta\omega_{\ell mn}(a)$

The first detector-facing quantity is the spin-dependent quasi-normal mode shift,

$$\delta\omega_{\ell mn}(a) = \omega_{\ell mn}^{\mathrm{FCLET}}(a) - \omega_{\ell mn}^{\mathrm{Kerr}}(a).$$

This quantity is the direct rotating analogue of the Schwarzschild benchmark shift measured in §8.6. The key difference is that on the Kerr background the mode correction is no longer sourced only by a radial shell location and radial reflectivity. It is sourced by four coupled ingredients:

- the spin-dependent shell-surface deformation $r_s(\theta; a)$,
- the rotating latency deformation of lapse and shift,
- the FCLET correction to the Teukolsky/GSN bulk operator,
- the rotating shell boundary operator $\mathbb{B}_{\mathrm{shell}}(a, \omega, \ell, m)$.

The total shift can therefore be decomposed schematically as

$$\delta\omega_{\ell mn}(a) = \delta\omega_{\ell mn}^{\mathrm{bg}}(a) + \delta\omega_{\ell mn}^{\mathrm{src}}(a) + \delta\omega_{\ell mn}^{\mathrm{bdry}}(a),$$

where the three pieces correspond respectively to background deformation, effective source structure, and shell boundary deformation.

In the slow-rotation branch, this shift admits an expansion

$$\delta\omega_{\ell mn}(a) = \delta\omega_{\ell mn}^{(0)} + \left(\frac{a}{M}\right)\delta\omega_{\ell mn}^{(1)} + \left(\frac{a}{M}\right)^2\delta\omega_{\ell mn}^{(2)} + \cdots .$$

The zero-order term $\delta\omega_{\ell mn}^{(0)}$ is precisely the Schwarzschild benchmark value determined in §8.6. This is the sense in which the numerical Schwarzschild benchmark becomes the zero-spin anchor of the Kerr spectral program.

The physically relevant output of this subsection is not a single number, but the family

$$\{\delta\omega_{\ell mn}(a)\}_{\ell,m,n},$$

tracked across the admissible rotating shell corridor. These curves define where the FCLET shell sector departs most strongly from standard Kerr spectroscopy and therefore where subsequent injection–recovery and event-level confrontation should focus.

9.2 Echo-delay family $\Delta t_{\mathrm{echo}}(a,\theta)$

The second detector-facing quantity is the rotating echo-delay family,

$$\Delta t_{\mathrm{echo}}(a,\theta).$$

In the Schwarzschild branch, the echo delay was controlled by the shell–barrier cavity scale associated with the shell radius and the exterior potential structure. In Kerr geometry, that statement is replaced by a family structure. The cavity scale acquires both spin dependence and angular dependence because the shell is now a surface rather than a radius:

$$r_s \to r_s(\theta; a).$$

The rotating echo delay therefore takes the schematic form

$$\Delta t_{\mathrm{echo}}(a,\theta) = \Delta t_{\mathrm{cav}}(a,\theta) + \Delta t_{\mathrm{drag}}(a,\theta),$$

where the first term is the geometric shell–barrier delay and the second term is the additional latency associated with the dragging-sensitive rotating background channel.

The equatorial sector,

$$\Delta t_{\mathrm{echo}}(a,\pi/2),$$

and the polar sector,

$$\Delta t_{\mathrm{echo}}(a,0),$$

bracket the relevant family. In practical use, the detector-facing timing prediction is not one scalar delay but an angularly projected delay family weighted by the dominant mode geometry.

As $a \to 0$, this family collapses smoothly to the Schwarzschild echo-delay scale already established in the non-rotating shell program. The rotating family is therefore a genuine deformation of the Schwarzschild cavity timing, not an independent timing construction.

9.3 Excitation branching coefficient $\mathcal{B}_{\ell mn}(a)$

The third detector-facing quantity is the excitation branching coefficient,

$\mathcal{B}_{\ell mn}(a)$.

This quantity measures how strongly a given mode is sourced in the rotating FCLET shell geometry relative to the surrounding mode family. In the Kerr shell problem, $\mathcal{B}_{\ell mn}(a)$ is no longer determined only by the source profile. It is also influenced by:

- shell-surface deformation,
- mode-dependent reflectivity,
- dragging-sensitive transfer structure,
- and perturbative angular mixing.

A schematic decomposition is

$$\mathcal{B}_{\ell mn}(a) = \mathcal{B}^{\mathrm{Kerr}}_{\ell mn} + \delta\mathcal{B}^{\mathrm{FCLET}}_{\ell mn}(a),$$

with

$$\delta\mathcal{B}^{\mathrm{FCLET}}_{\ell mn}(a) = \delta\mathcal{B}^{\mathrm{geom}}_{\ell mn} + \delta\mathcal{B}^{\mathrm{drag}}_{\ell mn} + \delta\mathcal{B}^{\mathrm{mix}}_{\ell mn}.$$

This coefficient is especially important for later papers because the raw existence of a spectral shift does not determine whether that mode is actually visible in detector data. Visibility depends on excitation. The role of $\mathcal{B}_{\ell mn}(a)$ is therefore to identify which FCLET Kerr-shell modes are spectroscopically important and which remain formally present but observationally subdominant.

9.4 Ringdown damping modification $\delta\tau_{\ell mn}(a)$

The fourth detector-facing quantity is the damping modification,

$\delta\tau_{\ell mn}(a)$.

This quantity is tied to the imaginary part of the full rotating mode spectrum. In the present article, its structural role is fully defined, but its complete numerical closure remains the task of the later Kerr FCLET spectroscopy program. In other words, the real-sector benchmark is

numerically anchored already at $a = 0$, while the damping-sector closure is structurally in place but not yet fully completed across the rotating branch.

Write

$$\omega_{\ell mn}^{\mathrm{FCLET}}(a) = \omega_{\ell mn}^{\mathrm{Kerr}}(a) + \delta\omega_{\ell mn}(a),$$

with

$$\delta\tau_{\ell mn}(a) \equiv -\frac{1}{\Im[\omega_{\ell mn}^{\mathrm{FCLET}}(a)]} + \frac{1}{\Im[\omega_{\ell mn}^{\mathrm{Kerr}}(a)]}.$$

The imaginary-sector interpretation follows the same physical logic already encountered in the Schwarzschild benchmark. A partially reflecting shell suppresses net absorption relative to the classical horizon channel and therefore tends to lengthen the mode lifetime. In Kerr geometry this effect is further modulated by frame dragging, shell-surface deformation, and superradiant consistency. The full rotating damping structure is therefore richer than the Schwarzschild one, but it is governed by the same physical principle: the shell replaces the purely absorptive inner boundary with a partially reflecting, capacity-limited saturation layer.

9.5 Spectroscopic role of the four observables

The four quantities

$$\delta\omega_{\ell mn}(a), \Delta t_{\mathrm{echo}}(a,\theta), \mathcal{B}_{\ell mn}(a), \delta\tau_{\ell mn}(a)$$

constitute the minimal FCLET spectroscopic discriminator in the Kerr sector. Together they define:

where the rotating shell departs from standard Kerr,

how long shell-induced delayed structure takes to return,

which modes are most strongly excited,

and how the ringdown damping channel is modified.

These are not descriptive outputs. They are the exact quantities required by Article 84 for injection–recovery and by Article 85 for event-level Bayesian confrontation.

10. No-Go Conditions, Separability Criteria, and Benchmark Outputs for Article 84

10.1 Why exclusion criteria must be stated explicitly

A rotating shell theory that does not define its own no-go conditions remains scientifically weak. The present paper therefore does not merely build the admissible branch. It also defines the excluded one.

The excluded branch can arise for three distinct reasons:

exact separability fails too strongly for the perturbative reduction to remain trustworthy,

angular mode mixing becomes uncontrolled,

shell reflectivity and rotation together produce a superradiantly unstable cavity.

These are not aesthetic concerns. They are the mathematical borders of the usable FCLET Kerr shell sector.

10.2 Separability criteria

The separability problem is controlled by the size of the FCLET deformation in the rotating background. Exact separability is maintained only if the background deformation can be absorbed into a form compatible with the Teukolsky separation structure. Denote the non-separable deformation strength by

$$\Xi_{\mathrm{sep}}.$$

Then the exact separable branch requires

$$\Xi_{\mathrm{sep}} = 0$$

or a perturbatively equivalent condition.

The controlled slow-rotation mixed branch requires

$$\Xi_{\mathrm{sep}} \neq 0, \varepsilon_{\mathrm{mix}} \ll 1,$$

so that non-separability remains perturbatively small.

The excluded branch begins when

$$\varepsilon_{\mathrm{mix}} \ll/1,$$

because the spectral outputs then cease to be reliably attributable to a controlled Kerr-shell perturbation problem.

10.3 Superradiant and ergoregion no-go conditions

The rotating shell must also remain outside the unstable cavity regime. A minimal no-go condition is

$$| \mathcal{R}_{\mathrm{shell}} \mathcal{A}_{\mathrm{sr}} | \geq 1.$$

If this bound is crossed, the shell plus rotation becomes dynamically unstable and the present perturbative shell branch is no longer admissible.

A second no-go channel is ergoregion instability. Even if the crude superradiant product remains below unity, a shell geometry that is badly placed relative to the rotating effective background may still support an ergoregion instability. The admissible branch therefore requires:

superradiant consistency,

ergoregion consistency,

perturbative separability or controlled weak mixing.

10.4 Benchmark output table for Article 84

The central deliverable of the present paper to Article 84 is a structured benchmark output table built from the four spin-dependent observables:

$$\delta\omega_{\ell mn}(a), \Delta t_{\mathrm{echo}}(a,\theta), \mathcal{B}_{\ell mn}(a), \delta\tau_{\ell mn}(a).$$

The benchmark should be evaluated at a discrete set of physically relevant spin values, for example

$$a/M = 0, 0.3, 0.5, 0.67, 0.9,$$

and for a minimal dominant mode family, beginning with

$$(\ell, n) = (2,0),$$

and then extending to $(3, 0)$ and selected overtone branches once dedicated continuation has been performed.

The $a = 0$ line of this benchmark is already fixed numerically by §8.6. This means that Article 84 will not begin from an unconstrained rotating phenomenology. It will begin from a Kerr deformation family whose zero-spin anchor has already been numerically stabilized.

10.5 Optimal spectral windows for later confrontation

A second deliverable of the present paper is the identification of the spin windows in which FCLET deviates most strongly from standard Kerr spectroscopy while remaining inside the admissible branch. These windows define the optimal targets for later confrontation.

The point is not merely to say that the shell deforms the spectrum. The point is to identify where the deformation is strongest, where the excitation remains high enough to matter observationally, and where superradiant or mixing pathologies do not destroy interpretability. The admissible FCLET Kerr shell branch is therefore not only a set of allowed parameters. It is also a set of optimal confrontation windows.

10.6 Export theorem

Theorem 10.1 (Export Theorem for Article 84).
The Kerr-shell outputs of the present paper can be compressed into a finite benchmark table of the four detector-facing FCLET observables evaluated along the admissible spin corridor. This table constitutes the necessary and sufficient numerical export from Article 83 to the injection–recovery program of Article 84.

11. Conclusion

This paper has constructed the Kerr extension of the FCLET shell theory. The saturation condition has been generalized from a Schwarzschild shell radius to a covariant saturation surface derived from the finite-capacity burden law on a rotating background. The latency field has been extended from a radial profile to a stationary axisymmetric lapse–shift–drag deformation. The perturbative FCLET shell problem has been projected into the Teukolsky/Generalized Sasaki–Nakamura language by decomposing the modification into background, source, and shell-boundary sectors. Exact separability has been treated as a special admissible branch rather than an unexamined assumption, and the generic rotating shell regime has been organized through a controlled slow-rotation, weak-mixing branch. Most importantly, the physically meaningful rotating shell corridor has been sharply restricted by superradiant and ergoregion admissibility criteria.

The paper also establishes the first stabilized numerical benchmark of the Schwarzschild FCLET shell spectrum. That benchmark verifies that the $a \to 0$ limit is not only analytic but numerically accessible, and it fixes the real-sector zero-spin anchor for the Kerr spectral program. The continuation-stabilized shifts in the Schwarzschild branch show that the rotating spectral analysis does not begin from an abstract deformation language. It begins from a numerically anchored non-rotating limit.

The main exported outputs of the Kerr shell program are now explicit:

$$\delta\omega_{\ell mn}(a),\ \Delta t_{\mathrm{echo}}(a,\theta),\ \mathcal{B}_{\ell mn}(a),\ \delta\tau_{\ell mn}(a).$$

These four quantities are the minimal FCLET spectroscopic discriminator in the Kerr sector. Together they provide the exact formal inputs required for the injection–recovery program of

Article 84 and for the direct LVK event confrontation of Article 85. In this sense, Article 83 does not merely extend the shell program. It makes later confrontation mathematically legitimate.

The compact-object branch of FCLET is therefore no longer restricted to Schwarzschild remnants. It now addresses the rotating astrophysical remnant population and closes the structural gap between the completed Schwarzschild shell program and genuine gravitational-wave confrontation.

Appendix A

Boyer–Lindquist Reduction of the FCLET Action

In this appendix we collect the reduced background structure of the FCLET action on a Kerr background in Boyer–Lindquist coordinates. The purpose is not merely computational convenience. It is to display explicitly how the finite-capacity sector couples to the rotating geometry before the perturbative projection is performed.

We begin from the Kerr metric in Boyer–Lindquist coordinates with

$$\Sigma = r^2 + a^2\cos^2\theta, \Delta = r^2 - 2Mr + a^2.$$

The rotating FCLET ansatz takes the form

$$g_{\mu\nu} = g_{\mu\nu}^{\text{Kerr}} + \delta g_{\mu\nu}^{\text{FCLET}}, \chi = \bar{\chi}(r,\theta;a), I = I(r,\theta;a).$$

The reduced background action is written schematically as

$$S_{\text{red}} = \int dt\, dr\, d\theta\, d\phi \sqrt{-g_{\text{Kerr}}}\left[\frac{R_{\text{Kerr}}}{16\pi G} + \delta\mathcal{L}_{\text{FCLET}}^{\text{bg}}\right],$$

where

$$\delta\mathcal{L}_{\text{FCLET}}^{\text{bg}} = -\frac{1}{2}K(\chi)(\nabla\chi)^2 - V(\chi) - \mathcal{U}(I,\chi,\Gamma_{\text{ov}}).$$

The corresponding reduced field equations organize naturally into three channels:

the lapse deformation channel,

the shift/dragging deformation channel,

the shell-threshold channel.

The shell-threshold condition is extracted from the reduced burden equation,

$$\mathcal{F}(r,\theta;a) = I(r,\theta;a) - I_{\mathrm{crit}}(a,\theta) = 0,$$

which defines the rotating saturation surface. The explicit perturbative extraction of this surface in the slow-rotation branch yields

$$r_s(\theta;a) = r_s^{(0)} + \left(\frac{a}{M}\right)^2 r_s^{(2)}(\theta) + O(a^4).$$

This appendix should be read as the background foundation for §4 and §5 of the main text. Its role is to make the rotating shell geometry derivable rather than assumptive.

Appendix B

Teukolsky–GSN Transformation Conventions

This appendix records the perturbative conventions used in the Kerr FCLET shell projection.

The starting point is the Teukolsky variable Ψ_s defined on a Kerr null tetrad. The FCLET-modified perturbation problem is represented in the bulk by

$$\left(\mathcal{T}_{\mathrm{Kerr}} + \delta\mathcal{T}_{\mathrm{bg}} + \delta\mathcal{T}_{\mathrm{src}}\right)\Psi_s = 0.$$

For detector-facing work, we transform to a generalized Sasaki–Nakamura variable X, satisfying

$$\frac{d^2X}{dr_*^2} + [\omega^2 - V_{\mathrm{GSN}} - \delta V_{\mathrm{FCLET}}]X = 0.$$

The FCLET correction is decomposed as

$$\delta V_{\mathrm{FCLET}} = \delta V_{\mathrm{bg}} + \delta V_{\mathrm{src}} + \delta V_{\mathrm{mix}}.$$

The shell boundary condition is encoded by a mode-dependent operator

$$\mathbb{B}_{\mathrm{shell}}(a,\omega,\ell,m),$$

which relates the amplitudes of the generalized radial variable at the saturation surface.

The essential transformation conventions are therefore:

definition of the Teukolsky radial and angular variables,

normalization of the GSN variable,

relation between the shell boundary data and the transformed radial variable,

residue and transfer-matrix conventions used later for detector-facing observables.

The role of this appendix is to ensure that the rotating FCLET shell observables are defined in a gauge-clean and formally transportable manner.

Appendix C

Slow-Rotation Expansion Bookkeeping

The slow-rotation branch of Article 83 is controlled by a hierarchy of expansions in the dimensionless spin parameter a/M. This appendix collects that hierarchy in one place.

The core quantities are expanded as

$$\bar{\chi}(r,\theta;a) = \chi_0(r) + \left(\frac{a}{M}\right)^2 \chi_2(r,\theta) + O(a^4),$$

$$r_s(\theta;a) = r_s^{(0)} + \left(\frac{a}{M}\right)^2 r_s^{(2)}(\theta) + O(a^4),$$

$$\mathbb{B}_{\text{shell}}(a) = \mathbb{B}^{(0)} + \left(\frac{a}{M}\right)\mathbb{B}^{(1)} + \left(\frac{a}{M}\right)^2 \mathbb{B}^{(2)} + \cdots .$$

Angular mode mixing is controlled by a small parameter

$$\varepsilon_{\text{mix}} \ll 1,$$

while the superradiant cavity control parameter is

$$\varepsilon_{\text{sr}} \equiv | \mathcal{R}_{\text{shell}} \mathcal{A}_{\text{sr}} |.$$

The analytically controlled window is therefore

$$\mathcal{W}_{\text{valid}} = \left\{ \frac{a}{M} \ll 1, \varepsilon_{\text{mix}} \ll 1, \varepsilon_{\text{sr}} < 1 \right\}.$$

C.4 Numerical Benchmark Implementation

The Schwarzschild FCLET shell benchmark of §8.6 is implemented in three files distributed as supplementary material. ref_qnm.py provides Schwarzschild reference QNM values from the qnm package or hardcoded Leaver-table values. shell_qnm_solver.py implements the Regge–Wheeler integrator, the FCLET thin-shell boundary condition, the QNM residual function, and the continuation module with adaptive step-halving and multi-seed acceptance filtering. run_continuation.py builds the two-segment path and produces the output tables. Integrations use DOP853 with tight tolerances, and root finding uses MINPACK hybr.

Three known limitations apply to the present implementation.

(i) The pure-outgoing outer boundary condition appears to require

$$r_{\mathrm{out}}/M \gtrsim 1000,$$

or else a more faithful ingoing-wave formulation, for the imaginary sector to become effectively insensitive to r_{out}. The damping-rate shift is therefore stated as preliminary.

(ii) The imaginary sector will be resolved in a subsequent calculation using either large outer radius or Leaver continued-fraction / ingoing-wave boundary conditions.

(iii) Branch-tracking for overtone modes $(n = 1)$ requires dedicated continuation before any quantitative claim is attached to that sector.

The important methodological conclusion is that these limitations do not invalidate the real-sector benchmark reported in §8.6. On the contrary, they cleanly separate two numerical tasks that were previously entangled: the real-sector Schwarzschild anchor is now stabilized and publication-grade, while the imaginary sector has been isolated as a distinct numerical program with a well-defined next technical step.

Appendix D

Horizon-Regular Formulation and Boundary-Data Invariance

This appendix records the conceptual reason the shell observables are not artifacts of a particular coordinate choice.

Boyer–Lindquist coordinates are useful for stationary background analysis and for standard Teukolsky separability. They are not themselves the physical observables. The shell observables of Article 83—frequency shifts, delay families, excitation coefficients, and damping modifications—must remain invariant under admissible horizon-regular reparameterizations and tetrad choices.

The shell boundary data therefore transform covariantly:

$$\mathbb{B}_{\mathrm{shell}} \to \widetilde{\mathbb{B}}_{\mathrm{shell}},$$

while the physical detector-facing quantities satisfy

$$\delta\omega_{\ell mn}, \Delta t_{\mathrm{echo}}, \mathcal{B}_{\ell mn}, \delta\tau_{\ell mn}$$

as invariant outputs of the admissible branch.

The purpose of this appendix is to make explicit that:

the shell matching data can be reformulated in horizon-regular variables,

the admissibility conditions are geometric rather than coordinate artifacts,

the spectroscopic outputs exported to later papers do not depend on the auxiliary parameterization chosen for the present derivation.

This completes the formal closure of the Kerr FCLET shell program at the level of geometry, perturbation theory, and boundary-data invariance.

Abstract

We construct the detector-facing spectroscopy and injection–recovery program of the finite-capacity latency–erasure theory on rotating compact-remnant backgrounds. Article 83 established the Kerr-sector shell theory in a mathematically controlled form and provided the first stabilized numerical benchmark of the Schwarzschild FCLET shell spectrum, anchoring the dominant $(2, 0)$ real-sector shift at approximately $+2.6\%$ and the $(3, 0)$ support anchor at approximately $+0.23\%$ in the zero-spin limit. The covariant saturation surface was defined, the stationary axisymmetric latency closure was derived, the Teukolsky/Generalized Sasaki–Nakamura projection was constructed, the admissible rotating-shell branch was isolated, and the principal detector-facing observables $\delta\omega_{\ell mn}(a)$, $\delta\tau_{\ell mn}(a)$, $\mathcal{B}_{\ell mn}(a)$, and $\Delta t_{\mathrm{obs}}(a, \theta)$ were obtained. What remained open was the decisive detector-level question. A rotating shell theory does not become scientifically relevant merely because its perturbation sector exists. It becomes relevant only when its signal family is recoverable, distinguishable, and non-mimickable under realistic inference conditions.

In this paper we build that recovery framework. We construct the first Kerr FCLET waveform family for post-merger spectroscopy by combining four structures inherited from the admissible branch of the rotating shell theory: spin-dependent quasi-normal frequency deformation, shell-induced damping modification, excitation-branch hierarchy, and delayed shell-response structure. The resulting waveform family is not an ad hoc echo toy model. It is a shell-informed rotating strong-field template family derived from the detector-facing outputs of the Kerr FCLET perturbation program. We then develop a full injection–recovery protocol over a benchmark atlas spanning weak-shell, moderate-shell, strong-but-admissible shell, and near-instability rotating branches. Synthetic FCLET signals are injected across controlled noise realizations and are recovered using three competing model families: standard Kerr ringdown, Kerr ringdown with overtone enrichment, and the Kerr FCLET shell model.

The central purpose of the analysis is identifiability. We determine which regions of admissible FCLET parameter space are absorbed by standard Kerr freedom, which remain ambiguous under realistic recovery, and which form decisive-island regions in which the delayed phase structure, excitation hierarchy, or mode-branch deformation cannot be reproduced by non-FCLET templates. To make this distinction sharp, we define a mimicry

map from FCLET effective parameters to their best false-Kerr counterparts and construct an identifiability corridor over theory space. We also quantify false alarm, false FCLET identification, and FCLET suppression by Kerr overfitting, thereby separating mere detectability from actual model-level discrimination.

The main outputs are a detector-facing Kerr FCLET waveform family, a benchmark injection atlas, a recovery protocol, a parameter-degeneracy map, a mimicry/exclusion classification, and a decisive-island search strategy for event-level confrontation. These results do not yet constitute direct confrontation with specific LVK events. They perform the indispensable prior task: they determine where the admissible Kerr FCLET branch is recoverable, where it is indistinguishable from standard Kerr spectroscopy, and where it becomes a falsifiable detector-level target. Article 85 will use this infrastructure for direct confrontation with real merger data. The benchmark atlas is therefore no longer qualitative only. It is numerically anchored by the stabilized Schwarzschild shell result of Article 83, so that the detector-facing recovery problem is organized around explicit spectral-departure scales with a calibrated zero-spin reference point.

Keywords: Kerr spectroscopy; injection–recovery analysis; detector-facing waveforms; ringdown inference; echo-delay families; excitation branching; mimicry map; identifiability corridor; decisive-island search; false-Kerr degeneracy; strong-field signal recovery; LVK readiness

1. Introduction: From Kerr Shell Theory to Detector-Facing Signal Recovery

The strong-field branch of the finite-capacity latency–erasure theory has now crossed the purely conceptual threshold. The non-rotating shell program established that compact collapse terminates not in an unstructured classical horizon, but in a finite-capacity saturation regime with a dynamically meaningful shell. The Kerr extension then completed the next indispensable task. It replaced the Schwarzschild shell radius by a covariant saturation surface, promoted the latency field to a stationary axisymmetric rotating-background burden field, projected the perturbation problem to the Teukolsky/Generalized Sasaki–Nakamura sector, and isolated the admissible rotating-shell branch by explicit separability, mode-mixing, and superradiant stability criteria.

That achievement was decisive. It was not yet detector-facing.

A strong-field theory is not brought into empirical contact merely by writing down perturbation equations and spectral shifts. The decisive question is more severe. Does the admissible theory branch generate a recoverable signal family under inference conditions that also admit a standard Kerr interpretation? Can the delayed shell response, excitation hierarchy, and spin-dependent spectral deformation survive noise, truncation, overtone freedom, and parameter degeneracy? Or does the detector only see a signal that standard Kerr freedom can absorb?

This paper answers that question.

The task here is not direct event-level discovery. That comes later. The task here is more foundational and more important. We determine whether the admissible Kerr FCLET branch produces a detector-level target at all. That means constructing a waveform family, defining an inference parameterization, building a benchmark atlas, injecting signals across controlled recovery environments, and classifying the results into recoverable, Kerr-mimickable, ambiguous, or decisive sectors. A theory that cannot survive this stage does not deserve event-level confrontation. A theory that does survive it enters the confrontation stage with formal legitimacy.

That is exactly the status of the present paper.

The central distinction is the one between existence and identifiability. Article 83 proved the existence of a rotating FCLET shell sector in perturbation theory. Article 84 determines its identifiability. This distinction is non-negotiable. A rotating shell may exist mathematically and yet produce no detector-resolvable signal. Conversely, a rotating shell may produce observable departures only in isolated regions of theory space rather than across its full admissible branch. The present work identifies those regions explicitly.

The detector-level problem is structured by four outputs inherited from the Kerr shell theory:

$$\delta\omega_{\ell mn}(a), \delta\tau_{\ell mn}(a), \mathcal{B}_{\ell mn}(a), \Delta t_{\mathrm{obs}}(a, \theta).$$

These are not decorative observables. Together they determine the full ringdown-plus-delayed-response architecture of the rotating shell signal. The frequency shift changes the modal skeleton. The damping correction changes the temporal leakage of each branch. The excitation hierarchy controls which spectral sectors actually appear with detector-facing weight. The observed delay fixes the shell-induced secondary structure. Once combined, these quantities define a signal family that is no longer identical to standard Kerr ringdown, even when the deviations are small.

But small is not enough. Detector science is not governed by symbolic nonzero differences. It is governed by recoverability and discrimination. The present paper therefore addresses three concrete questions.

First, which regions of admissible Kerr FCLET parameter space generate signals that can actually be recovered with stable parameter posteriors?

Second, which regions are degenerate with standard Kerr freedom, including overtone enrichment, amplitude reshuffling, start-time ambiguity, and nuisance-level phase freedom?

Third, which regions form decisive-island sectors in which the FCLET signal cannot be mimicked by a non-FCLET model family and therefore becomes a genuine target for falsification?

The present article is built around these three questions.

Its output is not a discovery claim. It is stronger than that in methodological terms. It establishes the exact inference geometry within which a later discovery claim would be

meaningful. By the end of the paper, the admissible Kerr FCLET branch is partitioned into detector-level classes: weak-shell sectors that are swallowed by Kerr mimicry, ambiguous sectors that require more information than ringdown alone can supply, and decisive sectors in which FCLET becomes statistically distinguishable. This classification becomes the launching platform for Article 85.

The logic is therefore exact and sequential:

Article 83 constructed the admissible Kerr shell theory.
Article 84 constructs its detector-facing recovery and identifiability program.
Article 85 performs the direct confrontation with real LVK events.

This order is not editorial convenience. It is the correct scientific order.

A decisive update relative to the purely structural version of the detector-facing program is now available from Article 83. The Schwarzschild FCLET shell benchmark has been numerically stabilized in the real sector under continuation, yielding a dominant $(\ell, n) = (2,0)$ real-frequency shift at the benchmark point of approximately

$$\delta \mathrm{Re}\omega / \mathrm{Re}\omega \approx +2.6\%,$$

with a smaller but stable support anchor in the $(3, 0)$ mode near

$$\delta \mathrm{Re}\omega / \mathrm{Re}\omega \approx +0.23\%.$$

These values provide the first calibrated numerical scale for the detector-facing FCLET shell branch before the rotating inference atlas is constructed. The benchmark atlas of the present paper is therefore no longer qualitative only. It is now anchored to an explicit zero-spin spectral departure scale inherited from the stabilized Schwarzschild limit.

2. Detector-Facing Outputs Inherited from Article 83

The present paper begins from the admissible rotating-shell branch already isolated in the Kerr FCLET shell theory. Nothing here is added by phenomenological improvisation. Every detector-facing structure used below is inherited from the perturbative outputs of the rotating shell program.

The first output is the total quasi-normal spectrum,

$$\omega_{\ell mn}^{\mathrm{tot}}(a) = \omega_{\ell mn}^{\mathrm{Kerr}}(a) + \delta\omega_{\ell mn}^{\mathrm{shell}}(a),$$

where $\omega_{\ell mn}^{\mathrm{Kerr}}(a)$ is the standard Kerr spectrum of the remnant and $\delta\omega_{\ell mn}^{\mathrm{shell}}(a)$ is the rotating-shell deformation generated by the admissible FCLET branch. This deformation already incorporates the combined contribution of background modification, effective source

structure, and shell boundary data. It is therefore the correct detector-facing spectral shift, not a toy perturbation appended by hand.

The second output is the damping structure,

$$\tau_{\ell mn}^{\mathrm{tot}}(a) = \tau_{\ell mn}^{\mathrm{Kerr}}(a) + \delta\tau_{\ell mn}(a).$$

This quantity carries the shell-modified decay law of each rotating mode. In the detector-facing problem it controls how quickly each branch leaks out of the observable ringdown sector and therefore how much information survives into later times.

The third output is the excitation hierarchy,

$$\mathcal{B}_{\ell mn}(a),$$

which measures the mode-by-mode strength with which each rotating-shell resonance enters the observable waveform. This object is decisive because a formal spectral pole does not automatically imply detector relevance. The detector sees poles only through excitation. Therefore $\mathcal{B}_{\ell mn}(a)$ determines which sectors of the rotating-shell spectrum are physically visible and which remain dynamically suppressed.

The fourth output is the observed shell delay,

$$\Delta t_{\mathrm{obs}}(a, \theta),$$

which is the detector-facing delayed-response scale after angular projection and mode weighting. This is not merely a geometric cavity time. It is the shell-informed, mode-resolved delay that determines when the secondary response reaches the detector channel. In a rotating shell theory, this quantity is inherently spin dependent and channel dependent.

Finally, the shell reflectivity enters through a frequency- and branch-dependent structure of the form

$$R_s(\omega, a),$$

which controls the leakage of signal energy into delayed shell responses. Together with the excitation hierarchy and observed delay, it determines the amplitude and phase architecture of the post-ringdown sector.

These objects define the full effective detector-facing output vector:

$$\Theta_{\mathrm{out}}^{\mathrm{FCLET}} = \{\delta\omega_{\ell mn}(a), \delta\tau_{\ell mn}(a), \mathcal{B}_{\ell mn}(a), \Delta t_{\mathrm{obs}}(a, \theta), R_s(\omega, a)\}.$$

This vector is the input of the present paper.

The crucial point is that Article 84 does not introduce an arbitrary waveform family and then claim FCLET relevance after the fact. It performs the opposite construction. It starts from the admissible Kerr FCLET outputs and builds the waveform family from them. That is what gives the present paper scientific force. The delayed shell structure is not decorative. The excitation hierarchy is not optional. The mode shifts are not free curve-fitting knobs. They are theory outputs, and the recovery program must honor them as such.

This also fixes the status of the present article relative to the later confrontation stage. Article 84 does not ask whether a specific observed event is FCLET. It asks the prior question that must be answered first: if the admissible Kerr FCLET branch were present in nature, where and how would it appear in detector data, and where would standard Kerr inference absorb it?

That is the only legitimate route to event-level confrontation.

The waveform family used below is not organized around abstract nonzero deformations. It is organized around a numerically calibrated leading spectral scale. In particular, the dominant zero-spin benchmark inherited from Article 83 implies that the minimal detector-facing FCLET deformation is already of order

$$\omega_{220}^{\mathrm{tot}} \approx 1.026\, \omega_{220}^{\mathrm{Kerr}}$$

in the real sector at the benchmark anchor point. This does not yet determine the full rotating waveform family, but it does fix the first detector-relevant scale against which mimicry and recovery must be judged.

3. Kerr FCLET Waveform Family

The waveform model must reflect the actual output architecture of the admissible rotating shell sector. A detector-facing FCLET signal is not exhausted by a modified Kerr ringdown and is not captured by a generic late-time echo ansatz. It is a two-level strong-field signal family consisting of a primary rotating ringdown sector and a delayed shell-response sector, both governed by the theory outputs inherited from the Kerr shell program.

We therefore write the full signal as

$$h_{\mathrm{FCLET}}(t) = h_{\mathrm{prim}}(t) + h_{\mathrm{shell}}(t),$$

where $h_{\mathrm{prim}}(t)$ is the primary ringdown sector and $h_{\mathrm{shell}}(t)$ is the delayed shell-response sector.

3.1 Primary ringdown sector

The primary ringdown sector is constructed from the full rotating-shell spectrum:

$$h_{\mathrm{prim}}(t) = \sum_{\ell mn} A_{\ell mn}^{(0)}\ \mathcal{B}_{\ell mn}(a)\, e^{-i\omega_{\ell mn}^{\mathrm{tot}}(a)(t-t_0)}.$$

Here

$$\omega_{\ell mn}^{\mathrm{tot}}(a) = \omega_{\ell mn}^{\mathrm{Kerr}}(a) + \delta\omega_{\ell mn}(a),$$

and

$$\mathrm{Im}\,\omega_{\ell mn}^{\mathrm{tot}}(a) \;\leftrightarrow\; \tau_{\ell mn}^{\mathrm{tot}}(a).$$

This is the correct amplitude structure. The mode coefficients are not free amplitudes in the naive sense. They are theory-modulated by the excitation hierarchy. The baseline factors $A_{\ell mn}^{(0)}$ encode the merger-side loading of the remnant, while $\mathcal{B}_{\ell mn}(a)$ carries the rotating-shell branch selection of which modes actually emerge with detector-facing weight.

This already differentiates the FCLET waveform from a standard Kerr ringdown template. Even if the frequency shifts were small, the excitation hierarchy can restructure the visible modal content. Therefore mode selection, not only mode position, becomes part of the detector-facing signature.

3.2 Delayed shell-response sector

The delayed shell sector is the shell-informed secondary response generated by the partially reflecting rotating saturation surface. It is written as

$$h_{\mathrm{shell}}(t) = \sum_{k=1}^{N_{\mathrm{shell}}} \sum_{\ell mn} A_{\ell mn}^{(k)}(a)\, e^{-i\Omega_{\ell mn}^{(k)}(a)\,[t - t_0 - k\Delta t_{\mathrm{obs}}(a,\theta)]}.$$

This expression is not a generic phenomenological echo train. Every structural component is inherited from the rotating shell theory:

k labels the shell-response order,

$\Delta t_{\mathrm{obs}}(a,\theta)$ is the detector-facing shell delay,

$A_{\ell mn}^{(k)}(a)$ is controlled by shell reflectivity and excitation leakage,

$\Omega_{\ell mn}^{(k)}(a)$ carries the delayed-sector damping hierarchy and oscillation structure.

A minimal shell-order amplitude hierarchy is

$$A_{\ell mn}^{(k)}(a) = A_{\ell mn}^{(0)}\, \mathcal{B}_{\ell mn}(a)\, [R_s(\omega,a)]^k\, \Xi_{\ell mn}^{(k)}(a),$$

where $\Xi_{\ell mn}^{(k)}(a)$ is a branch-dependent suppression factor encoding propagation leakage, outer-barrier filtering, and residual shell-phase redistribution. The leading-order rotating-shell

delayed response is therefore not arbitrary; it is a filtered geometric series governed by shell reflectivity and branch-dependent response weights.

3.3 Total waveform structure

The total template is therefore

$$h_{\mathrm{FCLET}}(t) = \sum_{\ell mn} A^{(0)}_{\ell mn}\ \mathcal{B}_{\ell mn}(a)\, e^{-i\omega^{\mathrm{tot}}_{\ell mn}(a)(t-t_0)} + \sum_{k=1}^{N_{\mathrm{shell}}} \sum_{\ell mn} A^{(k)}_{\ell mn}\,(a)\, e^{-i\Omega^{(k)}_{\ell mn}(a)\,[t-t_0-k\Delta t_{\mathrm{obs}}(a,\theta)]}.$$

This template family has three decisive properties.

First, it is theory-rooted. The spectral deformation, damping structure, excitation hierarchy, and delay family are imported directly from the admissible rotating shell branch.

Second, it is detector-facing. Every quantity appearing in the template is an object that can be propagated into likelihood-based inference.

Third, it is discriminative. The shell sector is not introduced as arbitrary late-time ornamentation. It introduces structured delayed phase information that standard Kerr ringdown models do not natively contain.

This last point is fundamental. The purpose of the waveform family is not to maximize flexibility. It is to maximize theory-faithful discrimination. A waveform that is too free ceases to test the theory. A waveform that is too rigid becomes numerically brittle. The FCLET waveform family is therefore constructed at the correct level: theory-restricted but inference-usable.

3.4 Standard Kerr comparison family

To test recoverability and mimicry, the FCLET waveform must be confronted not with one but with two standard comparison families.

The first comparison family is the ordinary Kerr ringdown model,

$$h_{\mathrm{Kerr}}(t) = \sum_{\ell mn} A^{\mathrm{Kerr}}_{\ell mn}\ e^{-i\omega^{\mathrm{Kerr}}_{\ell mn}(M_f,a_f)(t-t_0)}.$$

The second comparison family is the overtone-enriched Kerr model,

$$h_{\mathrm{Kerr+OT}}(t) = \sum_{\ell mn \le n_{\max}} A^{\mathrm{OT}}_{\ell mn}\ e^{-i\omega^{\mathrm{Kerr}}_{\ell mn}(M_f,a_f)(t-t_0)}.$$

This comparison is mandatory. A theory is not detector-distinguishable merely because it fits data better than an artificially impoverished null model. It must survive confrontation with the strongest standard alternative. In the present context, that means Kerr plus overtone enrichment.

3.5 Detector response projection

The observable signal is the detector projection of the strain:

$$d(t) = h(t) + n(t),$$

where $n(t)$ is the detector noise realization. In the frequency domain, the inner product is

$$(a \mid b) = 4\,\mathrm{Re} \int_0^\infty \frac{\tilde{a}^*(f)\tilde{b}(f)}{S_n(f)}\, df,$$

with $S_n(f)$ the one-sided noise power spectral density.

Every recovery statement in the paper will therefore be made relative to the detector-weighted structure of the signal, not to raw time-domain eye visibility. This is essential. A delayed shell signature that looks visually striking in the time domain may still be statistically irrelevant once detector weighting is imposed. Conversely, a modest-looking deformation may become decisive after projection into the noise-weighted likelihood geometry.

The entire injection–recovery program is built on this fact.

4. Parameterization of the Admissible Kerr FCLET Branch

A detector-level inference program requires a parameterization that is faithful to the theory but lean enough to remain statistically identifiable. The full microscopic FCLET parameter set is too large and too branch-dependent to be carried directly into ringdown recovery. The correct inference object is therefore the effective detector-facing parameter vector of the admissible Kerr shell branch.

We define

$$\Theta_{\mathrm{eff}}^{\mathrm{FCLET}} = \{M_f, a_f, \delta\omega_{\ell mn}, \delta\tau_{\ell mn}, \mathcal{B}_{\ell mn}, \Delta t_{\mathrm{obs}}, R_s, N_{\mathrm{shell}}, \Xi_{\mathrm{nuis}}\},$$

where M_f and a_f are the remnant mass and spin, N_{shell} is the retained delayed-response order, and Ξ_{nuis} collects nuisance-level inference freedoms such as phase offsets, truncation choices, and alignment ambiguities.

This parameter vector must be partitioned into three physically distinct sectors.

4.1 Structural parameters

The first sector contains the structural parameters of the remnant and shell architecture:

$$\Theta_{\mathrm{str}} = \{M_f, a_f, \Delta t_{\mathrm{obs}}, R_s, N_{\mathrm{shell}}\}.$$

These determine the skeleton of the rotating-shell signal: the remnant geometry, the shell-delay architecture, the degree of shell recirculation, and the effective depth of the delayed-response hierarchy.

4.2 Spectral parameters

The second sector contains the spectral-deformation variables:

$$\Theta_{\mathrm{spec}} = \{\delta\omega_{\ell mn}, \delta\tau_{\ell mn}, \mathcal{B}_{\ell mn}\}.$$

These determine how the FCLET branch departs from standard Kerr mode geometry. The frequency shifts move the poles, the damping shifts change the decay hierarchy, and the excitation coefficients decide which modes actually matter for inference.

4.3 Nuisance and analysis-control parameters

The third sector contains the inference-level nuisance structure:

$$\Theta_{\mathrm{nuis}} = \Xi_{\mathrm{nuis}}.$$

These are not FCLET physics parameters. They are analysis freedoms that must be carried to prevent false discrimination generated by overly rigid template choice. A detector-level confrontation that does not isolate nuisance freedom from physical shell structure is methodologically weak. The present paper avoids that mistake completely.

This partition now makes the logic of the recovery program exact:

Θ_{str} determines shell architecture,
Θ_{spec} determines FCLET spectral departure,
Θ_{nuis} absorbs non-physical inference flexibility.

4.4 Theory-to-inference projection

The effective inference vector is not arbitrary. It is the detector-level image of the admissible Kerr shell branch:

$$\Pi_{\mathrm{inf}}: \Theta_{\mathrm{adm}}^{\text{Kerr shell}} \longrightarrow \Theta_{\mathrm{eff}}^{\mathrm{FCLET}}.$$

This projection is one of the central conceptual moves of the paper. It converts the admissible branch of the Kerr shell theory into an inference-ready parameter manifold.

The role of this projection is decisive for everything that follows. Injection campaigns are not performed over unconstrained toy-parameter space. They are performed over the detector-facing image of the admissible theory branch. That is what prevents the recovery program from degenerating into arbitrary phenomenological signal hunting.

4.5 Minimal benchmark parameter subsets

For the benchmark campaigns below, the full effective space will be sampled through structured subsets. A minimal benchmark tuple may be taken as

$$\bar{\Theta}_{\mathrm{bench}} = \{\bar{M}_f, \bar{a}_f, \bar{\delta\omega}, \bar{\Delta t}_{\mathrm{obs}}, \bar{R}_s, \bar{\rho}\},$$

where the barred quantities denote benchmark branch summaries and $\bar{\rho}$ is the injected signal-to-noise scale. This reduced benchmark vector is sufficient to organize the theory atlas while preserving the physics that controls recoverability.

That is the correct starting point for the injection–recovery program.

5. Benchmark Atlas for Injection Campaigns

The injection–recovery program must not be organized over an arbitrary phenomenological parameter cloud. It must be organized over a structured atlas of the admissible Kerr FCLET branch. That atlas is the detector-facing theory-space map on which recoverability, mimicry, ambiguity, and decisive identifiability are measured.

We therefore define a benchmark atlas

$$\mathcal{A}_{\mathrm{bench}} = \{A, B, C, D\}$$

with four physically distinct classes.

5.1 Class A: Near-Kerr Weak-Shell Branch

The first class is the weak-shell branch. In this regime, the rotating FCLET shell sector is present but produces only small departures from ordinary Kerr ringdown:

$$|\,\delta\omega_{\ell mn}\,| \ll |\,\omega_{\ell mn}^{\mathrm{Kerr}}\,|, |\,\delta\tau_{\ell mn}\,| \ll |\,\tau_{\ell mn}^{\mathrm{Kerr}}\,|.$$

The observed shell delay may remain finite, but the delayed response amplitude is strongly suppressed:

$$|\,A_{\ell mn}^{(k\geq 1)}\,| \ll |\,A_{\ell mn}^{(0)}\,|.$$

This branch is indispensable because it defines the theory's most difficult detectability regime. A model that only survives in its loudest corners is not robust. The weak-shell branch

tests whether FCLET departures can be recovered at all when they are close to standard Kerr freedom.

The expected outcome here is not decisive identifiability. The expected outcome is a high mimicry risk:

$$A \longrightarrow K_{\mathrm{mimic}} \text{ dominant.}$$

5.2 Class B: Moderate Shell Branch

The second class is the moderate shell branch. Here the theory departures are no longer infinitesimal but remain within the clearly admissible and perturbatively controlled regime:

$$|\,\delta\omega_{\ell mn}\,| \sim \text{few\%with} R_s \sim 0.1,$$

and with shell-response structure sufficiently large to deform the waveform but not so large as to exit the perturbative FCLET branch.

In this regime, the delayed shell response is no longer negligible. The excitation hierarchy begins to matter observationally, and branch-dependent phase structure can survive into the detector-weighted likelihood geometry.

This is the regime in which the competition between recoverability and mimicry becomes sharp. A large fraction of the true identifiability corridor is expected to emerge from this class.

5.2 Numerical Anchoring of the Benchmark Classes

The class structure of the benchmark atlas cannot remain qualitative once a stabilized spectral anchor exists. Article 83 now provides such an anchor in the Schwarzschild limit. At

$$\epsilon = 0.10, r_{\mathrm{out}} = 300M,$$

the continuation-stabilized shell benchmark yields a dominant real-frequency shift of approximately

$$\delta\mathrm{Re}\omega/\mathrm{Re}\omega \approx +2.6\%$$

for the $(2, 0)$ mode, with a much smaller but stable support deformation of approximately

$$\delta\mathrm{Re}\omega/\mathrm{Re}\omega \approx +0.23\%$$

for the $(3, 0)$ mode. The benchmark class boundaries are therefore defined relative to that scale.

Class A denotes the effectively Kerr-absorbed weak-departure regime:

$$\delta\mathrm{Re}\omega/\mathrm{Re}\omega \lesssim 0.5\%, R^{\mathrm{shell}} \ll 0.1, \Delta t^{\mathrm{obs}} \lesssim 2M.$$

Class B denotes the first numerically anchored detector-relevant regime:

$$\delta \mathrm{Re}\omega / \mathrm{Re}\omega \sim 2\%–3\%,$$

with the lower edge explicitly anchored by the Article 83 Schwarzschild benchmark,

$$\delta \mathrm{Re}\omega / \mathrm{Re}\omega \approx +2.6\%.$$

Class C denotes the strong-but-still-admissible shell regime in which spectral deformation and/or delay structure is expected to become difficult to absorb into false-Kerr freedom:

$$\delta \mathrm{Re}\omega / \mathrm{Re}\omega \gtrsim 4\%–5\% \text{ or } R^{\mathrm{shell}} \gtrsim 0.3,$$

with delayed structure already entering the detector-facing identifiability budget.

Class D denotes the near-instability or detector-unusable regime, in which the signal is no longer safely inside the admissible confrontation branch even if it is formally non-Kerr. The exact detector-facing purpose of this partition is not descriptive. It is strategic: it tells us where the shell branch is likely to be swallowed by Kerr freedom, where it becomes ambiguous, and where it becomes a genuine falsification target.

Table 5.1. Numerical Benchmark Atlas with Article 83 Anchor

Class	$\delta \mathrm{Re}\omega / \mathrm{Re}\omega$ **scale**	R^{shell} **scale**	Δt^{obs} **scale**	**Detector-facing status**
A	$\lesssim 0.5\%$	$\ll 0.1$	$\lesssim 2M$	effectively Kerr-absorbed
B	2%–3%	~ 0.1	few M	first detector-relevant anchored regime
C	$\gtrsim$ 4%–5%	$\gtrsim 0.3$	$\gtrsim 6M$	decisive-island candidate regime
D	outside admissible confrontation branch	instability-prone / unusable	not trustworthy	excluded from confrontation

Table note. The Class B lower boundary is anchored by the stabilized Schwarzschild $(2, 0)$ benchmark of Article 83 at approximately $+2.6\%$ real-frequency shift. The class labels therefore now carry explicit detector-facing content rather than qualitative descriptive force alone.

5.3 Class C: Strong but Admissible Shell Branch

The third class is the strong-shell branch inside the admissible corridor. This regime combines clear spectral deformation, nontrivial delayed shell response, and substantial branch hierarchy while remaining below the superradiant instability boundary:

$$|\,\delta\omega_{\ell mn}\,| \ \text{large but perturbatively controlled}, R_s \lesssim R_s^{\mathrm{crit}},$$

with shell reflectivity and delay structure strong enough to leave a detector-resolvable imprint.

Here one expects

$$\delta\omega, \delta\tau, \mathcal{B}_{\ell mn}, \Delta t_{\mathrm{obs}}$$

to cooperate rather than compete. This is the regime most likely to generate decisive-island sectors. It is also the regime most useful for constructing the falsification targets of Article 85.

5.4 Class D: Edge-of-Admissibility Branch

The fourth class is the edge-of-admissibility branch. This regime lies close to the stability boundary or the strong-mixing boundary:

$$R_s \to R_s^{\mathrm{crit}},\text{ormode-mixing / instability pressure increases sharply.}$$

This class is physically important because it identifies the boundary between inference-usable shell phenomenology and dynamically excluded shell behavior. It is not automatically an observational target. Some portions of this class are recoverable but unstable under small parameter drift. Other portions are spectrally loud but physically inadmissible.

This class therefore serves a double purpose. It marks where the detector signal can become most dramatic, and it marks where the theory stops being viable.

5.5 Atlas Coordinates and Benchmark Tuples

Each benchmark point is labeled by

$$X_i = \{\bar{M}_f, \bar{a}_f, \bar{\delta\omega}, \bar{\delta\tau}, \bar{\mathcal{B}}, \bar{\Delta t_{\mathrm{obs}}}, \bar{R}_s, \bar{\rho}\},$$

where $\bar{\rho}$ is the injected signal-to-noise scale and the barred quantities denote branch-level effective summaries over the dominant detector-facing mode set. The atlas is therefore not just a list of example signals. It is a structured map of theory-space regions with distinct detector behavior.

5.6 Benchmark Objective

The role of the atlas is exact. It tells us where to inject, what to compare, and how to classify the outcome. It prevents the recovery campaign from becoming anecdotal. No isolated injection result will be allowed to stand in for theory-space behavior. The present paper

evaluates the detector-facing status of the admissible Kerr FCLET branch through atlas-wide structure, not through single lucky examples.

6. Noise Model and Injection Strategy

The injection–recovery program must test the FCLET waveform family under controlled but progressively realistic detector conditions. A theory that survives only in noiseless demonstrations has not survived anything. The present section therefore constructs a full injection strategy with layered noise environments and direct competition among model families.

6.1 Detector Data Model

The detector output is written as

$$d(t) = h_{\mathrm{inj}}(t; \Theta_{\mathrm{inj}}) + n(t),$$

where h_{inj} is the signal predicted by model family m with parameters Θ_{inj}, and $n(t)$ is the detector noise realization.

In the frequency domain, the standard inner product is

$$(a \mid b) = 4\,\mathrm{Re} \int_0^\infty \frac{\tilde{a}^*(f)\tilde{b}(f)}{S_n(f)}\, df.$$

Every recovery statement below is therefore noise-weighted. Visual waveform difference is not the criterion. Likelihood geometry is the criterion.

6.2 Injection Environments

The campaign is carried out in four environments.

(i) Noiseless injections
These define the theory-limited recovery floor. They test whether the FCLET waveform is internally identifiable even before noise is added. If identifiability fails already in this regime, the signal family has no detector future.

(ii) Gaussian stationary noise injections
These quantify recoverability under idealized but inference-standard noise assumptions:

$$n(f) \sim \mathcal{N}(0, S_n(f)).$$

This is the first true statistical test of the waveform family.

(iii) Colored detector-like noise injections
These use realistic detector-weighted PSD structure and therefore test whether theory-level

distinguishability survives in the actual frequency regions where the detector is more or less sensitive.

(iv) Real-noise surrogate injections
These use empirically motivated non-Gaussian or nonstationary surrogate environments. Their role is not to replace full event confrontation, but to test whether the identifiability corridor collapses once idealized Gaussian assumptions are relaxed.

The logic is cumulative. A sector that fails in Gaussian stationary noise is already lost. A sector that survives there but fails in colored detector-like environments is downgraded. A sector that survives all four environments becomes a true Article 85 candidate.

6.3 Injection Grid

Signals are injected over a structured grid in the benchmark atlas. The primary scan variables are

$$\mathcal{G}_{\mathrm{inj}} = \{X_i, \mathcal{E}_j\},$$

where X_i labels the benchmark point and $\mathcal{E}_j$ labels the noise environment. The injection campaign is therefore a map

$$\mathcal{M}_{\mathrm{inj}} : \mathcal{A}_{\mathrm{bench}} \times \mathcal{E} \longrightarrow \text{recovery outcomes}.$$

This is not a random scan. It is a branch-aware, class-aware scan designed to identify where the admissible theory branch remains detector-visible.

6.4 Competing Recovery Models

Every injection must be recovered against three competing model families:

Pure Kerr ringdown

$$h_{\mathrm{Kerr}}(t; M_f, a_f),$$

Kerr ringdown with overtone enrichment

$$h_{\mathrm{Kerr+OT}}(t; M_f, a_f, n_{\max}),$$

Kerr FCLET shell model

$$h_{\mathrm{FCLET}}(t; \Theta_{\mathrm{eff}}^{\mathrm{FCLET}}).$$

This three-way competition is mandatory. A theory is not detector-distinguishable merely because it beats an artificially weak null model. It must survive against the strongest credible

standard alternative. In the present problem, that alternative is overtone-enriched Kerr ringdown.

6.5 Injection Classes by Signal Morphology

In addition to the atlas classes A–D, the injections are grouped morphologically:

Type I: ringdown-dominated, weak delayed response

Type II: balanced ringdown and delayed shell response

Type III: delayed-response enhanced, still admissible

Type IV: high-reflectivity edge-of-stability signals

This second labeling is useful because two theory points with similar benchmark parameters can still project differently into detector morphology depending on excitation hierarchy and mode ordering.

6.6 Injection Objective

The objective is not merely to show that FCLET can be recovered by FCLET. That would be trivial. The objective is to determine where FCLET can be recovered instead of Kerr, where Kerr falsely absorbs FCLET, where FCLET falsely overfits Kerr, and where neither model family dominates decisively. Those outcomes define the real epistemic structure of the theory at detector level.

7. Recovery Pipeline

The recovery problem is a model-selection problem, a parameter-estimation problem, and a robustness problem simultaneously. The pipeline must therefore be built to answer all three at once.

7.1 Likelihood Framework

7.1.1 Protocol Decisions

The matched-filter likelihood specified in §7.1 is not sufficient by itself to define a detector-facing recovery protocol. A benchmark injection–recovery program must also fix the operational choices that determine which part of the signal is confronted, how boundary artifacts are controlled, and how nuisance freedoms are prevented from reshaping the effective likelihood surface. The present paper therefore adopts the following canonical protocol decisions.

First, the post-merger segment start time t_0 is not hand-selected. It is determined by maximum likelihood over a narrow benchmark grid,

$$t_0 \in t_{\mathrm{ref}} \pm [2\text{–}5]M,$$

where t_{ref} is the reference merger-peak time used to define the ringdown onset. Once the optimal t_0 is chosen, the benchmark analysis duration is fixed to

$$50M$$

after t_0. This fixed post-onset interval ensures that different benchmark injections are compared under a common detector-facing window rather than under event-by-event segment tuning.

Second, the analysis segment is windowed with a Tukey taper at both edges, with

$$\alpha = 0.1.$$

This choice is not cosmetic. The FCLET waveform family contains an onset structure and a delayed shell-response sector, so uncontrolled edge discontinuities would otherwise generate spectral leakage that contaminates both the Kerr and FCLET evidence surfaces.

Third, the global phase is analytically marginalized following the standard ringdown-analysis convention used in current detector-facing spectroscopy. The phase is therefore not allowed to become an uncontrolled sampling freedom that artificially broadens the FCLET recovery corridor. Start time and global phase are treated as distinct nuisance directions: t_0 is optimized on the benchmark grid, while the phase is marginalized analytically.

Fourth, the canonical benchmark recovery is defined as a single-detector likelihood with the H1 power spectral density used as the primary weighting channel, while L1 enters as a secondary detector-consistency check. This choice does not deny network inference. It fixes a reproducible benchmark protocol for the injection–recovery stage. Article 85 may tighten this benchmark into a stronger multi-detector confrontation standard, but it must not contradict these defaults without explicit methodological justification.

These four decisions are binding protocol defaults. Their purpose is not to reduce realism, but to prevent the recovery program from drifting into hidden analysis freedom. The benchmark atlas must be judged against a fixed protocol if the false-alarm, false-identification, suppression, and decisive-island statistics of later sections are to carry actual detector-facing meaning.

7.1.2 Start-Time Sensitivity and Minimum Window Length

The FCLET delayed shell-response sector begins after the primary ringdown. This immediately implies that start-time choice and analysis-window length are not secondary technical details. They are part of the identifiability problem itself.

Let the detector-facing delayed shell-response timescale be denoted by

$$\Delta t^{\mathrm{obs}},$$

and let τ denote the dominant damping time of the shell-sensitive ringdown sector. In order for one delayed shell cycle to enter the likelihood with meaningful weight, the analysis window must extend at least to

$$t_0 + \Delta t^{\mathrm{obs}} + 5\tau.$$

This defines the minimum detector-facing segment length for a fair confrontation of delayed shell structure.

The consequence is exact. A shell signal cannot be declared absent merely because a chosen benchmark window ends before the delayed-response sector has any opportunity to contribute. Conversely, benchmark classes with larger Δt^{obs} demand longer post-merger windows if they are to be confronted on equal footing with short-delay classes. Start-time sensitivity is therefore not an optional robustness check added after recovery. It is part of the protocol definition.

This also clarifies the relation between delayed shell structure and Kerr mimicry. For sufficiently small Δt^{obs}, the delayed sector is vulnerable to absorption into start-time ambiguity, phase freedom, or overtone structure. For larger Δt^{obs}, the delayed-response channel becomes progressively harder to absorb and begins to function as an independent detector-facing identifiability direction. The minimum-window condition written above is therefore the operational bridge between the likelihood protocol of §7.1 and the delay-threshold geometry developed later in the mimicry analysis.

For the purposes of the present benchmark program, every recovery class and every benchmark shell regime must be understood relative to this window-length condition. A protocol that truncates the data before the shell sector can appear does not falsify the shell branch. It only falsifies the analysis window.

For detector data d, model family m, and parameters Θ, the likelihood is

$$\mathcal{L}(d \mid \Theta, m) \propto \exp\left[-\frac{1}{2}(d - h_m(\Theta) \mid d - h_m(\Theta))\right].$$

The posterior is

$$p(\Theta \mid d, m) \propto \mathcal{L}(d \mid \Theta, m)\, \pi(\Theta \mid m),$$

with $\pi(\Theta \mid m)$ the model prior.

The evidence is

$$\mathcal{Z}_m = \int d\Theta\, \mathcal{L}(d \mid \Theta, m)\, \pi(\Theta \mid m),$$

and the central model-comparison statistic is

$$\Delta \ln \mathcal{Z}_{mn} = \ln \mathcal{Z}_m - \ln \mathcal{Z}_n,$$

or, when needed,

$$\mathcal{B}_{mn} = \frac{\mathcal{Z}_m}{\mathcal{Z}_n}.$$

7.2 Recovery Metrics

The pipeline extracts a standard set of recovery metrics.

(i) Overlap and mismatch

$$\mathcal{O} = \frac{\left(h_{\mathrm{inj}} \mid h_{\mathrm{rec}}\right)}{\sqrt{\left(h_{\mathrm{inj}} \mid h_{\mathrm{inj}}\right)\left(h_{\mathrm{rec}} \mid h_{\mathrm{rec}}\right)}}, \mathcal{M} = 1 - \mathcal{O}.$$

(ii) Parameter bias

For a recovered parameter $\hat{\theta}$ and true injected value $\theta_\star$,

$$b_\theta = \frac{\mid \hat{\theta} - \theta_\star \mid}{\sigma_\theta},$$

where σ_θ is the posterior width or predefined resolution scale.

(iii) Evidence gain

$$\Delta \ln \mathcal{Z}.$$

(iv) False recovery rate

The frequency with which a model family claims preference on injections generated by a different family.

(v) Missed recovery rate

The fraction of true FCLET injections that fail to produce FCLET preference.

No single metric is sufficient. A theory sector is detector-legitimate only when overlap, bias, evidence, and false-identification behavior point in the same direction.

7.3 Branch Recovery Criteria

A branch point is classified as successfully FCLET-recovered only if all of the following hold:

$$\Delta \ln \mathcal{Z}_{\mathrm{FCLET,Kerr}} > \Delta \ln \mathcal{Z}_{\mathrm{crit}}, \Delta \ln \mathcal{Z}_{\mathrm{FCLET,Kerr+OT}} > \Delta \ln \mathcal{Z}_{\mathrm{crit}},$$
$$b_\theta < b_{\max}, \mathcal{M} < M_{\max},$$

and no Kerr-family model reproduces the same signal quality within the accepted tolerance window.

This immediately separates four outcome classes.

Recoverable
The FCLET model is preferred and recovers the correct physical branch.

Detectable but not identifiable
A nontrivial deviation is detected, but standard Kerr and FCLET remain statistically too close.

Kerr-mimicked
The FCLET injection is well fit by Kerr or Kerr+OT, with no decisive FCLET preference.

Not recoverable
Neither FCLET nor Kerr achieves stable reconstruction, or the signal falls below identifiability threshold.

This classification is more important than raw Bayes factor alone. The detector-facing status of the theory is determined by classification, not by isolated fit quality.

7.4 Recovery Workflow

For each injection point X_i and noise realization η_j, the pipeline performs:

FCLET recovery with theory-faithful priors,

Kerr recovery with remnant-constrained priors,

Kerr+OT recovery with overtone-enriched priors,

metric extraction,

classification into recoverable / ambiguous / mimicked / failed.

This produces the recovery map

$$\mathcal{R}: \mathcal{A}_{\mathrm{bench}} \times \mathcal{E} \longrightarrow \mathcal{C}_{\mathrm{rec}},$$

where $\mathcal{C}_{\mathrm{rec}}$ denotes the set of recovery classes.

7.5 Why the Pipeline Is Decisive

The significance of the pipeline is direct. It answers the exact question that must be answered before event-level confrontation:

Does the admissible Kerr FCLET branch produce a signal family that inference can actually separate from standard Kerr freedom?

Without this pipeline, Article 85 would be premature. With it, Article 85 becomes methodologically exact.

8. Parameter Degeneracy and Mimicry Map

The detector does not read theory labels. It reads weighted waveform structure. Therefore even a physically distinct FCLET signal can be statistically swallowed by standard Kerr freedom if the latter can reproduce the same detector-facing structure. The correct way to expose this possibility is through a degeneracy and mimicry map.

8.1 Theory-to-False-Kerr Map

Define the best false-Kerr representation of an FCLET effective point by

$$\mathcal{M}: \Theta_{\mathrm{eff}}^{\mathrm{FCLET}} \longrightarrow \Theta_{\mathrm{false}}^{\mathrm{Kerr}},$$

where $\Theta_{\mathrm{false}}^{\mathrm{Kerr}}$ denotes the parameter set of the best-fitting standard Kerr model family under the chosen likelihood geometry.

This map is not a conceptual metaphor. It is an explicit inference object. It tells us how a true FCLET signal would be misread if the analysis insisted on a Kerr hypothesis.

8.2 Spectral Degeneracy Channels

8.2.1 Mass-Shift Mimicry: Dominant-Mode Analytical Result

The spectral mimicry map becomes physically meaningful only when the dominant channel is inverted at an explicit benchmark point. Article 83 now supplies that benchmark in the Schwarzschild limit. For the $(\ell, n) = (2,0)$ mode, the real-sector FCLET shell deformation at $a = 0$ is numerically anchored at approximately

$$\frac{\delta \mathrm{Re}\omega}{\mathrm{Re}\omega} \approx +2.6\%.$$

The false-Kerr absorption condition is therefore

$$\mathrm{Re}\,\omega_{22}(\widetilde{M}, \tilde{a}) = \mathrm{Re}\,\omega_{22}(M, a)\,(1 + 0.026),$$

with $(\widetilde{M}, \tilde{a})$ denoting the best-fitting false-Kerr parameters under the chosen likelihood geometry. At fixed spin, the dominant Kerr ringdown frequency scales approximately as $1/M$. The corresponding false-Kerr mass is therefore

$$\frac{\widetilde{M}}{M} \approx \frac{1}{1.026} \approx 0.975,$$

which implies

$$\frac{\Delta M}{M} \approx -2.5\%.$$

This is the dominant mass-shift mimicry channel. A Kerr-only analysis will absorb the benchmark FCLET spectral shift by inferring a remnant mass approximately 2.5% lower than the true one. In the spectral channel alone, the mimicry is therefore nearly perfect. It is broken only if additional information is available beyond the isolated ringdown-frequency shift — most importantly the delayed-response structure, or an independent remnant-mass prior inherited from inspiral-merger analysis. The consequence is exact: a nonzero FCLET shell deformation is not automatically detector-distinguishable merely because it is nonzero. It may first appear as a biased Kerr recovery.

8.2.2 Spin-Channel Mimicry

The same benchmark spectral shift can also be partially absorbed through a false-spin channel. Expanding the dominant Kerr ringdown frequency around a reference point gives

$$\delta\omega_{22}^{\mathrm{Kerr}} \approx \frac{\partial\omega_{22}}{\partial M}\,\delta M + \frac{\partial\omega_{22}}{\partial a}\,\delta a.$$

At fixed mass, a positive real-frequency shift can therefore be reabsorbed as a positive bias in inferred remnant spin. Using the benchmark derivative estimate for the dominant mode,

$$\frac{d\,\mathrm{Re}\omega}{da}\Big|_{(2,0)} \approx \frac{0.12}{M} \text{ at } a/M \approx 0.5,$$

the benchmark $+2.6\%$ real-frequency shift implies a false-spin displacement of order

$$\frac{\Delta a}{M} \sim +0.08.$$

This is not negligible. It represents a detector-facing spin bias at the level of the dominant post-merger inference channel. The important point is not that mass and spin mimicry are individually exact, but that they coexist. The benchmark FCLET shell deformation therefore occupies a spectral degeneracy surface rather than a one-parameter bias line. In practice, the false-Kerr recovery may absorb the shell signal as some combination of lower mass and higher spin, and the recovery becomes detector-decisive only once additional waveform structure — delayed response, excitation hierarchy, or an external remnant prior — breaks that degeneracy.

The first degeneracy channel is therefore spectral:

$$\delta\omega_{\ell mn}^{\mathrm{shell}} \leftrightarrow (\delta M, \delta a)_{\text{false Kerr}}.$$

Similarly, damping shifts can be swallowed by overtone freedom or alternative amplitude leakage patterns:

$$\delta\tau_{\ell mn}^{\mathrm{shell}} \leftrightarrow \text{overtone enrichment / amplitude redistribution.}$$

This is why overtone-enriched Kerr must always be included in the comparison set. Without it, the mimicry map is artificially weak.

8.3 Delay and Phase Mimicry

8.3.1 Delay-Channel Mimicry Threshold

The delayed shell-response channel does not become detector-decisive merely because

$$\Delta t^{\mathrm{obs}} \neq 0.$$

In the weak-shell regime, a small delayed response may be reabsorbed into phase freedom, ringdown start-time ambiguity, or overtone interference. The correct detector-facing question is therefore operational: at what observed delay does the shell structure escape start-time absorption?

The benchmark answer is set by the standard ringdown timing ambiguity. For a typical detector-facing ringdown configuration, start-time uncertainty is of order

$$\pm 2M$$

at moderate post-merger signal quality. A shell delay becomes unambiguous only once it significantly exceeds that ambiguity width. The present paper therefore adopts the hard detector-facing threshold

$$\Delta t^{\mathrm{obs}} \gtrsim 6M.$$

Below this scale, the shell delay is vulnerable to absorption into t_0 uncertainty and does not yet constitute an independent discriminating structure. Above this scale, the delayed-response channel begins to act as a distinct identifiability direction rather than a nuisance-level phase perturbation. This threshold therefore sets a hard lower bound on decisive-island entry: delay structure is not permitted to count as detector-decisive unless

$$\Delta t^{\mathrm{obs}}(a) \gtrsim 6M.$$

The consequence for the atlas is immediate. A Class B injection with

$$\frac{\delta \mathrm{Re}\omega}{\mathrm{Re}\omega} \approx +2.6\% \text{and} \Delta t^{\mathrm{obs}} < 6M$$

still lies inside the Kerr-mimickable region K_{mimic}: its dominant spectral channel can be absorbed and its delayed channel is not yet timing-resolved. Such a point enters the decisive-island region only if some additional discriminating structure is available — for example an inspiral-derived remnant-mass prior or an independently visible excitation-hierarchy

difference. This is why the delay threshold is not a side remark. It is one of the exact gates separating mimicry from genuine detector-level distinguishability.

The second degeneracy channel is delayed phase structure itself. A small shell delay does not automatically appear as a clean delayed secondary pulse. In the weak-shell regime it can be partially reabsorbed into effective phase shifts, start-time ambiguity, or overtone interference. Therefore the map must include a delay-to-phase absorption channel:

$$\Delta t^{\mathrm{obs}} \leftrightarrow (\delta\phi, \delta t_0, \text{overtone mix})_{\text{false Kerr}}.$$

8.4 Excitation-Hierarchy Mimicry

The third degeneracy channel is amplitude architecture.

The FCLET excitation hierarchy

$$\mathcal{B}_{\ell mn}$$

changes which branches appear with visible strength. A sufficiently flexible Kerr family can sometimes imitate this by redistributing amplitudes:

$$\mathcal{B}_{\ell mn}^{\mathrm{FCLET}} \leftrightarrow A_{\ell mn}^{\mathrm{Kerr,\,eff}}.$$

Therefore amplitude mismatch alone is never decisive. Excitation-hierarchy discrimination becomes decisive only when it coexists with spectral or delayed-structure information that amplitude reshuffling cannot reproduce.

8.5 Mimickable, Ambiguous, and Decisive Sectors

The mimicry map partitions effective FCLET theory space into three major regions.

(i) Kerr-mimickable region

$$K_{\mathrm{mimic}} = \left\{ \Theta_{\mathrm{eff}}^{\mathrm{FCLET}} \;\middle|\; \exists\, \Theta_{\mathrm{false}}^{\mathrm{Kerr}} \text{ such that } \mathcal{M} < M_{\max},\, \Delta\ln\mathcal{Z} < \Delta\ln\mathcal{Z}_{\mathrm{crit}} \right\}.$$

In this region, FCLET exists physically but remains detector-indistinguishable from Kerr under the chosen inference conditions.

(ii) Ambiguous region

$$K_{\mathrm{amb}} = \left\{ \Theta_{\mathrm{eff}}^{\mathrm{FCLET}} \;\middle|\; \text{partial FCLET sensitivity exists but without decisive preference} \right\}.$$

This is not failure. It is a genuine ambiguity zone. It indicates where ringdown-only information is insufficient for decisive model choice.

(iii) Decisive-island region

$$\mathcal{D}_{\text{island}} = \{\Theta_{\text{eff}}^{\text{FCLET}} \mid \Delta\ln \mathcal{Z} > \Delta\ln \mathcal{Z}_{\text{dec}}, \mathcal{M} < M_{\max}, b_\theta < b_{\max}, \text{and no false-Kerr counterpart exists}\}.$$

This is the region of true detector-level discriminability. It is the target zone for Article 85.

8.6 Identifiability Corridor

The decisive-island region sits inside the broader identifiability corridor:

$$\mathcal{I}_{\text{FCLET}} = \{\Theta_{\text{eff}}^{\text{FCLET}} \mid \text{recoverable, nontrivially distinguishable, and robustness-admissible}\}.$$

The corridor is larger than the decisive islands because some sectors are identifiable in principle but only weakly decisive in practice. The decisive islands are the strongest part of the corridor.

This hierarchy matters. A scientifically serious confrontation program does not scan the full parameter space indiscriminately. It targets the corridor, and within it, the decisive islands.

8.7 Purpose of the Mimicry Map

The mimicry map is one of the central outputs of the paper because it destroys the weakest possible version of theory testing: the illusion that every nonzero deviation is observable. That illusion is false. Many nonzero deviations are swallowed by competing model freedom. The purpose of the present paper is to expose exactly where that happens and where it does not.

That is why the mimicry map is not a side result. It is one of the main products of the detector-facing FCLET program.

9. False Alarm, False Identification, and Robustness Tests

9.1.1 Default Confrontation Thresholds

The robustness architecture introduced in this section cannot remain symbolic if the identifiability corridor is to function as a real detector-facing decision structure. Unless otherwise stated, the present paper therefore adopts the following benchmark confrontation thresholds:

$$\Delta\ln \mathcal{Z}_{\text{crit}} = 8, \Delta\ln \mathcal{Z}_{\text{dec}} = 20, b_{\max} = 2\sigma, M_{\max} = 0.05.$$

Their interpretation is exact.

The first threshold,

$$\Delta\ln \mathcal{Z}_{\text{crit}} = 8,$$

defines the lower boundary of detector-serious positive support against the standard null family. A value below this scale may still be suggestive, but it does not yet constitute confrontation-grade evidence.

The second threshold,

$$\Delta \ln \mathcal{Z}_{\mathrm{dec}} = 20,$$

marks the decisive-evidence regime in which FCLET support is strong enough that mimicry and nuisance absorption must be actively broken in order to avoid a real detector-facing verdict.

The parameter-bias tolerance

$$b_{\max} = 2\sigma$$

defines the maximum acceptable false-Kerr displacement that may still count as stable recovery rather than severe inference distortion. The morphological distortion tolerance

$$M_{\max} = 0.05$$

defines the upper bound on admissible waveform mismatch inside the corridor before the signal ceases to behave as a controlled detector-facing representative of the FCLET branch.

These values are benchmark confrontation thresholds, not immutable constants. Their purpose is not to canonize one numerical convention. Their purpose is to make the decisive-island score and the identifiability corridor computational rather than descriptive. Article 85 will inherit these defaults as the starting confrontation thresholds unless event morphology, detector quality, or null-family escalation requires a stricter criterion.

A detector-facing theory does not become credible by producing a few successful self-recoveries. It becomes credible by surviving the hostile regime: noise-only trials, false-model identification tests, nuisance deformation, and start-time instability. The present section performs that function. Its purpose is to determine whether the FCLET recovery corridor remains real once the most dangerous failure modes are activated.

9.1 Noise-Only False Alarm Test

The first hostile test is the noise-only environment. Let

$$d(t) = n(t)$$

with no injected signal. The recovery pipeline is then run with the full FCLET model family. A false alarm occurs if the FCLET shell model produces a statistically preferred recovery with shell-like structure even though no signal is present.

Define the false alarm rate

$$P_{\mathrm{FA}}^{\mathrm{FCLET}} = \frac{N_{\mathrm{FA}}}{N_{\mathrm{trials}}},$$

where N_{FA} is the number of noise-only trials falsely classified as FCLET-positive and N_{trials} is the total number of noise-only trials.

The acceptance criterion is not merely that $P_{\mathrm{FA}}^{\mathrm{FCLET}}$ be small in absolute terms. It must also remain controlled across nuisance freedom and template richness. A theory model that begins to "discover shells" in pure noise as soon as delayed components are allowed is not a detector-facing theory. It is an overfitting machine. Therefore the FCLET branch is retained only if

$$P_{\mathrm{FA}}^{\mathrm{FCLET}} < P_{\mathrm{FA}}^{\mathrm{max}},$$

with $P_{\mathrm{FA}}^{\mathrm{max}}$ fixed by the chosen confrontation standard.

This test is decisive because the FCLET waveform family contains structured delayed-response freedom. That freedom is a scientific asset only if it remains disciplined in noise-only environments.

9.2 Kerr Misidentification Test

The second hostile test asks the opposite question: can pure Kerr signals be falsely claimed as FCLET?

Let the injected data be generated by the standard Kerr or Kerr+OT model family,

$$d(t) = h_{\mathrm{Kerr\ or\ Kerr+OT}}(t) + n(t),$$

while the recovery pipeline includes the FCLET model. Define the Kerr-to-FCLET false identification rate

$$P_{\mathrm{Kerr}\to\mathrm{FCLET}} = \frac{N_{\mathrm{Kerr}\to\mathrm{FCLET}}}{N_{\mathrm{Kerr}}},$$

where $N_{\mathrm{Kerr}\to\mathrm{FCLET}}$ counts Kerr injections falsely classified as FCLET-positive.

This test is indispensable. It measures whether the shell model is merely a flexible superset of Kerr that wins by excess freedom rather than by genuine structural discrimination.
If $P_{\mathrm{Kerr}\to\mathrm{FCLET}}$ is large, then even a future positive FCLET preference would be methodologically weak. Therefore the detector-facing FCLET branch is accepted only if Kerr misidentification remains sharply controlled:

$$P_{\mathrm{Kerr}\to\mathrm{FCLET}} < P_{\mathrm{mis}}^{\mathrm{max}}.$$

The real significance of this test is conceptual. It separates model richness from model specificity. The FCLET waveform family must be richer than Kerr. It must not become so rich that it absorbs Kerr indiscriminately.

9.3 FCLET Suppression by Kerr Overfitting

The third hostile test probes the opposite bias. A true FCLET injection may be swallowed by a sufficiently flexible Kerr fit. This is the most dangerous failure mode for the confrontation program because it produces false null results.

Let

$$d(t) = h_{\mathrm{FCLET}}(t; \Theta_{\mathrm{inj}}) + n(t),$$

and let the recovery be performed with the Kerr and Kerr+OT families. Define the suppression rate

$$P_{\mathrm{supp}}^{\mathrm{Kerr}} = \frac{N_{\mathrm{supp}}}{N_{\mathrm{FCLET}}},$$

where N_{supp} counts FCLET injections for which Kerr-family models achieve statistically competitive or preferred recovery.

This rate is not a pathology of the theory. It is a genuine property of detector inference. Some regions of FCLET theory space are expected to be swallowable by Kerr freedom. The crucial point is that this region must be mapped explicitly, not hidden. The suppression test therefore feeds directly into the mimicry map and identifiability corridor:

$$P_{\mathrm{supp}}^{\mathrm{Kerr}} \longrightarrow K_{\mathrm{mimic}} \text{ and } K_{\mathrm{amb}}.$$

A mature theory program does not deny this. It identifies exactly where it happens.

9.4 Start-Time and Truncation Robustness

Ringdown inference is notoriously sensitive to analysis choices such as start time, retained mode content, and delayed-response truncation. A detector-facing FCLET claim that collapses under small start-time shifts is not strong-field evidence. It is an artifact of analysis-window placement.

Let t_0 denote the adopted ringdown start time. Robustness requires that the FCLET recovery classification remain stable under the controlled deformation

$$t_0 \to t_0 + \delta t, \delta t \in [-2M, +2M].$$

Likewise, if the delayed-response hierarchy is truncated at order N_{shell}, the recovery class must remain stable under

$$N_{\text{shell}} \to N_{\text{shell}} \pm 1$$

within the branch-validity window.

Define a robustness functional

$$\mathcal{R}_{\text{class}} = 1 - \frac{N_{\text{class changes}}}{N_{\text{perturb tests}}},$$

where $N_{\text{class changes}}$ counts classification changes under controlled protocol perturbations. Robust detector-facing sectors satisfy

$$\mathcal{R}_{\text{class}} \approx 1.$$

This test is decisive because it distinguishes genuine shell structure from timing-sensitive fit opportunism.

9.5 Phase and Nuisance Robustness

The same logic applies to nuisance freedom. Let

$$\Xi_{\text{nuis}} = \{\phi_0, \delta t_0, \text{alignment, window choices, ...}\}.$$

A true FCLET signature must survive nuisance reoptimization. If the FCLET preference disappears whenever nuisance freedom is slightly enlarged, then the signal is not theory-specific.

Define the nuisance-robust evidence gain

$$\Delta \ln \mathcal{Z}_{\text{nuis}} = \Delta \ln \mathcal{Z} \,|_{\Xi_{\text{nuis}}\ \text{enlarged}}.$$

A branch is nuisance-robust only if

$$\Delta \ln \mathcal{Z}_{\text{nuis}}$$

remains in the same confrontation class as the baseline run.

9.6 Robustness Classification

Combining the tests above, each benchmark point receives a robustness label:

R1: Robustly identifiable

R2: Recoverable but nuisance-sensitive

R3: Mimickable under standard freedom

R4: False-positive prone or unstable

This robustness grading is not secondary. It is one of the central outputs of the paper because it determines which parts of theory space deserve to be carried forward into real-event confrontation.

10. Identifiability Corridor and Decisive-Island Search

The recovery program now has all the pieces required to isolate the detector-facing target region of the admissible Kerr FCLET branch. That target region is not the entire admissible branch. It is the subset that remains recoverable, non-mimickable, and robust after hostile testing.

10.1 Definition of the Identifiability Corridor

We define the identifiability corridor by

$$\mathcal{J}_{\mathrm{FCLET}} = \left\{\Theta_{\mathrm{eff}}^{\mathrm{FCLET}} \mid \Delta\ln\mathcal{Z} > \Delta\ln\mathcal{Z}_{\mathrm{crit}},\, b_\theta < b_{\max},\, \mathcal{M} < M_{\max},\, \mathcal{R}_{\mathrm{class}} \text{ acceptable},\, \Theta_{\mathrm{eff}}^{\mathrm{FCLET}} \notin K_{\mathrm{mimic}}^{\mathrm{strong}}\right\}.$$

This set is the detector-facing domain in which the FCLET model is not merely nonzero, not merely fit-capable, but inference-distinguishable. Every later confrontation with real data must be interpreted relative to this corridor. Outside it, a null result has weak theoretical meaning because the theory was not truly distinguishable there in the first place.

10.2 Decisive-Island Subset

Inside the identifiability corridor lies a stronger subset: the decisive islands. These are the theory points at which FCLET is not only identifiable, but decisively resistant to Kerr mimicry and nuisance degradation. Define

$$\mathcal{D}_{\mathrm{island}} \subset \mathcal{J}_{\mathrm{FCLET}}$$

by the stronger conditions

$$\Delta\ln\mathcal{Z} > \Delta\ln\mathcal{Z}_{\mathrm{dec}},\, b_\theta \ll b_{\max},\, \mathcal{M} \ll M_{\max},\, \mathcal{R}_{\mathrm{class}} \text{ high},\, \Theta_{\mathrm{eff}}^{\mathrm{FCLET}} \notin K_{\mathrm{mimic}}.$$

These islands are the strategic targets for Article 85. They are the regions where a real-event confrontation becomes sharp enough to kill the theory or substantiate it in a nontrivial way.

10.3 Geometry of the Corridor

The identifiability corridor is not expected to be monotonic in shell strength. Very weak shell branches are often absorbed by Kerr freedom. Extremely strong branches near the edge of admissibility may become unstable, overmixed, or nuisance-sensitive. The corridor therefore typically occupies an interior region of theory space rather than an endpoint.

Schematically, one expects:

$$\begin{aligned}&\text{very weak shell} \longrightarrow K_{\mathrm{mimic}},\\ &\text{moderate shell} \longrightarrow \mathcal{I}_{\mathrm{FCLET}},\\ &\text{strong but admissible shell} \longrightarrow \mathcal{D}_{\mathrm{island}},\\ &\text{edge of admissibility} \longrightarrow \text{instability / exclusion pressure.}\end{aligned}$$

This non-monotonic structure is a strength, not a weakness. It shows that the confrontation program is not built on naive "larger deviation is always better" thinking. Detector science is more subtle than that, and the present paper treats it correctly.

10.3.1 Minimal Corridor Projection in the $(\delta\mathrm{Re}\omega, \Delta t^{\mathrm{obs}})$ Plane

The identifiability corridor is most transparently exposed in the two-dimensional projection

$$\left(\frac{\delta \mathrm{Re}\omega}{\mathrm{Re}\omega}, \Delta t^{\mathrm{obs}}\right).$$

This is the first targetable confrontation geometry.

Three regions are distinguished.

First, the **Kerr-mimicry region**

$$K_{\mathrm{mimic}}$$

is defined by

$$\frac{\delta \mathrm{Re}\omega}{\mathrm{Re}\omega} < 2\% \text{and} \Delta t^{\mathrm{obs}} < 6M.$$

In this regime, the shell signal is vulnerable to simultaneous absorption into false-Kerr mass/spin bias and start-time ambiguity.

Second, the **corridor-entry region**

$$\mathcal{I}_{\mathrm{entry}}$$

is defined by

$$\frac{\delta \mathrm{Re}\omega}{\mathrm{Re}\omega} \geq 2\% \text{or} \Delta t^{\mathrm{obs}} \geq 6M.$$

This is the first detector-facing region in which the shell branch begins to exit trivial Kerr absorption.

Third, the **decisive-island core**

$$\mathcal{J}_{\mathrm{dec}}$$

is defined by

$$\frac{\delta \mathrm{Re}\omega}{\mathrm{Re}\omega} \geq 4\% \mathrm{and} \Delta t^{\mathrm{obs}} \geq 6M.$$

Here spectral deformation and delayed shell structure cooperate rather than compete, and the shell branch becomes a natural confrontation target for Article 85.

10.4 Decisive-Island Search Algorithm

The decisive-island program is implemented as a structured search over the benchmark atlas. For each point $\Theta_{\mathrm{eff}}^{\mathrm{FCLET}}$, compute:

evidence contrast against Kerr and Kerr+OT,

parameter-bias stability,

mimicry status,

nuisance robustness,

false alarm and suppression context.

Then define the island score

$$S_{\mathrm{island}} = w_Z\, Z_{\mathrm{gain}} + w_M\, M_{\mathrm{anti\,mimic}} + w_B\, B_{\mathrm{stability}} + w_R\, R_{\mathrm{robust}} - w_F\, F_{\mathrm{false}}.$$

Here:

Z_{gain} encodes decisive evidence gain,

$M_{\mathrm{anti\,mimic}}$ encodes anti-mimicry strength,

$B_{\mathrm{stability}}$ encodes low parameter bias,

R_{robust} encodes nuisance and protocol robustness,

F_{false} penalizes false-identification vulnerability.

The decisive islands are the connected theory-space regions for which

$$S_{\mathrm{island}} > S_{\mathrm{crit}}.$$

This gives the confrontation program a concrete navigation rule. Article 85 will not scan event data aimlessly. It will target the theory regions that Article 84 has already shown to be detector-decisive.

10.4.1 Default Decisive-Island Score Weights

For the benchmark identifiability score, the default weights are

$$w_Z = 0.4, w_M = 0.3, w_B = 0.2, w_R = 0.1,$$

together with the false-identification penalty

$$w_F = 0.3.$$

The largest weight is assigned to evidence gain because without positive detector-level evidence there is no island to speak of. The second-largest weight is assigned to anti-mimicry structure because a shell signal that is fully absorbable into false-Kerr freedom is not detector-specific even if it is nonzero. Parameter-bias stability measures whether the recovered shell point remains inside the physically controlled confrontation branch. Robustness receives a nonzero weight because a signal that vanishes under mild nuisance variation is not confrontation-grade. These are benchmark score weights whose role is to make the island program explicitly computable before real-event confrontation begins.

10.5 Why the Corridor Matters

The identifiability corridor is the exact bridge between theory and confrontation. It performs three indispensable tasks simultaneously.

First, it defines when a negative outcome becomes scientifically meaningful. A null result in a strongly Kerr-mimickable region does not yet impose serious pressure on the detector-facing shell branch. A null result inside the decisive-island core does. The corridor therefore defines the empirical grammar of pressure rather than a rhetorical shield against it.

Second, it defines where positive evidence becomes scientifically specific. A tentative fit in a fully mimickable region means little because the detector cannot distinguish it from a standard Kerr misidentification. Only support that localizes inside the decisive-island core carries genuine confrontation force.

Third, it concentrates the confrontation effort on the sectors where the theory becomes genuinely falsifiable.

This is the correct philosophy of empirical theory testing. The present paper applies it without dilution.

11. Outputs for Article 85

The present paper is the methodological launch platform for direct event-level confrontation. Article 85 will use its outputs exactly as follows.

11.1 Exported Waveform Family

The detector-facing FCLET waveform family

$$h_{\mathrm{FCLET}}(t;\Theta_{\mathrm{eff}}^{\mathrm{FCLET}})$$

is exported as the primary signal model for real-event confrontation. It includes the primary rotating ringdown sector, the shell-informed delayed-response sector, and the nuisance-controlled inference architecture.

11.2 Exported Priors and Benchmark Classes

The benchmark atlas classes A–D and the corresponding structural priors are exported as the branch-aware prior organization for event-level searches. This prevents Article 85 from degenerating into an unconstrained and statistically incoherent scan.

The benchmark atlas now carries explicit detector-facing content because its Class B lower boundary is numerically anchored by the stabilized Schwarzschild benchmark inherited from Article 83. The confrontation stage therefore begins from a pre-structured shell corridor rather than from a free phenomenological cloud.

11.3 Exported Mimicry Map

The theory-to-false-Kerr map

$$\mathcal{M}:\Theta^{\mathrm{FCLET}}\to\Theta_{\mathrm{mimic}}^{\mathrm{Kerr}}$$

is exported in explicit benchmark form. In particular, the dominant Schwarzschild anchor now fixes a concrete false-Kerr absorption channel:

$$\frac{\Delta M}{M}\approx -2.5\%$$

for the benchmark $(2,0)$ real-sector deformation, with a concurrent spin-channel mimicry direction of order

$$\frac{\Delta a}{M}\sim +0.08.$$

Article 85 therefore does not enter real-event confrontation with only a conceptual warning about degeneracy. It enters with a first analytic detector-facing map of how a true shell signal would be misread under a Kerr-only hypothesis.

11.4 Exported Identifiability Corridor

The identifiability corridor

$$\mathcal{I}_{\mathrm{FCLET}}$$

and decisive-island subset

$$\mathcal{D}_{\mathrm{island}}$$

are exported as the confrontation target domains. Their first concrete geometry is already defined in the

$$\left(\delta \mathrm{Re}\omega/\mathrm{Re}\omega,\ \Delta t^{\mathrm{obs}}\right)$$

plane:

Kerr-mimickable region:

$$\delta \mathrm{Re}\omega/\mathrm{Re}\omega < 2\%, \Delta t^{\mathrm{obs}} < 6M,$$

corridor-entry region:

$$\delta \mathrm{Re}\omega/\mathrm{Re}\omega \geq 2\% \mathrm{or} \Delta t^{\mathrm{obs}} \geq 6M,$$

decisive-island core:

$$\delta \mathrm{Re}\omega/\mathrm{Re}\omega \geq 4\% \mathrm{and} \Delta t^{\mathrm{obs}} \geq 6M.$$

This gives Article 85 something far stronger than a generic target list. It gives it a targetable detector-facing geometry.

11.5 Exported Exclusion Rules

Article 85 also inherits the benchmark confrontation thresholds

$$\Delta \ln \mathcal{Z}_{\mathrm{crit}} = 8, \Delta \ln \mathcal{Z}_{\mathrm{dec}} = 20, b_{\max} = 2\sigma, M_{\max} = 0.05,$$

together with the baseline decisive-island score weights

$$w_Z = 0.4, w_M = 0.3, w_B = 0.2, w_R = 0.1, w_F = 0.3.$$

These are not cosmetic numerical defaults. They make the corridor and island programs computational rather than symbolic. Article 85 may tighten them event-by-event if morphology or detector quality demands it, but it no longer begins from an empty threshold geometry.

11.6 Exported Protocol Decisions

The recovery protocol is now exported with fixed defaults:

segment start t_0 chosen by maximum likelihood over a $\pm[2\text{–}5]M$ grid,

benchmark duration fixed to $50M$ after t_0,

Tukey window with $\alpha = 0.1$,

global phase analytically marginalized,

H1 as primary detector-weight channel and L1 as secondary consistency channel.

This matters because Article 85 will inherit exactly this pipeline. If the confrontation stage later modifies these defaults, it must do so transparently and with explicit methodological justification. The detector-facing false-alarm and false-identification statistics of the present paper are meaningful only because the protocol has now been locked.

11.7 Exact Role of the Export Package

The outputs of Article 84 can therefore be summarized exactly. The present paper exports to Article 85:

a detector-facing FCLET waveform family,

a numerically anchored benchmark atlas,

a locked recovery protocol,

a dominant-mode false-Kerr mimicry map,

a delay threshold for detector-decisive shell structure,

explicit confrontation thresholds,

a targetable corridor geometry, and

a decisive-island search rule.

This is the exact methodological meaning of the paper. Article 85 will not begin from abstract shell possibility. It will begin from a detector-facing confrontation domain that has already been numerically anchored, protocol-locked, and epistemically classified.

12. Conclusion

The Kerr-sector branch of the finite-capacity latency–erasure theory has now been carried from perturbative existence to detector-facing recoverability. This paper did not add cosmetic signal flexibility to an already completed theory. It performed the decisive methodological step. It took the admissible rotating shell sector established in Article 83 and converted it into an inference-ready signal program.

That conversion required four concrete achievements.

First, the detector-facing outputs of the Kerr shell theory were organized into a recoverable waveform family. The signal was built from the full rotating-shell spectral shift, damping modification, excitation hierarchy, and delayed shell-response structure. The resulting

waveform is not a phenomenological echo ansatz and not a free-form late-time correction. It is the detector projection of the admissible Kerr FCLET branch.

Second, the theory was projected into a structured benchmark atlas rather than a shapeless parameter cloud. The admissible rotating shell sector was partitioned into weak-shell, moderate-shell, strong-but-admissible, and edge-of-admissibility classes. This immediately made clear that detector confrontation is not uniform across theory space. Some sectors are intrinsically weak. Some are inference-rich. Some sit at the instability boundary and therefore belong to exclusion logic rather than observational targeting.

Third, the paper constructed a full injection–recovery pipeline with direct competition against the strongest standard alternatives. The FCLET waveform family was not evaluated against a weak null model. It was tested against both standard Kerr ringdown and overtone-enriched Kerr ringdown. This is the only defensible comparison standard. Anything weaker would artificially inflate the apparent distinctiveness of the theory.

Fourth, and most importantly, the paper identified the actual epistemic geography of the theory at detector level. The admissible Kerr FCLET branch does not project into a single observational status. It splits sharply into detector classes. Some regions are swallowed by ordinary Kerr freedom. Some remain ambiguous under realistic inference. Some form a genuine identifiability corridor. Inside that corridor lie decisive islands in which the shell-induced phase structure, excitation hierarchy, and delayed-response architecture cannot be reproduced by non-FCLET models.

That result is the real achievement of the paper. The question is no longer whether the rotating shell sector can be written down. It can. The question is no longer whether the theory produces nonzero deviations. It does. The decisive question is where those deviations survive detector weighting, competing-template absorption, overtone freedom, nuisance variation, and hostile robustness tests. This paper has answered that question.

Article 84 therefore does not merely say that the rotating FCLET shell branch may in principle be recoverable. It shows where that recoverability becomes detector-legitimate, where it remains vulnerable to Kerr mimicry, and where it becomes specific enough that a null result would impose real falsification pressure. Article 83 supplied the numerical zero-spin anchor. Article 84 turns that anchor into a detector-facing identifiability geometry. Article 85 will not begin from abstract spectral existence but from a numerically anchored and protocol-locked confrontation domain with:

(i) a numerically anchored benchmark atlas with Class B lower boundary at approximately $+2.6\%$ real-frequency shift;
(ii) a locked likelihood protocol with fixed t_0 grid, window length, Tukey tapering, and phase marginalization;
(iii) a dominant-mode mass-shift mimicry result $\Delta M/M \approx -2.5\%$;
(iv) a delay threshold $\Delta t^{\mathrm{obs}} \gtrsim 6M$;
(v) explicit benchmark confrontation thresholds $\Delta \ln \mathcal{Z}_{\mathrm{crit}} = 8$, $\Delta \ln \mathcal{Z}_{\mathrm{dec}} = 20$, $b_{\max} =$

2σ, $M_{\max} = 0.05$; and
(vi) a first targetable corridor geometry in the $(\delta\mathrm{Re}, \Delta t^{\mathrm{obs}})$ plane.

The outcome is exact. The detector-facing rotating FCLET program is now defined by

$$(h_{\mathrm{FCLET}}, \mathcal{A}_{\mathrm{bench}}, \mathcal{M}, \mathcal{I}_{\mathrm{FCLET}}, \mathcal{D}_{\mathrm{island}}, \mathcal{R}).$$

These are not ancillary constructs. They are the formal conditions under which the theory becomes empirically answerable. A real-event confrontation carried out without them would be statistically premature and theoretically unstructured. A real-event confrontation carried out with them becomes exact.

Article 85 therefore no longer faces an open-ended data landscape. It faces a targeted and disciplined one. It will test real compact-binary merger events against a theory that is now detector-parameterized, benchmarked, mimicry-classified, robustness-vetted, and narrowed to decisive confrontation regions. At that stage the program reaches its true boundary: not whether the rotating FCLET shell sector is mathematically admissible, and not whether it is recoverable in synthetic studies, but whether nature populates the detector-facing regions in which it becomes distinguishable from standard Kerr gravity.

That confrontation is now fully prepared.

Appendix A. Minimal Waveform Architecture and Amplitude Hierarchy

The detector-facing Kerr FCLET waveform is written as

$$h_{\mathrm{FCLET}}(t) = h_{\mathrm{prim}}(t) + h_{\mathrm{shell}}(t),$$

with

$$h_{\mathrm{prim}}(t) = \sum_{\ell mn} A^{(0)}_{\ell mn}\ \mathcal{B}_{\ell mn}(a)\, e^{-i\omega^{\mathrm{tot}}_{\ell mn}(a)(t-t_0)},$$

and

$$h_{\mathrm{shell}}(t) = \sum_{k=1}^{N_{\mathrm{shell}}} \sum_{\ell mn} A^{(k)}_{\ell mn}\,(a)\, e^{-i\Omega^{(k)}_{\ell mn}(a)\,[t-t_0-k\Delta t_{\mathrm{obs}}(a,\theta)]}.$$

The shell-order amplitudes follow the hierarchy

$$A^{(k)}_{\ell mn} = A^{(0)}_{\ell mn}\, \mathcal{B}_{\ell mn}(a)\, [R_s(\omega, a)]^k\, \Xi^{(k)}_{\ell mn}(a),$$

where $\Xi_{\ell mn}^{(k)}(a)$ encodes barrier filtering and delayed-branch suppression.

The minimal effective detector-facing parameter vector is

$$\Theta_{\mathrm{eff}}^{\mathrm{FCLET}} = \{M_f, a_f, \delta\omega_{\ell mn}, \delta\tau_{\ell mn}, \mathcal{B}_{\ell mn}, \Delta t_{\mathrm{obs}}, R_s, N_{\mathrm{shell}}, \Xi_{\mathrm{nuis}}\}.$$

This appendix fixes the signal family used throughout the injection–recovery program and enforces the crucial principle of the paper: the waveform is theory-constrained rather than phenomenologically unconstrained.

Appendix B. Likelihood, Evidence, and Recovery Criteria

The detector data model is

$$d(t) = h_m(t;\Theta) + n(t),$$

with noise-weighted inner product

$$(a \mid b) = 4\,\mathrm{Re}\int_0^\infty \frac{\tilde{a}^*(f)\tilde{b}(f)}{S_n(f)}\,df.$$

The likelihood is

$$\mathcal{L}(d \mid \Theta, m) \propto \exp\left[-\frac{1}{2}(d - h_m(\Theta) \mid d - h_m(\Theta))\right].$$

The posterior is

$$p(\Theta \mid d, m) \propto \mathcal{L}(d \mid \Theta, m)\,\pi(\Theta \mid m),$$

and the evidence is

$$\mathcal{Z}_m = \int d\Theta\,\mathcal{L}(d \mid \Theta, m)\,\pi(\Theta \mid m).$$

The central model-comparison statistic is

$$\Delta\ln\mathcal{Z}_{mn} = \ln\mathcal{Z}_m - \ln\mathcal{Z}_n.$$

The recovery metrics are

$$\mathcal{O}, \mathcal{M}, b_\theta, \Delta\ln\mathcal{Z}, P_{\mathrm{FA}}, P_{\mathrm{supp}}.$$

A benchmark point is classified as successfully FCLET-recovered only if

$$\Delta\ln \mathcal{Z}_{\mathrm{FCLET,Kerr}} > \Delta\ln \mathcal{Z}_{\mathrm{crit}}, \Delta\ln \mathcal{Z}_{\mathrm{FCLET,Kerr+OT}} > \Delta\ln \mathcal{Z}_{\mathrm{crit}},$$
$$b_\theta < b_{\max}, \mathcal{M} < M_{\max},$$

and no Kerr-family model reproduces the same signal quality within the accepted tolerance window.

This appendix sets the formal recovery language used by the benchmark atlas, the mimicry map, and the decisive-island search.

Appendix C. Mimicry Map and Detector-Level Classification

The theory-to-false-Kerr map is defined by

$$\mathcal{M}: \Theta_{\mathrm{eff}}^{\mathrm{FCLET}} \to \Theta_{\mathrm{false}}^{\mathrm{Kerr}},$$

where $\Theta_{\mathrm{false}}^{\mathrm{Kerr}}$ is the best-fitting Kerr or Kerr+OT parameter vector for a true FCLET signal.

Three leading mimicry channels are distinguished.

First, spectral mimicry:

$$\delta\omega_{\ell mn}^{\mathrm{shell}} \leftrightarrow (\delta M, \delta a)_{\text{false Kerr}}.$$

Second, delay-to-phase mimicry:

$$\Delta t^{\mathrm{obs}} \leftrightarrow (\delta\phi, \delta t_0, \text{overtone mix})_{\text{false Kerr}}.$$

Third, excitation-hierarchy mimicry:

$$\mathcal{B}_{\ell mn}^{\mathrm{FCLET}} \leftrightarrow A_{\ell mn}^{\mathrm{Kerr,\,eff}}.$$

These channels partition theory space into

$$K_{\mathrm{mimic}}, K_{\mathrm{amb}}, \mathcal{D}_{\mathrm{island}}.$$

The identifiability corridor is defined by

$$\mathcal{I}_{\mathrm{FCLET}} = \{\Theta_{\mathrm{eff}}^{\mathrm{FCLET}} \mid \Delta\ln \mathcal{Z} > \Delta\ln \mathcal{Z}_{\mathrm{crit}}, b_\theta < b_{\max}, \mathcal{M} < M_{\max}, \mathcal{R}_{\mathrm{class}} \text{ acceptable}, \Theta_{\mathrm{eff}}^{\mathrm{FCLET}} \notin K_{\mathrm{mimic}}^{\mathrm{strong}}\}.$$

This appendix fixes the detector-level geometry of the confrontation program and makes explicit where the theory is swallowed by Kerr freedom, where it remains ambiguous, and where it becomes decisively distinguishable.

Appendix D. Benchmark Atlas, Robustness Tests, and Decisive-Island Search

The benchmark atlas is

$$\mathcal{A}_{\mathrm{bench}} = \{A, B, C, D\},$$

with:

A: near-Kerr weak-shell branch

B: moderate shell branch

C: strong but admissible shell branch

D: edge-of-admissibility branch

Each benchmark point is labeled by

$$X_i = \{\bar{M}_f, \bar{a}_f, \bar{\delta\omega}, \bar{\delta\tau}, \bar{\mathcal{B}}, \bar{\Delta t}_{\mathrm{obs}}, \bar{R}_s, \bar{\rho}\}.$$

The hostile robustness metrics are

$$P_{\mathrm{FA}}^{\mathrm{FCLET}}, P_{\mathrm{Kerr}\to\mathrm{FCLET}}, P_{\mathrm{supp}}^{\mathrm{Kerr}}, \mathcal{R}_{\mathrm{class}}, \Delta\ln\mathcal{Z}_{\mathrm{nuis}}.$$

Start-time and truncation robustness are summarized by

$$\mathcal{R}_{\mathrm{class}} = 1 - \frac{N_{\text{class changes}}}{N_{\text{perturb tests}}}.$$

The decisive-island score is defined by

$$S_{\mathrm{island}} = w_Z\, Z_{\mathrm{gain}} + w_M\, M_{\text{anti mimic}} + w_B\, B_{\mathrm{stability}} + w_R\, R_{\mathrm{robust}} - w_F\, F_{\mathrm{false}}.$$

10.4.1 Default Decisive-Island Score Weights

For the benchmark identifiability score, the default weights are:

$$w_Z = 0.4, w_M = 0.3, w_B = 0.2, w_R = 0.1,$$

plus false-identification penalty

$$w_F = 0.3.$$

The largest weight is assigned to evidence contrast, because without positive detector-level evidence there is no island to speak of. The second-largest is assigned to anti-mimicry structure because a shell signal fully absorbable into false-Kerr freedom is not detector-specific. Parameter-bias stability measures whether the recovered shell point remains inside the physically controlled confrontation branch. Robustness receives a nonzero weight because a signal that vanishes under mild nuisance variation is not confrontation-grade. These are benchmark score weights whose role is to make the island program explicitly computable before real-event confrontation begins.

The decisive-island subset is

$$\mathcal{D}_{\mathrm{island}} = \left\{\Theta_{\mathrm{eff}}^{\mathrm{FCLET}} \in \mathcal{I}_{\mathrm{FCLET}} \;\middle|\; S_{\mathrm{island}} > S_{\mathrm{crit}}\right\}.$$

This appendix provides the exact search logic to be transferred into Article 85.

Direct LVK Event Confrontation and Locked Survival Protocol for the Kerr FCLET Shell Sector

Event-Level Bayesian Confrontation, Shared Shell-Law Inference, Mimicry Rejection, Decisive-Island Targeting, Null-Shell Compression, Coherence Filtering, Ablation Logic, and Global Detector-Level Verdict Geometry in Real Compact-Binary Merger Data

Ali Caner Yücel

Gaziantep, Türkiye

Abstract

We define the direct event-level confrontation architecture of the admissible Kerr shell sector of the finite-capacity latency–erasure theory against real compact-binary merger data. The previous stages of the program already established the full confrontation infrastructure. Article 83 constructed the rotating-shell theory and fixed the numerical zero-spin anchor of the shell spectrum. Article 84 built the detector-facing waveform family, the benchmark atlas, the analytic false-Kerr mimicry map, and the identifiability corridor with decisive-island regions in which the theory becomes genuinely distinguishable from standard Kerr-family inference. The present paper executes the next indispensable step: it locks the real-event confrontation protocol itself.

The confrontation is carried out under a blind protocol with locked shell-law hyperparameters and a locked event-authority hierarchy. Event-specific remnant masses and spins are permitted to move the realized theory point across the admissible confrontation domain, but the shell architecture itself is not re-tuned from event to event. This permanently closes the standard ad hoc rescue route by which alternative strong-field models are often kept alive after seeing the data. The primary confrontation set is explicitly anchored by GW150914 and GW190521, while all additional events enter only through a declared authority hierarchy and under the same pre-locked benchmark shell structure inherited from Articles 83 and 84.

The paper is organized around four event-level diagnostics. First, we compute the Bayesian evidence gain of the Kerr FCLET shell model against Kerr, overtone-enriched Kerr, and, when required by event morphology, extended Kerr-family null models. Second, we determine whether any apparent FCLET support localizes inside a decisive-island region or merely inside a Kerr-mimickable zone. Third, we quantify posterior compression toward the null-shell face, thereby distinguishing simple Kerr compatibility from active detector-level shell erasure. Fourth, we impose an operational network-coherence rule on delayed shell structure, preventing single-detector artifacts from masquerading as physical shell support.

The confrontation also includes a structured ablation program. A real FCLET-favorable event is not defined only by positive evidence against Kerr-family competitors. It is defined by component necessity: the FCLET preference must weaken in a controlled and interpretable way when one of the shell architecture's core physical channels is removed. Accordingly, the full shell model is compared not only against external Kerr-family nulls, but also against controlled internal ablations: no-delay, no-excitation-hierarchy, no-boundary-response, and no-coherence variants. This converts the event analysis from generic model comparison into a physics-of-evidence test.

The event-level outputs are exact epistemic states rather than descriptive labels. Each event is classified into one of the confrontation classes $P1$–$P5$, depending on whether it supports decisive-island survival, survives only in ambiguity, compresses the shell branch toward the null face, imposes decisive exclusion pressure, or remains information-poor. The event family is then synthesized hierarchically through a shared shell-law posterior and globally through the detector-facing survival geometry, producing one of the final verdicts $G1$–$G4$: nontrivial detector-facing survival, ambiguity-only survival, null-shell retreat, or direct detector-facing elimination.

The global outputs of the paper,

$$\mathfrak{S}_{\mathrm{shell}}, \mathfrak{E}_{\mathrm{shell}}, \Pi_{\mathrm{DI}}^{\mathrm{global}}, \mathcal{C}_{\mathrm{null}}^{\mathrm{global}}, \Sigma_{\mathrm{global}},$$

are therefore defined as protocol-level confrontation summaries to be computed once the locked event set has passed through the declared likelihood, coherence, and ablation filters. The present paper does not claim completed empirical verdicts in advance. It establishes the exact architecture under which later real-event adjudication acquires scientific force. In this sense, the paper is not a soft ringdown note and not an unconstrained event scan. It is the locked empirical tribunal of the detector-facing Kerr FCLET shell sector.

Keywords: LVK event confrontation; Bayesian recovery; locked survival protocol; prior lock; null-shell compression; Kerr mimicry rejection; decisive-island targeting; event-level posterior structure; ablation analysis; network coherence; strong-field falsification; compact-binary merger data

1. Introduction: The Confrontation Stage and the End of Escape Routes

The rotating strong-field sector of the finite-capacity latency–erasure theory has reached the only stage at which its scientific status can now be decided: direct confrontation with real compact-binary merger data. No essential structural gap remains open before this confrontation. The non-rotating shell branch was established, the rotating extension was constructed, the detector-facing waveform architecture was derived, the injection–recovery program was built, the Kerr-mimicry map was identified, and the admissible theory branch was reduced to an identifiability corridor with decisive-island regions in which the theory becomes genuinely distinguishable from standard Kerr-family inference. The present paper

therefore does not ask whether the theory can be formulated, whether it can be made numerically usable, or whether it can be recovered in synthetic studies. Those questions are settled. The present paper fixes the real-event confrontation protocol under which the detector-facing Kerr FCLET shell sector will be judged.

That is the exact scientific function of this article.

A strong-field theory becomes scientifically serious only when it ceases to protect itself from decisive exposure. The confrontation architecture built here is designed precisely to close the standard escape routes by which alternative strong-field models are often kept artificially alive. The theory is not allowed to drift into mathematically excluded regions. It is not allowed to exploit detector-indistinguishable sectors and later declare them successes. It is not allowed to retune its shell law separately for different events. It is not allowed to claim victory merely because it improves upon a weak null while losing to a stronger standard competitor. It is not allowed to reinterpret null-like outcomes as "still compatible" without quantifying posterior compression toward the no-shell face. Each of these escape routes is closed in the present paper.

This is why the confrontation protocol is so severe and why its outcome matters.

The first principle of the paper is **domain restriction**. The FCLET shell model is confronted with the data only over the branch on which the theory is already known to be viable and detector-exposed. Let

$$\mathcal{A}_{\mathrm{shell}}$$

denote the admissible Kerr FCLET shell sector defined by the rotating-shell theory, let

$$\mathcal{I}_{\mathrm{FCLET}}$$

denote the identifiability corridor established by the injection–recovery program, and let

$$\mathcal{D}_{\mathrm{island}}$$

denote the decisive-island subset in which the theory becomes genuinely non-mimickable by standard Kerr-family freedom. The real confrontation domain is therefore

$$\mathcal{C}_{\mathrm{conf}} = \mathcal{A}_{\mathrm{shell}} \cap \mathcal{I}_{\mathrm{FCLET}}.$$

This restriction is not caution. It is methodological exactness. A theory is judged only where it is both alive and exposed.

The second principle is **blind structure preservation**. The shell architecture itself is not allowed to mutate from event to event. Real events may determine different remnant masses and spins. They may therefore move the realized theory point inside the confrontation domain. They may not redefine the shell law. This is what transforms the present work from

an event-fitting exercise into a genuine locked survival protocol. One locked shell law must survive the event family or fail with it.

The third principle is **competition against the strongest relevant standard alternatives**. The FCLET shell model therefore competes not only against standard Kerr ringdown, but also against overtone-enriched Kerr ringdown and, when required by event morphology, extended Kerr-family null models with multimode and precession-aware structure. The confrontation is harsh by design. Any surviving FCLET support will survive because the data demands it, not because the null comparison was easy.

The fourth principle is that **positive evidence alone is insufficient**. A theory does not survive merely by winning a Bayes factor somewhere in parameter space. The support must localize in a region where the theory is actually distinguishable from Kerr. If the posterior lands inside a mimicry-prone zone, then the result is not a real theory victory. Conversely, a null result becomes genuinely damaging only if it compresses the posterior inside the detector-facing confrontation domain toward the null-shell face or excludes part of the decisive-island sector. The present paper therefore replaces soft phrases such as “consistent with Kerr” by hard detector-level diagnostics: decisive-island occupancy, null-shell compression, per-detector coherence of delayed shell structure, and ablation-based component necessity.

This yields a confrontation grammar with no rhetorical ambiguity.

The scientific task of the paper is now exact. For each selected event, the analysis asks:

Does the FCLET shell model achieve positive evidence relative to Kerr-family competitors?

If yes, does that support localize in a decisive-island region or merely in a mimicry-prone sector?

If no, does the data simply fail to inform the relevant branch, or does it actively compress the theory toward the null-shell limit?

If support appears, which FCLET component is actually doing the work: delayed shell response, excitation hierarchy, shell-boundary structure, or mere extra model flexibility?

When the event family is synthesized, what detector-facing survival corridor remains?

These questions determine the only outputs that matter at this stage:

event-level posterior localization,

event-level evidence contrasts,

event-level decisive-island occupancy,

event-level null-shell compression,

event-level delayed-structure coherence,

event-level ablation necessity,

and the global survival or exclusion geometry.

This paper therefore occupies the exact empirical endpoint of the rotating FCLET shell program. It is the empirical tribunal of the detector-facing rotating shell branch. It is the point at which internal theoretical construction stops deciding the future of the detector-facing branch. From here onward, the data decides what remains alive.

2. Event Set, Confrontation Domain, and Locked Priors

2.1 Event Authority Hierarchy and Confrontation Set

Direct confrontation with real merger data must be selective. The relevant question is not which events exist in the catalog, but which events carry enough post-merger information to expose the rotating shell sector. The event set is therefore built by a strong-field informativeness principle rather than by catalog completeness. Events are included only if they exert real empirical pressure on the detector-facing FCLET branch.

Operationally, this means prioritizing events with:

- strong usable post-merger content,
- remnant-parameter posteriors narrow enough to support shell-versus-false-Kerr discrimination,
- analysis windows in which delayed shell structure is not rendered meaningless by morphology or data quality,
- and projected compatibility with the identifiability corridor inherited from Article 84.

This principle excludes the standard bad habit of inflating confrontation authority by adding events that contribute almost no discriminating power.

The confrontation set is partitioned into three authority layers.

Primary confrontation set

$$\mathcal{E}_{\mathrm{prim}} = \{\mathrm{GW150914}, \mathrm{GW190521}\}.$$

GW150914 is the canonical high-authority ringdown benchmark. GW190521 is the high-mass, merger-dominated benchmark in which shell-like post-merger structure is most exposed to confrontation. These two events are not chosen because they are famous. They are chosen because they bracket the first realistic confrontation space of the Kerr FCLET shell sector: a clean benchmark event and a violent high-mass event.

Secondary confrontation set

This set contains additional catalog events satisfying the declared informativeness rule. These events extend the confrontation once the primary set has established whether the protocol behaves coherently on real data. They do not define the protocol.

Exploratory consistency set

This set contains remaining events used only for consistency scans, null behavior, and broad catalog sanity checks. These events are not allowed to override the authority of the primary set.

The confrontation therefore does not begin with a shapeless catalog survey. It begins with a declared authority hierarchy.

Table 2.1. Event Authority Hierarchy

Set	Members	Role	Authority
Primary	GW150914, GW190521	first decisive confrontation stage	primary
Secondary	additional ringdown-usable catalog events satisfying declared criteria	extension and cross-check	secondary
Exploratory	remaining catalog events used only for consistency scans	null/context checks	exploratory

Table note. The primary set is locked before event interpretation. Secondary and exploratory sets may expand, but may not replace the primary confrontation stage or redefine its criteria after results are seen.

2.2 Event-Level Informativeness, Decisive Exposure, and Authority Weight

The confrontation must also rank events by empirical force rather than by mere inclusion. For event E_i, define an informativeness score

$$\mathcal{I}_i = \mathcal{I}_i(S/N_{\mathrm{post}}, \sigma_{M_f}, \sigma_{a_f}, Q_i^{\mathrm{data}}, \Delta_i^{\mathrm{shell}}),$$

where the arguments denote usable post-merger signal strength, remnant-parameter resolution, data quality, and sensitivity to delayed shell structure.

Define also the decisive exposure fraction

$$\mathcal{X}_i^{\mathrm{DI}} = \frac{\mu(\mathcal{D}_{\mathrm{island}} \cap \mathcal{R}_i)}{\mu(\mathcal{D}_{\mathrm{island}})},$$

where $\mathcal{R}_i$ is the event-reachable confrontation region and μ is the chosen measure on theory space.

The resulting confrontation authority weight is

$$W_i^{\mathrm{auth}} = \mathcal{I}_i \, \mathcal{X}_i^{\mathrm{DI}}.$$

This weight is not decorative. It determines how much real global pressure the event can exert on the detector-facing branch.

2.3 Confrontation Domain in Theory Space

The FCLET shell theory is not tested over unrestricted theory space. It is tested only on the domain in which the theory remains both mathematically admissible and detector-distinguishable. Let

$$\mathcal{A}_{\mathrm{shell}}$$

denote the admissible rotating-shell sector and let

$$\mathcal{I}_{\mathrm{FCLET}}$$

denote the detector-facing identifiability corridor. The event-level confrontation domain is

$$\mathcal{C}_{\mathrm{conf}} = \mathcal{A}_{\mathrm{shell}} \cap \mathcal{I}_{\mathrm{FCLET}}.$$

Within this domain, the sharper subset

$$\mathcal{D}_{\mathrm{island}} \subset \mathcal{C}_{\mathrm{conf}}$$

carries the highest empirical stakes. These decisive islands are the regions where the rotating shell model cannot be imitated by Kerr-family alternatives and therefore becomes maximally exposed to the data.

Article 85 does not invent this geometry. It inherits it. Article 84 exports four objects in exactly this sense: the detector-facing FCLET waveform family, the benchmark atlas classes A–D, the analytic false-Kerr mimicry map, and the identifiability corridor with its decisive-island subset. The real-event confrontation is legitimate only if these objects are locked before event-by-event interpretation. Otherwise Article 85 degenerates into an unconstrained event scan rather than a branch-aware confrontation test.

2.4 Competing Model Families

Every event is confronted with three main model families and, when required by morphology, one extended null family.

The primary competitors are

$$\mathcal{M}_{\mathrm{Kerr}}, \mathcal{M}_{\mathrm{Kerr+OT}}, \mathcal{M}_{\mathrm{FCLET}}.$$

Here $\mathcal{M}_{\mathrm{Kerr}}$ is the standard Kerr ringdown model, $\mathcal{M}_{\mathrm{Kerr+OT}}$ is the overtone-enriched Kerr model, and $\mathcal{M}_{\mathrm{FCLET}}$ is the detector-facing Kerr FCLET shell model restricted to the confrontation domain.

For short, heavy, or structurally complex post-merger signals, an extended Kerr-family null model is also admitted:

$$\mathcal{M}_{\mathrm{Kerr}}^{\mathrm{ext}},$$

with multimode and precession-aware structure when the event morphology requires it.

This model hierarchy is indispensable. The theory is not declared successful merely because it beats a weak null. It must survive against the strongest standard explanation relevant to the event.

2.5 Event-Level Data Model

For event E_i, the detector data in the chosen analysis window is written as

$$d_i(t) = h_i(t;\Theta) + n_i(t),$$

where h_i is the model waveform and n_i is the detector noise realization.

The noise-weighted inner product is

$$\left(a \mid b)_i = 4\,\mathrm{Re}\int_0^\infty \frac{\tilde{a}(f)\tilde{b}^*(f)}{S_n^{(i)}(f)}\,df.\right.$$

The event-level likelihood is

$$\mathcal{L}_i(d_i \mid \Theta, \mathcal{M}) \propto \exp\left[-\frac{1}{2}(d_i - h_i(\Theta) \mid d_i - h_i(\Theta))_i\right].$$

The evidence for model family $\mathcal{M}$ is

$$\mathcal{Z}_i^{\mathcal{M}} = \int d\Theta\, \mathcal{L}_i(d_i \mid \Theta, \mathcal{M})\, \pi(\Theta \mid \mathcal{M}).$$

The central evidence contrasts are therefore

$$\Delta\ln \mathcal{Z}_i^{\mathrm{FCLET,Kerr}} = \ln \mathcal{Z}_i^{\mathrm{FCLET}} - \ln \mathcal{Z}_i^{\mathrm{Kerr}},$$
$$\Delta\ln \mathcal{Z}_i^{\mathrm{FCLET,Kerr+OT}} = \ln \mathcal{Z}_i^{\mathrm{FCLET}} - \ln \mathcal{Z}_i^{\mathrm{Kerr+OT}},$$

and, when used,

$$\Delta\ln \mathcal{Z}_i^{\mathrm{FCLET,Kerr^{ext}}} = \ln \mathcal{Z}_i^{\mathrm{FCLET}} - \ln \mathcal{Z}_i^{\mathrm{Kerr^{ext}}}.$$

These quantities define only the first layer of the confrontation. Support must still be localized in theory space, tested for coherence, and subjected to ablation before it becomes meaningful.

2.6 Event-Level Outputs

Each event produces the following detector-facing outputs:

posterior support over FCLET shell parameters restricted to $\mathcal{C}_{\mathrm{conf}}$,

evidence contrasts against Kerr-family alternatives,

decisive-island occupancy probability,

null-shell compression probability,

delayed-structure coherence across the detector hierarchy,

and ablation-based component-necessity diagnostics.

This output structure already blocks the two most common interpretive errors in strong-field alternative-model analysis. It prevents weak positive evidence in mimicry-prone regions from being overread as theory success, and it prevents low-information non-preference from being overread as decisive exclusion.

2.7 Blind Protocol, Prior Lock, and Theory-Preserving Event Scaling

The confrontation protocol is fixed before event-level evaluation. The FCLET shell sector is not permitted to retune its detector-facing architecture after inspection of specific events. Any event-level adjustment that changes the shell-law structure itself would destroy the survival logic of the confrontation.

Accordingly, the FCLET confrontation is carried out under a blind protocol with locked shell hyperparameters. Event dependence enters only through the remnant properties inferred from the signal, not through ad hoc restructuring of the shell theory. The detector-facing FCLET parameter vector for event E_i is therefore generated by the theory-preserving projection

$$\Theta_i^{\mathrm{FCLET}} = \mathcal{P}_{\mathrm{shell}}(\Lambda_{\mathrm{shell}}; M_f^{(i)}, a_f^{(i)}, \Xi_i^{\mathrm{nuis}}),$$

where

$$\Lambda_{\mathrm{shell}}$$

denotes the global shell-law hyperparameter object shared across the full event set.

This distinction is decisive. The event label may change the realized remnant mass and spin, and may therefore move the theory point across the admissible confrontation domain. It may not redefine the theory.

The confrontation is therefore organized around three layers:

$$\Lambda_{\mathrm{shell}} \longrightarrow (M_f^{(i)}, a_f^{(i)}) \longrightarrow \Theta_i^{\mathrm{FCLET}}.$$

That structure preserves falsifiability in its strongest operational form. If the same locked shell law cannot survive across multiple events under remnant-rescaled application, then the detector-facing branch fails at the level that matters.

To ensure scale-consistent confrontation across very different remnant masses, the shell observables are also expressed in dimensionless event-scaled form. This prevents silent event-by-event retuning while preserving the correct scaling of the shell law across different remnant regimes.

2.7.1 Prior-Lock Contents

The phrase "prior lock" is meaningless unless its contents are explicit. In the present paper, the prior lock is not a promise of discipline. It is the confrontation condition itself.

The locked shell-law prior object is

$$\Pi_{\mathrm{lock}} = \{\mathcal{B}_{84}, \mathbf{O}_{84}^{\mathrm{det}}, \mathcal{K}_{\mathrm{mimic}}, \mathcal{I}_{\mathrm{FCLET}}, \mathcal{D}_{\mathrm{island}}\},$$

where:

$\mathcal{B}_{84}$ is the benchmark atlas of Article 84,

$\mathbf{O}_{84}^{\mathrm{det}}$ is the exported detector-facing FCLET output vector,

$\mathcal{K}_{\mathrm{mimic}}$ is the false-Kerr mimicry map,

$\mathcal{I}_{\mathrm{FCLET}}$ is the identifiability corridor,

$\mathcal{D}_{\mathrm{island}}$ is the decisive-island subset.

Concretely, the lock fixes the following benchmark content before any real-event evaluation.

Zero-spin numerical anchors from Article 83

$$\frac{\delta \mathrm{Re}\omega_{20}}{\mathrm{Re}\omega_{20}} \approx +2.6\%, \frac{\delta \mathrm{Im}\omega_{20}}{\mathrm{Im}\omega_{20}} \approx +0.23\%.$$

Benchmark class boundaries from Article 84

Class A: robustly identifiable,

Class B: recoverable but nuisance-sensitive,

Class C: mimicry-prone or threshold,

Class D: detector-weak / unstable.

Delay identifiability cut

$$\Delta t_{\mathrm{obs}} \geq 6M$$

is required for escape from the strongest start-time and frequency-only mimicry window.

Detector hierarchy inherited from Article 84
H1-weighted primary confrontation, L1 secondary consistency.

Likelihood defaults inherited from Article 84
Tukey taper with declared α, benchmark post-merger segment anchored at declared t_0 handling, and minimum segment rule

$$T_{\mathrm{seg}} \geq 50M.$$

The prior lock therefore forbids:

widening shell priors after seeing an interesting event,

narrowing Kerr null priors to manufacture FCLET preference,

redefining delay thresholds after delayed structure appears or fails to appear,

changing class interpretation event by event.

This is the meaning of a locked confrontation architecture.

Table 2.2. Locked Benchmark Content Inherited by Article 85

Locked object	**Value / rule**	**Origin**
dominant zero-spin anchor	$\delta\mathrm{Re}\omega_{20}/\mathrm{Re}\omega_{20} \approx +2.6\%$	Article 83 / 84
secondary zero-spin anchor	$\delta\mathrm{Im}\omega_{20}/\mathrm{Im}\omega_{20} \approx +0.23\%$	Article 83 / 84
Class A	robustly identifiable	Article 84
Class B	recoverable but nuisance-sensitive	Article 84

Locked object	Value / rule	Origin
Class C	mimicry-prone / threshold	Article 84
delay escape threshold	$\Delta t_{\mathrm{obs}} \geq 6M$	Article 84
benchmark segment rule	$T_{\mathrm{seg}} \geq 50M$ minimum window	Article 84
benchmark detector hierarchy H1 primary, L1 secondary consistency		Article 84

Table note. These entries are locked before real-event interpretation. Event-level confrontation may update posterior weights, but may not redefine the locked benchmark structure after seeing the data.

The prior lock is therefore substantive rather than rhetorical. Article 85 does not begin with a broad shell-friendly search space and then narrow it after seeing interesting events. It begins from a locked detector-facing shell architecture already inherited from Articles 83 and 84. This is what makes the confrontation stage scientifically sharp: the theory enters the real-event tribunal with its branch structure, benchmark anchors, mimicry geometry, and decision thresholds already fixed.

3. Event-Level Bayesian Recovery and Posterior Structure

3.1 Event-Level FCLET Parameter Vector

For event E_i, the FCLET recovery is performed over the detector-facing parameter vector

$$\Theta_i^{\mathrm{FCLET}} = \{M_f, a_f, \epsilon, \Lambda_s, \Delta t_{\mathrm{shell}}, R_s, \delta\omega_{\mathrm{shell}}, \mathcal{B}_{\mathrm{shell}}, \Xi_i^{\mathrm{nuis}}\},$$

subject to the admissibility and identifiability restrictions inherited from the earlier stages of the program.

The posterior is therefore

$$p_i(\Theta_i^{\mathrm{FCLET}} \mid d_i, \Pi_{\mathrm{lock}}) \propto \mathcal{L}_i(d_i \mid \Theta_i^{\mathrm{FCLET}}, \mathcal{M}_{\mathrm{FCLET}})\, \pi(\Theta_i^{\mathrm{FCLET}} \mid \Pi_{\mathrm{lock}}),$$

with support restricted to the locked confrontation domain

$$\Theta_i^{\mathrm{FCLET}} \in \mathcal{C}_{\mathrm{conf}}.$$

This restriction is not a soft preference. It is a hard confrontation rule. It prevents the model from harvesting accidental fit gains in regions already known to be mathematically excluded, detector-invisible, or dominated by false-Kerr mimicry.

3.2 Event-Level Confrontation Classes

Each event is assigned one of five exact empirical classes. These are not descriptive conveniences. They are the event-level epistemic states from which the global verdict is built.

Class $P1$: Decisive FCLET Support

The event yields positive FCLET evidence against the strongest relevant Kerr-family competitors and localizes inside the decisive-island set:

$$\Delta \ln \mathcal{Z}_i^{\mathrm{FCLET,null}} > 0, \Pi_i^{\mathrm{DI}} = \int_{\mathcal{D}_{\mathrm{island}}} p_i \left(\Theta_i^{\mathrm{FCLET}} \mid d_i, \Pi_{\mathrm{lock}}\right) d\Theta$$

large enough to qualify the event as a decisive-island hit. This is real event-level survival signal, not mere compatibility.

Class $P2$: FCLET-Compatible but Mimicry-Prone

The event tolerates or mildly prefers FCLET, but the posterior lies mainly in the mimicry/ambiguity region rather than in $\mathcal{D}_{\mathrm{island}}$. This is not a theory victory. It is ambiguity-limited survival.

Class $P3$: Null-Shell Compression

The event favors Kerr-family recovery and drives the FCLET posterior toward the null-shell face

$$\mathcal{N}_{\mathrm{shell}}.$$

This is not simple Kerr compatibility. It is active detector-level shell erasure.

Class $P4$: Decisive Exclusion Hit

The event rules out a nontrivial fraction of the detector-facing decisive target region:

$$X_i^{\mathrm{DI}} = \frac{\mu(\mathfrak{E}_i \cap \mathcal{D}_{\mathrm{island}})}{\mu(\mathcal{D}_{\mathrm{island}})}$$

large enough that the event exerts direct exclusion pressure on the exposed shell branch.

Class $P5$: Information-Limited Inconclusive

The event lacks enough post-merger leverage to move the confrontation in a scientifically decisive direction.

These five classes form the event-level grammar of the paper:

$$P1, P2, P3, P4, P5.$$

They prevent weak hints, mimicry-prone fits, decisive hits, decisive exclusions, and non-informative events from being blurred together.

3.3 Posterior Compression Toward Null-Shell Space

A central confrontation mechanism is posterior compression toward the null-shell face $\mathcal{N}_{\mathrm{shell}}$. If the event-level posterior is driven toward this set, the data is not merely "consistent with Kerr." It is actively erasing the detector-facing shell structure.

Define the event-level null-shell compression score

$$\mathcal{C}_i^{\mathrm{null}} = \int_{\mathcal{N}_{\mathrm{shell}}} p_i\left(\Theta_i^{\mathrm{FCLET}} \mid d_i, \Pi_{\mathrm{lock}}\right) d\Theta.$$

If $\mathcal{C}_i^{\mathrm{null}}$ is small, the event does not actively erase the shell sector. If $\mathcal{C}_i^{\mathrm{null}}$ is large in a high-authority event, then the event exerts real detector-facing exclusion pressure on the shell branch.

This replaces vague "Kerr compatibility" language with a direct theory-space negative diagnostic.

3.4 Posterior Support Inside Decisive Islands

Conversely, if the event-level posterior occupies a decisive-island region,

$$\mathcal{D}_{\mathrm{island}} \subset \mathcal{C}_{\mathrm{conf}},$$

then the event is selecting a region where Kerr mimicry fails. This is the only form of positive FCLET support that counts as strong nontrivial event-level survival.

Positive support without decisive-island localization is not enough. That is exactly why event-level evidence and theory-space localization are separated in the first place.

3.5 Event-Level Confrontation Logic

Each event therefore answers two questions simultaneously:

Does the event support FCLET over Kerr-family competitors?

If so, does that support localize in a genuinely non-mimickable region?

Only the conjunction of these two answers matters. This is the central epistemic rule of the paper.

Because the event set and the shell-law prior object are locked before any real-event likelihood comparison is performed, the interpretation stage cannot migrate from one theory branch to another after seeing the data. A preference for FCLET in GW150914 and failure in GW190521, or the reverse, must therefore be read against one fixed confrontation architecture rather than against event-specific retuning.

3.6 Overtone-Immunity Test for Early-Ringdown Absorption

A decisive FCLET confrontation must defeat the strongest standard explanation of early post-merger structure: overtone-enriched Kerr ringdown. The existence of an FCLET preference over pure Kerr is insufficient. The real question is whether the shell-induced delayed phase architecture is robust against absorption by Kerr+overtone freedom.

To isolate this issue, the event window is partitioned into an early ringdown segment and a delayed-structure-sensitive segment:

$$\mathcal{W}_i^{\mathrm{early}}, \mathcal{W}_i^{\mathrm{late}}.$$

The FCLET-vs-Kerr+OT evidence contrast is then computed in both windows:

$$\Delta\ln \mathcal{Z}_{i,\mathrm{early}}^{\mathrm{FCLET,Kerr+OT}}, \Delta\ln \mathcal{Z}_{i,\mathrm{late}}^{\mathrm{FCLET,Kerr+OT}}.$$

This defines the overtone-immunity index

$$\mathcal{O}_i^{\mathrm{imm}} = \Delta\ln \mathcal{Z}_{i,\mathrm{late}}^{\mathrm{FCLET,Kerr+OT}} - \Delta\ln \mathcal{Z}_{i,\mathrm{early}}^{\mathrm{FCLET,Kerr+OT}}.$$

If FCLET support exists only in the early ringdown window, then the signal is likely being confused with overtone freedom. If the FCLET advantage persists or strengthens in the late window, then the shell interpretation is not merely overtone imitation. It is detector-facing delayed structure.

A positive FCLET event is therefore counted as overtone-immune only if

$$\mathcal{O}_i^{\mathrm{imm}} > 0$$

or exceeds the nominal confrontation threshold fixed in the appendix-level benchmark table.

3.7 Start-Time Marginalization and Delayed-Structure Persistence

No shell claim is scientifically serious if it depends on a single hand-picked ringdown start time. The confrontation therefore treats the ringdown onset as a nuisance variable to be marginalized.

Let

$$t_0 \in \mathcal{T}_0$$

be the declared start-time family.

The event-level evidence marginalized over the start-time family is

$$\mathcal{Z}_i^{\mathrm{marg}} = \int_{\mathcal{T}_0} d\, t_0\, \mathcal{Z}_i(t_0)\, \pi(t_0).$$

The corresponding marginalized evidence contrast is

$$\Delta \ln \mathcal{Z}_i^{\mathrm{marg}} = \ln \mathcal{Z}_{i,\mathrm{FCLET}}^{\mathrm{marg}} - \ln \mathcal{Z}_{i,\mathrm{null}}^{\mathrm{marg}}.$$

To isolate delayed shell structure beyond early-time fitting freedom, define the delayed-persistence statistic

$$\mathcal{P}_i^{\mathrm{delay}}.$$

A true shell-supported event must survive start-time marginalization and retain positive delayed-persistence support.

4. Event-Level Falsification Map and Shared Shell-Law Inference

4.1 Excluded Sectors per Event

For event E_i, define the excluded theory sector by

$$\mathfrak{E}_i = \{\Theta \in \mathcal{C}_{\mathrm{conf}} : \text{event } E_i \text{ rules out } \Theta\}.$$

This set contains the parts of detector-facing FCLET theory space that the event actively rules out.

4.2 Falsification Pressure on Decisive Islands

The most important exclusion question is whether the event kills part of its own decisive targeting set:

$$\mathfrak{E}_i \cap \mathcal{D}_{\text{island}}.$$

If this intersection is large, then the event exerts real falsification pressure on the most empirically exposed FCLET sectors.

4.3 Global Event Synthesis

Across the selected event set $\mathcal{E}$, the globally surviving region is

$$\mathfrak{S}_{\text{shell}} = \bigcap_{E_i \in \mathcal{E}} (\mathcal{C}_{\text{conf}} \setminus \mathfrak{E}_i),$$

and the globally excluded region is

$$\mathfrak{E}_{\text{shell}} = \bigcup_{E_i \in \mathcal{E}} \mathfrak{E}_i .$$

The empirical status of the detector-facing shell sector is determined by where $\mathfrak{S}_{\text{shell}}$ lies relative to the decisive-island set, the mimicry map, and the null-shell face.

4.4 Survival Categories

The global synthesis produces four exact outcomes.

$G1$: Nontrivial detector-facing survival

$$\mathfrak{S}_{\text{shell}} \cap \mathcal{D}_{\text{island}} \neq \emptyset, \mathfrak{S}_{\text{shell}} \not\subset \mathcal{K}_{\text{mimic}} \cup \mathcal{N}_{\text{shell}}.$$

$G2$: Mimicry-only or ambiguity-only survival

$$\mathfrak{S}_{\text{shell}} \neq \emptyset, \mathfrak{S}_{\text{shell}} \subset \mathcal{K}_{\text{mimic}} \cup \mathcal{K}_{\text{amb}}, \mathfrak{S}_{\text{shell}} \not\subset \mathcal{N}_{\text{shell}}.$$

$G3$: Null-shell retreat

$$\mathfrak{S}_{\text{shell}} \neq \emptyset, \mathfrak{S}_{\text{shell}} \subset \mathcal{N}_{\text{shell}}^{(\epsilon)}.$$

$G4$**: Direct elimination of the detector-facing branch**

$$\mathfrak{S}_{\mathrm{shell}} = \emptyset.$$

These outcomes are not interpretive shorthand. They are the global decision states of the paper.

4.5 Hierarchical Shared Shell-Law Inference Across Events

The strongest version of the confrontation does not fit each event with a different shell. It tests whether one shared FCLET shell law can survive across the event set. Let the global shell-law hyperparameters be

$$\Lambda_{\mathrm{shell}}.$$

For each event E_i, the detector-facing FCLET parameters are generated by

$$\Theta_i^{\mathrm{FCLET}} = \mathcal{P}_{\mathrm{shell}}(\Lambda_{\mathrm{shell}}; M_f^{(i)}, a_f^{(i)}, \Xi_i^{\mathrm{nuis}}).$$

The joint posterior over the shared shell law and event-specific nuisance structure is

$$p\left(\Lambda_{\mathrm{shell}}, \{\Xi_i^{\mathrm{nuis}}\} | \{d_i\}, \Pi_{\mathrm{lock}}\right).$$

The corresponding hierarchical FCLET evidence is

$$\mathcal{Z}_{\mathrm{hier}}^{\mathrm{FCLET}} = \int d\Lambda_{\mathrm{shell}}\, d\Xi \prod_i \mathcal{L}_i\left(d_i \mid \mathcal{P}_{\mathrm{shell}}(\Lambda_{\mathrm{shell}}; M_f^{(i)}, a_f^{(i)}, \Xi_i^{\mathrm{nuis}})\right) \pi(\Lambda_{\mathrm{shell}}, \Xi \mid \Pi_{\mathrm{lock}}).$$

This architecture permanently closes the most dangerous ad hoc escape route. The theory is no longer allowed to explain GW150914 with one shell logic and GW190521 with another. The same shell law must survive across the event set under remnant-rescaled application.

4.6 High-Mass Capacity-Saturation Scaling for GW190521-Class Events

Very high-mass merger remnants probe the shell sector in a distinct regime. Their observed signal is concentrated near merger and ringdown, with limited inspiral leverage and compressed time-domain structure. The FCLET confrontation must therefore scale correctly in the high-mass capacity-saturation regime.

The confrontation is organized using the dimensionless shell variables

$$\hat{\epsilon}, \widehat{\Lambda}_s, \widehat{\Delta t}_{\mathrm{shell}}, \widehat{\delta\omega}_{\mathrm{shell}},$$

defined by the event-scale reduction inherited from the shared shell-law projection.

The FCLET event prior for GW190521-class systems is induced from the same dimensionless shell-law prior:

$$\pi_i^{\text{high-mass}}(\Theta_i^{\text{FCLET}}) = \pi(\Lambda_{\text{shell}})\, J_i(M_f^{(i)}, a_f^{(i)}),$$

where J_i is the Jacobian of the remnant-rescaled parameterization.

This is the correct confrontation procedure for extremely massive post-merger events. The shell law is scaled, not tuned.

5. Event Ranking, Null-Shell Compression, Decisive-Island Occupancy, and Per-Detector Coherence

The direct confrontation of the Kerr FCLET shell sector with real merger data cannot be organized as a flat catalog exercise. Events do not carry equal empirical authority, and not every posterior structure has the same scientific meaning. The present section therefore introduces the event-ranking logic and the three decisive diagnostics that govern interpretation at event level: null-shell compression, decisive-island occupancy, and per-detector coherence of delayed shell structure.

5.1 Event-Level Informativeness and Confrontation Authority

Each event E_i is assigned an informativeness score

$$\mathcal{I}_i = \mathcal{I}_i\left(S/N_{\text{post}}, \sigma_{M_f}, \sigma_{a_f}, Q_i^{\text{data}}, \Delta_i^{\text{shell}}\right),$$

where the arguments denote usable post-merger signal strength, remnant-parameter resolution, data quality, and sensitivity to delayed shell structure. The point of $\mathcal{I}_i$ is not to create an aesthetic ranking of catalog events. It is to quantify how much real pressure an event can exert on the detector-facing shell branch. Low-information events may be retained as consistency checks, but they are not allowed to dominate the confrontation grammar.

To this one adds the decisive exposure fraction

$$\mathcal{X}_i^{\text{DI}} = \frac{\mu(\mathcal{D}_{\text{island}} \cap \mathcal{R}_i)}{\mu(\mathcal{D}_{\text{island}})},$$

where $\mathcal{R}_i$ is the event-reachable confrontation region and μ is the adopted measure on theory space. The confrontation authority of the event is then

$$W_i^{\text{auth}} = \mathcal{I}_i\, \mathcal{X}_i^{\text{DI}}.$$

This is the correct weighting object for multi-event synthesis. An event that barely touches the decisive detector-facing branch cannot carry the same judicial force as an event that strikes it directly.

5.2 Null-Shell Compression as Detector-Level Retreat

A major strength of the present paper is the replacement of soft interpretive language by exact detector-level diagnostics. The first of these is null-shell compression. Let

$$\mathcal{N}_{\mathrm{shell}}$$

denote the detector-facing no-shell face of the admissible rotating FCLET branch. The event-level null-shell compression score is

$$\mathcal{C}_i^{\mathrm{null}} = \int_{\mathcal{N}_{\mathrm{shell}}} p_i\left(\Theta_i^{\mathrm{FCLET}} \mid d_i, \Pi_{\mathrm{lock}}\right) d\Theta.$$

If $\mathcal{C}_i^{\mathrm{null}}$ is small, the event does not actively erase the shell sector. It may still be weak, ambiguous, or only mildly supportive, but it is not pushing the theory toward detector-level self-erasure. If $\mathcal{C}_i^{\mathrm{null}}$ is large in a high-authority event, then the event is not merely "Kerr compatible." It is compressing the shell branch toward its null face. That is genuine detector-level retreat pressure.

This distinction is critical. Mere compatibility language is too weak to capture what the confrontation is actually doing to the detector-facing branch. The correct language is compression, retreat, or erasure.

5.3 Decisive-Island Occupancy as the Real Positive-Support Metric

A positive evidence shift for FCLET is not automatically meaningful. It becomes meaningful only if the posterior support lies in a region where Kerr-family alternatives cannot mimic the same signal structure. That region is the decisive-island set

$$\mathcal{D}_{\mathrm{island}} \subset \mathcal{C}_{\mathrm{conf}}.$$

We therefore define the decisive-island occupancy probability

$$\Pi_i^{\mathrm{DI}} = \int_{\mathcal{D}_{\mathrm{island}}} p_i\left(\Theta_i^{\mathrm{FCLET}} \mid d_i, \Pi_{\mathrm{lock}}\right) d\Theta.$$

If Π_i^{DI} is small, then even a nonzero evidence advantage is not yet a real theory victory. The support lives in a region where standard Kerr-family freedom can still imitate the same

structure. If Π_i^{DI} is large, then the event is selecting a region where the shell branch is genuinely distinguishable. That is the only form of positive event-level support that counts as a serious detector-facing survival signal.

5.4 Per-Detector Coherence of Delayed Shell Structure

A genuine rotating-shell delayed-response structure must be coherent across the detector network after accounting for inter-site timing, antenna response, and waveform projection. A fluctuation confined to one detector is not a physical shell signature. For detectors D, define the detector-specific evidence contrasts

$$\Delta\ln \mathcal{Z}_{i,D}^{\mathrm{FCLET|null}},$$

and the coherent network contrast

$$\Delta\ln \mathcal{Z}_{i,\mathrm{net}}^{\mathrm{FCLET|null}}.$$

The delayed-structure coherence score is then

$$\gamma_i^{\mathrm{coh}} = \frac{\min\left(\Delta\ln \mathcal{Z}_{i,\mathrm{H1}}^{\mathrm{FCLET|null}}, \Delta\ln \mathcal{Z}_{i,\mathrm{L1}}^{\mathrm{FCLET|null}}\right)}{\Delta\ln \mathcal{Z}_{i,\mathrm{net}}^{\mathrm{FCLET|null}} + \varepsilon}.$$

Operationally, the benchmark interpretation is:

$\gamma_i^{\mathrm{coh}} \geq 0.20$: coherent network support,

$0.10 \leq \gamma_i^{\mathrm{coh}} < 0.20$: fragile or partial coherence,

$\gamma_i^{\mathrm{coh}} < 0.10$: single-detector dominated.

A detector veto is also imposed if one principal detector is actively negative beyond the weak-noise regime. This prevents the protocol from promoting a one-detector artifact to a shell-support claim merely because the network average remains superficially positive.

5.5 Three-Layer Event-Level Decision Logic

Each event is evaluated through a three-layer decision hierarchy.

At the **evidence layer**, the confrontation asks whether FCLET outperforms the strongest relevant Kerr-family alternatives:

$$\Delta\ln \mathcal{Z}_i^{\mathrm{FCLET,Kerr}}, \Delta\ln \mathcal{Z}_i^{\mathrm{FCLET,Kerr+OT}}, \Delta\ln \mathcal{Z}_i^{\mathrm{FCLET,Kerr^{ext}}}.$$

At the **localization layer**, the confrontation asks where in theory space the posterior lies:

$$\mathcal{K}_{\mathrm{mimic}}, \mathcal{K}_{\mathrm{amb}}, \mathcal{D}_{\mathrm{island}}, \mathcal{N}_{\mathrm{shell}}.$$

At the **physical-validity layer**, the confrontation asks whether the support survives the detector-facing reality checks:

$$\gamma_i^{\mathrm{coh}}, \mathcal{O}_i^{\mathrm{imm}}, \mathcal{P}_i^{\mathrm{delay}}, \Delta_{\mathrm{abl}}^{(a)}.$$

Only when all three layers point in the same direction does an event acquire decisive scientific force. Weak FCLET evidence in a mimicry-prone region is not success. Strong localization without coherence is not success. Apparent delayed structure that disappears under start-time marginalization is not success. The three-layer hierarchy exists precisely to prevent those interpretive mistakes.

5.6 Revised Event-Level Positive Criterion

An event counts as a serious positive FCLET hit only if all of the following hold simultaneously:

$$\Delta\ln \mathcal{Z}_i^{\mathrm{FCLET,Kerr}} > \Delta\ln \mathcal{Z}_{\mathrm{crit}}, \Delta\ln \mathcal{Z}_i^{\mathrm{FCLET,Kerr+OT}} > \Delta\ln \mathcal{Z}_{\mathrm{crit}},$$
$$\Pi_i^{\mathrm{DI}} > \Pi_{\mathrm{DI}}^{\mathrm{crit}}, \mathcal{C}_i^{\mathrm{null}} < \mathcal{C}_{\mathrm{null}}^{\mathrm{max}}, \gamma_i^{\mathrm{coh}} > \gamma_{\mathrm{coh}}^{\mathrm{crit}},$$

together with satisfaction of the ablation-necessity rule and positive delayed-persistence support.

This criterion is intentionally severe. A theory that survives only after these filters are weakened has not survived the confrontation in any serious sense.

5.7 Revised Event-Level Exclusion Criterion

An event is counted as a decisive exclusion hit if

$$\Delta\ln \mathcal{Z}_i^{\mathrm{FCLET,null}} < -\Delta\ln \mathcal{Z}_{\mathrm{crit}},$$

together with at least one of

$$\mathcal{C}_i^{\mathrm{null}} > \mathcal{C}_{\mathrm{null}}^{\mathrm{crit}}, X_i^{\mathrm{DI}} > X_{\mathrm{DI}}^{\mathrm{crit}},$$

where

$$X_i^{\mathrm{DI}} = \frac{\mu(\mathfrak{E}_i \cap \mathcal{D}_{\mathrm{island}})}{\mu(\mathcal{D}_{\mathrm{island}})}.$$

This prevents exclusion from being assigned casually. To count as a real negative result, the event must either directly strike the decisive detector-facing branch or drive the shell sector toward detector-level erasure.

6. Multi-Event Synthesis, Global Survival Geometry, and Source of FCLET Evidence Gain

The detector-facing empirical status of the Kerr FCLET shell sector is not determined by isolated event narratives. It is determined by the geometry of survival across the event set. The present section constructs that geometry and, at the same time, isolates the physical source of any FCLET evidence gain.

6.1 Combined Evidence Structure

For statistically independent event segments, the combined evidence contrast is

$$\Delta\ln \mathcal{Z}_{\mathrm{set}}^{\mathrm{FCLET|null}} = \sum_i W_i^{\mathrm{auth}}\ \Delta\ln \mathcal{Z}_i^{\mathrm{FCLET|null}}.$$

This quantity summarizes catalog-level evidence support for FCLET relative to a chosen null family. But evidence aggregation alone does not decide the theory's status. A model can accumulate weak evidence advantages entirely inside mimicry-prone regions and still fail to survive as a genuine strong-field competitor. The global confrontation therefore combines evidence with localization and compression geometry.

6.2 Global Survival and Exclusion Sets

For each event E_i, define the allowed region

$$\mathfrak{S}_i = \mathcal{C}_{\mathrm{conf}} \setminus \mathfrak{E}_i.$$

The global survival region is then

$$\mathfrak{S}_{\mathrm{shell}} = \bigcap_i \mathfrak{S}_i\,,$$

and the global exclusion region is

$$\mathfrak{E}_{\mathrm{shell}} = \bigcup_i \mathfrak{E}_i\,.$$

These two sets carry the full empirical content of the global confrontation. They determine not only whether any shell sector survives, but where it survives relative to the decisive-island structure and the null-shell face.

6.3 Global Decisive-Island Retention

The most important global question is whether the surviving region retains overlap with the decisive-island manifold:

$$\mathfrak{S}_{\text{shell}} \cap \mathcal{D}_{\text{island}} \neq \emptyset.$$

This leads to the global decisive-island occupancy fraction

$$\Pi_{\text{DI}}^{\text{global}} = \frac{\mu(\mathfrak{S}_{\text{shell}} \cap \mathcal{D}_{\text{island}})}{\mu(\mathcal{D}_{\text{island}})}.$$

If this quantity remains nonzero and substantial, then the theory retains a detector-facing region in which it is genuinely distinguishable from Kerr. If it collapses to zero, then even if some FCLET sectors remain formally allowed, the theory no longer survives where it is hardest to fake.

6.4 Global Null-Shell Compression

The global confrontation must also measure how strongly the surviving FCLET branch is being driven toward detector-level erasure. The global null-shell compression score is defined by

$$\mathcal{C}_{\text{null}}^{\text{global}} = \int_{\mathfrak{S}_{\text{shell}}} d_{\text{null}}(\Theta)\, p_{\text{hier}}(\Theta)\, d\Theta,$$

or, geometrically,

$$\mathcal{C}_{\text{null}}^{\text{global}} \sim \mu\left(\mathfrak{S}_{\text{shell}} \cap \mathcal{N}_{\text{shell}}^{(\epsilon)}\right).$$

This quantity expresses whether the multi-event confrontation is leaving a real shell sector alive or merely allowing the theory to survive by retreating toward a detector-invisible limit.

6.5 Global Survival Categories

The global synthesis produces four exact outcomes.

$G1$: Nontrivial detector-facing survival

$$\mathfrak{S}_{\text{shell}} \cap \mathcal{D}_{\text{island}} \neq \emptyset, \mathfrak{S}_{\text{shell}} \not\subset \mathcal{K}_{\text{mimic}} \cup \mathcal{N}_{\text{shell}}.$$

$G2$: Ambiguity-only survival

$$\mathfrak{S}_{\text{shell}} \neq \emptyset, \mathfrak{S}_{\text{shell}} \subset \mathcal{K}_{\text{mimic}} \cup \mathcal{K}_{\text{amb}}, \mathfrak{S}_{\text{shell}} \not\subset \mathcal{N}_{\text{shell}}.$$

$G3$: Null-shell retreat

$$\mathfrak{S}_{\text{shell}} \neq \emptyset, \mathfrak{S}_{\text{shell}} \subset \mathcal{N}_{\text{shell}}^{(\epsilon)}.$$

$G4$: Direct detector-facing elimination

$$\mathfrak{S}_{\text{shell}} = \emptyset.$$

These are not different "moods" of the paper. They are different death-or-survival states of the detector-facing branch.

6.6 Weighted Global Synthesis

Because events have unequal confrontation authority, the global synthesis is also tracked through a weighted survival score:

$$\Sigma_{\text{global}} = w_E E_{\text{supp}} + w_D \Pi_{\text{DI}}^{\text{global}} - w_X X_{\text{DI}}^{\text{global}} - w_N \mathcal{C}_{\text{null}}^{\text{global}},$$

where the four terms measure weighted evidence support, decisive-island retention, decisive-island exclusion, and global null-shell compression, respectively.

This score is not a substitute for the set-theoretic decision states above. The set structure decides the theory's status. The score summarizes how strongly that status is realized across the weighted event set.

6.7 Revised Global Survival Criterion

The detector-facing Kerr FCLET shell sector survives in a nontrivial sense only if

$$\mathfrak{S}_{\text{shell}} \cap \mathcal{D}_{\text{island}} \neq \emptyset \text{and} \mathfrak{S}_{\text{shell}} \not\subset \mathcal{N}_{\text{shell}}^{(\epsilon)},$$

and the combined evidence remains positive against the strongest null family:

$$\Delta \ln \mathcal{Z}_{\text{set}}^{\text{FCLET|null}} > 0.$$

If these conditions fail, the theory survives at best in a weak mimicry sense, retreats toward null-shell space, or is directly eliminated on its detector-facing branch.

6.8 What Counts as a Real Empirical Result

A real positive result is not obtained by weak FCLET preference spread across low-authority events. A real positive result requires at least one of the following:

one or more high-authority events satisfying the full positive event criterion,

nontrivial multi-event retention of decisive-island support,

a global posterior that remains outside both the mimicry manifold and the null-shell face.

A real negative result is not obtained by low-information non-preference. A real negative result requires:

decisive-island exclusion by one or more high-authority events,

global collapse of the surviving region into mimicry-only or null-shell space,

or elimination of the identifiability corridor.

This is the exact empirical grammar of the paper. Nothing weaker counts as a decisive confrontation, and nothing stronger is needed.

6.9 Ablation Structure and Source of FCLET Evidence Gain

A confrontation paper becomes scientifically decisive only when it isolates the exact origin of any claimed evidence gain. A flexible model can outperform a null family for the wrong reason: excess functional freedom, hidden nuisance absorption, or delayed overfitting of detector noise. The present article does not permit that ambiguity. Any FCLET advantage must be decomposed and traced to a physically identifiable sector of the shell theory.

Let the full detector-facing shell model be denoted by

$$\mathcal{M}_{\mathrm{FCLET}}^{\mathrm{full}}.$$

The confrontation protocol defines four controlled ablations:

$$\mathcal{M}_{\mathrm{no-delay}}, \mathcal{M}_{\mathrm{no-excitation}}, \mathcal{M}_{\mathrm{no-boundary}}, \mathcal{M}_{\mathrm{no-coherence}}.$$

For each ablation family a, define the penalty

$$\Delta_{\mathrm{abl}}^{(a)}(E_i) = \ln \mathcal{Z}_i^{\mathrm{full}} - \ln \mathcal{Z}_i^{(a)}.$$

These penalties identify the physical source of any FCLET evidence gain. The interpretation is exact:

if support collapses under no-delay ablation, delayed shell structure is doing real work;

if support collapses under no-boundary ablation, shell-boundary response is doing real work;

if excitation flattening leaves the result unchanged, the claimed shell support is not hierarchy-driven;

if no-coherence ablation improves the apparent support, the signal is detector-fragile rather than physically strengthened.

6.9.1 Event-Level Component Attribution

The ablation architecture yields a component-attribution vector

$$\mathbf{A}_i = \left(\Delta_{\mathrm{abl}}^{\mathrm{delay}}, \Delta_{\mathrm{abl}}^{\mathrm{exc}}, \Delta_{\mathrm{abl}}^{\mathrm{bound}}, \Delta_{\mathrm{abl}}^{\mathrm{coh}}\right).$$

This vector answers the decisive interpretive question:

What part of FCLET, if any, is the data actually rewarding?

Three benchmark attribution patterns are especially important:

delay-dominated pattern,

spectral-boundary pattern,

hierarchy-supported pattern.

This is what turns FCLET preference from a scalar slogan into a physically decomposed event statement.

6.10 Protocol Summary for Reproducible Confrontation

For full operational clarity, the confrontation protocol is executed in the following fixed order.

First, the shell-law hyperparameters, event-selection rule, prior object, and threshold tables are locked before any real-event evaluation.

Second, the primary event set

$$\mathcal{E}_{\mathrm{prim}} = \{\mathrm{GW150914}, \mathrm{GW190521}\}$$

is fixed by the declared authority hierarchy.

Third, detector conditioning is performed under the fixed pipeline: strain extraction, PSD estimation, whitening, tapering, veto application, multi-detector alignment, and window construction.

Fourth, each event is confronted against the three core comparison families:

$$\mathcal{M}_{\mathrm{Kerr}}, \mathcal{M}_{\mathrm{Kerr+OT}}, \mathcal{M}_{\mathrm{FCLET}},$$

and, where required, $\mathcal{M}_{\mathrm{Kerr}}^{\mathrm{ext}}$.

Fifth, start-time marginalization is performed, followed by overtone-immunity and delayed-persistence diagnostics.

Sixth, the full ablation program is executed to determine the physical source of any FCLET evidence gain.

Seventh, the event-level diagnostics

$$\Pi_i^{\mathrm{DI}}, \mathcal{C}_i^{\mathrm{null}}, \gamma_i^{\mathrm{coh}}, \mathbf{A}_i$$

are computed and the event is assigned to its confrontation class.

Eighth, the event set is synthesized hierarchically through the shared shell-law posterior and globally through the survival geometry.

Ninth, the detector-facing verdict is assigned in the $G1$–$G4$ framework.

This sequence is exact, blind, and reproducible. It ensures that the confrontation is not a retrospective interpretation of an interesting fit, but a pre-declared empirical test of the rotating detector-facing FCLET shell sector. The protocol summary must therefore be read as executable architecture rather than as completed empirical verdict.

7. Conclusion

The confrontation stage of the rotating strong-field FCLET program is now complete in architecture and final in scientific intent. This paper does not reopen foundational theoretical questions. It does not widen the shell sector in response to difficult events. It does not permit event-by-event reinvention of the shell law. It does not compare the theory against an artificially weak null. It does the opposite. It closes the standard escape routes, fixes the confrontation domain in advance, and forces the detector-facing Kerr FCLET shell sector to answer to real compact-binary merger data under the strongest relevant comparison standards.

The theory is confronted only where it is already known to be both viable and detector-distinguishable. The shell law is locked across the event set through a shared hyperparameter structure. Event-specific remnant masses and spins are allowed to scale the realized detector-facing theory point, but not to redefine the theory. The confrontation is carried out against standard Kerr, overtone-enriched Kerr, and, when required by event morphology, extended

Kerr-family null models with multimode and precession-aware structure. Positive evidence is not allowed to count unless it localizes inside decisive-island regions. Negative outcomes are not softened into vague “Kerr consistency” language, but are quantified through null-shell compression and decisive-island exclusion. Per-detector coherence is imposed to prevent local noise artifacts from masquerading as delayed shell structure.

The empirical status of the detector-facing shell sector is therefore no longer a matter of rhetorical interpretation. It is carried by exact theory-space objects:

$$\mathfrak{S}_{\mathrm{shell}}, \mathfrak{E}_{\mathrm{shell}}, \Pi_{\mathrm{DI}}^{\mathrm{global}}, \mathcal{C}_{\mathrm{null}}^{\mathrm{global}}, \Sigma_{\mathrm{global}}.$$

These are protocol-defined confrontation outputs. In the present article they are introduced as summary objects to be computed once the locked event set has passed through the declared likelihood, coherence, and ablation pipeline. They are not yet empirical measurements and should not be described as if the real-event analysis had already been executed. This distinction is what gives a later verdict paper scientific force.

If the global survival region retains nontrivial overlap with the decisive-island manifold, the theory survives as a genuine strong-field competitor. If the surviving branch collapses into mimicry-only space, the theory remains mathematically present but detector-weak. If the surviving branch retreats into the null-shell face, then the observable shell sector has effectively disappeared under confrontation. If the identifiability corridor is emptied, the detector-facing Kerr FCLET shell sector is directly eliminated. This is the proper standard of judgment. The theory is not asked whether it can fit something somewhere. It is asked whether it can survive where it is forced to be specific, non-mimickable, coherent across the detector network, and stable under the strongest standard alternatives.

The ablation architecture is the decisive strengthening of Article 85. It prevents the confrontation program from mistaking generic extra flexibility for theory-specific success. A real FCLET-favorable event must now answer a harder question than “does the shell model fit better?” It must answer “which FCLET ingredient is doing the work, and does that ingredient remain necessary once Kerr-family competition and detector-coherence requirements are imposed?” That is the correct standard for event-level confrontation. It is also the standard that gives later positive or negative outcomes genuine scientific force.

The rotating strong-field FCLET program has therefore reached its decisive boundary. It is no longer a framework awaiting empirical interpretation. It is a locked confrontation architecture. Article 83 made the rotating shell sector mathematically legitimate. Article 84 made it detector-facing and identifiability-aware. The present article is the empirical tribunal of that branch. It does not yet announce the final numerical verdict, but it fixes the exact conditions under which such a verdict will have scientific meaning.

This also defines the exact export relation to Article 88. Article 85 supplies the strong-field branch with seven judgment-ready objects:

a finite high-authority event set with confrontation weights,

a locked shared shell-law hyperparameter structure,

exact event-level confrontation classes $P1$–$P5$,

exact global verdict categories $G1$–$G4$,

a detector-facing null-shell compression diagnostic,

decisive-island retention and exclusion geometry,

and an ablation-resolved account of where any FCLET evidence gain actually comes from.

Article 88 therefore does not inherit a speculative strong-field branch. It inherits a judgment-ready survival corridor. From this point onward, the future of the rotating shell sector is no longer a matter of internal theoretical optimism. It is a matter of whether one locked shell law survives real merger data under data-weighted, null-competitive, detector-coherent judgment.

From this point onward, the internal architecture of the theory is no longer the arbiter of its future. The data is.

Appendix A. Event Selection Rule and Event-Authority Hierarchy

The primary event set is not chosen after looking for interesting residuals. It is constructed by a formal selection rule. The rule elevates events only if they satisfy the declared post-merger informativeness conditions of the protocol. The authority hierarchy is therefore part of the blind design, not part of later interpretation.

The primary confrontation set is

$$\mathcal{E}_{\mathrm{prim}} = \{\mathrm{GW150914}, \mathrm{GW190521}\}.$$

Secondary and exploratory sets are admitted only under the locked hierarchy:

$$\mathcal{E}_{\mathrm{sec}}, \mathcal{E}_{\mathrm{exp}}.$$

The authority weight assigned to event E_i is

$$W_i^{\mathrm{auth}} = W_i^{\mathrm{ring}} + W_i^{\mathrm{delay}} + W_i^{\mathrm{coh}} + W_i^{\mathrm{morph}} + W_i^{\mathrm{scale}},$$

where:

W_i^{ring} measures usable post-merger ringdown content,

W_i^{delay} measures leverage on delayed shell structure,

W_i^{coh} measures detector-coherence quality,

W_i^{morph} measures robustness against overtone and start-time confusion,

W_i^{scale} measures relevance to shell-law scaling, especially in the high-mass regime.

The primary confrontation set is chosen from events with the largest W_i^{auth} subject to data quality, post-merger visibility, and detector-conditioning stability. Secondary events extend the confrontation only after the primary set has been fixed. Exploratory events are retained for consistency scans and null/context checks only. This appendix exists to eliminate the strongest methodological attack available to a hostile referee: the claim that event choice drifted after seeing the data. It did not. The event set is locked before interpretation, and its authority hierarchy is part of the protocol itself.

Appendix B. Blind Protocol, Prior Lock, and Event-Preserving Shell Scaling

The shell-law hyperparameters

$$\Lambda_{\mathrm{shell}}$$

are locked before event comparison. The confrontation thresholds are fixed before event comparison. The event-selection rule is fixed before event comparison. No event-specific shell-law retuning is permitted. No threshold is moved in response to posterior inspection.

The FCLET event-level posterior is therefore

$$p_i(\Theta_i^{\mathrm{FCLET}} \mid d_i, \Pi_{\mathrm{lock}}),$$

while the hierarchical multi-event posterior is built from the same locked prior object:

$$p\,(\Lambda_{\mathrm{shell}}, \{\Theta_i^{\mathrm{rem}}\} | \{d_i\}, \Pi_{\mathrm{lock}}).$$

The confronting theory structure is therefore divided into three layers:

$$\Lambda_{\mathrm{shell}} \longrightarrow \Theta_i^{\mathrm{rem}} \longrightarrow \Xi_i^{\mathrm{nuis}}.$$

This factorization makes the governing principle exact: **same shell law, remnant-rescaled application, no event-specific retuning**.

For the standard Kerr family, the baseline prior object is the remnant-constrained Kerr prior. For the overtone-enriched Kerr family, the prior extends the modal space without altering the remnant-centered null architecture. For the extended Kerr-family null, the prior includes only the multimode and precession-aware freedom appropriate to the event morphology. The detector pipeline is fixed by declared start-time grid, fixed detector-facing window rule, Tukey tapering and phase marginalization, H1 primary weighting, L1 secondary consistency gate, and network coherence only after single-detector consistency is checked. No

conditioning choice is allowed to move after inspecting FCLET-versus-Kerr evidence. That route is closed.

Appendix C. Core Confrontation Diagnostics and Decision Thresholds

The confrontation uses five primary detector-facing diagnostics:

overtone-immunity index $\mathcal{O}_i^{\mathrm{imm}}$,

delayed-persistence statistic $\mathcal{P}_i^{\mathrm{delay}}$,

null-shell compression score $\mathcal{C}_i^{\mathrm{null}}$,

decisive-island occupancy probability Π_i^{DI},

per-detector coherence score γ_i^{coh}.

The decision thresholds are fixed in advance and evaluated under three regimes: conservative, nominal, and aggressive. The nominal thresholds define the primary scientific verdict. The conservative thresholds define the robustness verdict. The aggressive thresholds are used only for sensitivity scans and do not determine the main conclusion.

Table C1. Pre-Declared Confrontation Decision Thresholds

Metric	Symbol	Conservative	Nominal	Aggressive
FCLET evidence gain vs Kerr	$\Delta\ln \mathcal{Z}^{\mathrm{FCLET,Kerr}}$	10	8	6
FCLET evidence gain vs Kerr+OT	$\Delta\ln \mathcal{Z}^{\mathrm{FCLET,Kerr+OT}}$	10	8	6
FCLET evidence gain vs extended null	$\Delta\ln \mathcal{Z}^{\mathrm{FCLET,Kerr^{ext}}}$	12	10	8
decisive-island occupancy	Π_i^{DI}	0.7	0.5	0.3
null-shell compression	$\mathcal{C}_i^{\mathrm{null}}$	0.7	0.5	0.3
coherence score	γ_i^{coh}	0.25	0.20	0.10
overtone-immunity index	$\mathcal{O}_i^{\mathrm{imm}}$	2	1	0

Metric	Symbol	Conservative	Nominal	Aggressive
delayed-persistence score	$\mathcal{P}_i^{\mathrm{delay}}$	2	1	0
decisive exclusion fraction	X_i^{DI}	0.5	0.3	0.2
mismatch ceiling	$\mathcal{M}_i$	0.03	0.05	0.08

Table note. The confrontation is not allowed to drift into verbal compromise once the numbers are known. Event-level success and failure must pass through declared thresholds rather than retrospective rhetoric.

The primary positive event criterion is the conjunction of:

positive FCLET evidence against Kerr and Kerr+OT above the declared benchmark,

sufficient decisive-island occupancy,

low null-shell compression,

sufficient per-detector coherence,

and satisfaction of the ablation-necessity rule.

The primary exclusion criterion is negative FCLET evidence beyond the declared benchmark together with either substantial null-shell compression or decisive-island exclusion. This appendix makes the confrontation judicial rather than interpretive.

Appendix D. Global Survival Geometry, Hierarchical Synthesis, and Ablation Structure

For each event E_i, define the excluded region

$$\mathfrak{E}_i$$

and the surviving region

$$\mathfrak{S}_i.$$

The global survival region is

$$\mathfrak{S}_{\mathrm{shell}} = \bigcap_i \mathfrak{S}_i \,,$$

and the global exclusion region is

$$\mathfrak{E}_{\text{shell}} = \bigcup_i \mathfrak{E}_i \,.$$

The global decisive-island occupancy is

$$\Pi_{\text{DI}}^{\text{global}} = \frac{\mu(\mathfrak{S}_{\text{shell}} \cap \mathcal{D}_{\text{island}})}{\mu(\mathcal{D}_{\text{island}})},$$

and the global null-shell compression is

$$\mathcal{C}_{\text{null}}^{\text{global}} = \int_{\mathfrak{S}_{\text{shell}}} d_{\text{null}}\,(\Theta)\; p_{\text{hier}}(\Theta)\; d\Theta.$$

The hierarchical FCLET evidence is

$$\Delta \ln \mathcal{Z}_{\text{hier}}^{\text{FCLET|null}} = \sum_i W_i^{\text{auth}}\, \Delta \ln \mathcal{Z}_i^{\text{FCLET|null}},$$

with corresponding combined evidence contrasts against Kerr-family alternatives. The global survival score is

$$\Sigma_{\text{global}} = w_E E_{\text{supp}} + w_D \Pi_{\text{DI}}^{\text{global}} - w_X X_{\text{DI}}^{\text{global}} - w_N \mathcal{C}_{\text{null}}^{\text{global}}.$$

The global detector-facing verdict categories are $G1$–$G4$, defined in the main text:

$G1$: nontrivial detector-facing survival,

$G2$: ambiguity-only survival,

$G3$: null-shell retreat,

$G4$: direct detector-facing elimination.

These are not different “moods” of the paper. They are different death-or-survival states of the branch. The appendix therefore preserves the distinction between branch survival, ambiguity survival, retreat survival, and elimination. A hostile referee must not be able to flatten all negative outcomes into one vague notion of failure. The paper does not do that.

This appendix also formalizes the ablation program. Let the full detector-facing shell model be

$$\mathcal{M}_{\text{FCLET}}^{\text{full}},$$

and define the reduced ablation families:

$$\mathcal{M}_{\mathrm{no-delay}}, \mathcal{M}_{\mathrm{no-excitation}}, \mathcal{M}_{\mathrm{no-boundary}}, \mathcal{M}_{\mathrm{no-coherence}}.$$

For each ablation family a, define

$$\Delta_{\mathrm{abl}}^{(a)}(E_i) = \ln \mathcal{Z}_i^{\mathrm{full}} - \ln \mathcal{Z}_i^{(a)}.$$

These penalties identify the physical source of any FCLET evidence gain. A real detector-facing shell signal must survive not only comparison against Kerr-family nulls, but also its own internal ablation breakdown. The confrontation is therefore not only inter-model. It is intra-model and physics-resolved. This appendix closes the final referee escape route. It demonstrates that the paper does not merely compare models. It determines exactly what survives, what is excluded, and what part of the shell architecture, if any, the data actually supports.

Primordial Tensor Modes, Early-Universe Saturation, and the Shell–Cosmology Bridge in the Finite-Capacity Latency–Erasure Theory

A Unified Origin of Primordial Gravitational-Wave Structure, Horizon-Scale Freeze-Out, and Strong-Field Saturation Shells from a Common Capacity-Limited Background

Ali Caner Yücel
Independent Researcher
Gaziantep, Türkiye

Abstract

We construct the early-universe to strong-field bridge of the finite-capacity latency–erasure theory by unifying primordial tensor generation, horizon-scale freeze-out, and late-time compact-object shell formation within a single capacity-limited dynamical framework. Earlier articles of the program established the bounded-load ontology, the cosmological moderated-erasure branch, the primordial scalar sector associated with latency fluctuations, the detector-facing Kerr shell program, the direct event-level confrontation framework for rotating compact remnants, and the microstate completion of finite accessible capacity. What remained open was the missing bridge between the two ends of the theory: the early high-load universe and the late strong-field shell sector. The present paper builds that bridge explicitly.

The central claim is exact. The same finite-capacity architecture that drives local saturation shells in compact remnants also governs the tensor sector of the early universe. In the primordial regime, the universe occupies a high-load state in which the effective latency background, burden fraction, and moderated-erasure source jointly determine tensor propagation, freeze-out, and spectral transfer. Primordial tensor modes are therefore not treated as external relics appended to the theory, nor as inflaton-sector leftovers borrowed from an unrelated framework. They arise from the same capacity-limited dynamical substrate that later produces strong-field shell formation when local load approaches saturation. The early universe and the compact-remnant shell sector are not parallel branches. They are two regime limits of a single burden-latency system.

We derive the tensor perturbation equation on the FCLET cosmological background, identify the effective tensor transport and damping structure induced by the latency sector, and construct the primordial tensor power spectrum generated during the high-load freeze-out epoch. We then show that horizon-scale tensor freeze-out and compact-object shell onset are controlled by the same saturation logic expressed in different kinematic regimes: in cosmology through mode-exit and capacity-regulated freeze-out, and in strong fields through

local burden accumulation and shell formation near the saturation threshold. This allows a direct shell–cosmology bridge to be written in terms of a common control hierarchy over load fraction, latency response, overwrite moderation, and effective transport. The result is a single tensor-to-shell continuity map across the full theory.

In the strengthened benchmark branch, the common bridge object is made explicit through the universal saturation coordinate

$$\Upsilon(I) \equiv -\ln(1 - I).$$

In the cosmological regime it is evaluated at horizon crossing,

$$\Upsilon_*(k) = -\ln\,(1 - I_*(k)),$$

while in the strong-field branch it is evaluated locally,

$$\Upsilon_{\mathrm{loc}} = -\ln\,(1 - I_{\mathrm{loc}}).$$

This is not a second function distinct from the latency map $\chi(I)$. It is the same logarithmic branch used in the background sector, now elevated to the role of universal saturation coordinate for the bridge. The suppression law is therefore explicit:

$$S_T(k) = \exp\,[-\beta_T \Upsilon_*(k)] = (1 - I_*(k))^{\beta_T}.$$

The benchmark-unified closure fixes

$$\frac{\beta_T}{\beta_S} = 1.$$

Hence the scalar–tensor saturation consistency relation becomes a numerical prediction map rather than a merely symbolic identity. In the nearly scale-invariant reference branch $n_s^{(0)} \simeq 1$, one obtains the benchmark forecast

$$\Delta n_T \equiv n_T - n_T^{(0)} \simeq n_s - 1.$$

Using the benchmark scalar input $n_s - 1 \simeq -0.04$, the benchmark tensor displacement is therefore

$$\Delta n_T \simeq -0.04.$$

This numerical value belongs specifically to the benchmark reference branch. The full relation remains valid more generally, but the benchmark number must be read with that branch caveat attached.

The paper also establishes the mathematical viability conditions of the FCLET tensor sector. We show that saturation in the early universe is not a ghost or gradient catastrophe, but a transport threshold. A positive-definite tensor sector is constructed with

$$Q_T > 0, c_T^2 > 0$$

throughout the admissible high-load branch, while a low-load attractor enforces luminal tensor propagation as $I \to 0$. The cosmological branch is then connected parametrically to the shell branch through descendant calibrations of the same local threshold family:

$$\epsilon = \epsilon(\Xi_{\mathrm{crit}}), \Lambda_s = \Lambda_s(\Xi_{\mathrm{crit}}),$$

with leading-order calibration about the benchmark point. The familiar strong-field benchmark point $\epsilon = 0.10$ is therefore not an independent shell law; it is one calibrated descendant point on the same saturation-threshold family that cosmology reads through Υ.

The paper produces five main outputs. First, it derives the primordial tensor sector of FCLET in covariant and cosmological form. Second, it identifies the tensor freeze-out architecture in a capacity-limited early universe and obtains the corresponding primordial gravitational-wave spectrum. Third, it proves the ghost-free, gradient-stable, and low-load luminal viability of the tensor branch. Fourth, it derives the modified scalar–tensor saturation consistency relation that removes arbitrariness from tensor suppression. Fifth, it constructs the regime map connecting early-universe tensor saturation and late-time compact-object shell saturation, together with the transferred observational forecast linking CMB tensors, relic low-frequency structure, and strong-field shell descendants. The result is the first fully explicit early-universe and strong-field tensor bridge in the finite-capacity latency–erasure program.

Keywords: primordial tensor modes; early-universe saturation; shell–cosmology bridge; gravitational-wave background; horizon-scale freeze-out; relic tensor structure; capacity-limited cosmology; inflation alternative; primordial gravitational waves; saturation branch; early-universe FCLET; cosmological bridge dynamics

1. Introduction: From Primordial Tensor Freeze-Out to Compact-Object Shell Formation

The finite-capacity latency–erasure theory has now developed two sectors that, taken separately, are already substantial. On one side stands the cosmological branch: the universe is described as a bounded substrate with finite informational capacity, its expansion history is regulated by moderated erasure, and its primordial perturbations arise from high-load fluctuations of the latency field rather than from an externally appended inflaton mechanism. On the other side stands the strong-field branch: gravitational collapse does not culminate in a featureless horizon, but in a saturation regime where local burden approaches a finite-capacity threshold and generates a shell structure with detector-facing spectral consequences. These

two sectors were never philosophically disconnected. Until now, however, they were not mathematically unified. This paper closes that gap.

The missing bridge is the tensor sector. Scalar cosmological fluctuations and compact-object shell formation already belong to the program, but without a primordial tensor-to-shell continuity law the theory remains split between early-universe phenomenology and late-time strong-field structure. The present paper removes that split. It shows that primordial gravitational-wave structure and late compact-object shell formation are controlled by one and the same capacity-limited burden-latency architecture.

This claim must be stated with precision. The point is not that early and late regimes merely look similar, nor that they both involve large curvature, nor that they can both be described by general information language. The point is that they are both governed by the same dynamical control hierarchy:

$$I, \chi, Y, T_{\mathrm{eff}},$$

together with the same logarithmic saturation coordinate

$$\Upsilon(I) = -\ln(1 - I).$$

In the early universe, this hierarchy controls tensor propagation and horizon-scale freeze-out. In the compact-remnant regime, the same hierarchy controls local saturation and shell onset. The background symmetries differ. The observational windows differ. The governing architecture does not.

The significance of this bridge is profound. A theory that derives primordial tensor structure from the same substrate that later produces shell formation gains two decisive strengths at once. First, it ceases to be a collection of disconnected explanatory sectors. Second, it becomes vulnerable to a far sharper empirical confrontation. The tensor sector can no longer be treated as an optional phenomenological add-on. It becomes part of the same empirical program that already constrains the shell branch. If the bridge holds, the theory gains real unification power. If it fails, the failure strikes cosmology and strong-field phenomenology simultaneously. That is exactly the level of pressure a serious theory must accept.

The early-universe regime is the natural place to build this bridge because it is the regime of maximal background load. In the FCLET picture, the primordial universe is not a dilute geometric stage on which fluctuations are later placed. It is a high-burden state in which accessible capacity, latency response, and transport moderation are dynamically nontrivial from the outset. Tensor modes therefore do not propagate on a passive background. They propagate through a capacity-limited medium whose effective transport law depends on the same bounded-load structure that later becomes decisive in strong gravitational collapse.

This immediately suggests the central unifying picture of the paper: the same finite-capacity substrate undergoes two first macroscopic threshold events. The first occurs when primordial tensor modes leave the effective transport horizon of a high-load universe and become frozen

as relic structure. The second occurs when local burden accumulation drives the strong-field geometry toward shell formation before classical horizon completion. The kinematics differ. The saturation logic does not.

The role of the present paper inside the late-stage FCLET sequence is now exact. Article 83 exposed the first stabilized strong-field shell benchmark. Article 84 turned that benchmark into a detector-facing identifiability atlas. Article 85 converted the strong-field branch into a locked empirical tribunal. The present article does not compete with those steps. It closes the missing cosmology-facing branch of the same saturation law. Once the bridge is built, the shell branch and the primordial tensor branch cease to be separate shelters for the theory. They become mutually constraining projections of one universal saturation architecture.

The present paper therefore proceeds in five steps. First, the FCLET cosmological background is written in the form needed for tensor perturbation analysis. Second, the tensor propagation equation is derived on that background, including the latency-induced effective transport and damping structure. Third, the viability of the tensor sector is established by proving positivity of the kinetic and gradient coefficients throughout the admissible branch and by identifying the low-load luminal attractor. Fourth, the freeze-out regime is analyzed and the primordial tensor spectrum is constructed in capacity-limited form together with its scalar-linked consistency relation. Fifth, that cosmological tensor-saturation regime is mapped onto the late-time shell-saturation regime, producing a direct shell–cosmology bridge.

The result is not merely another cosmological branch paper. It is the article that unifies the early-universe tensor sector with the late strong-field shell sector and thereby converts the program into a genuinely continuous theory of saturation across scales. It is also the first benchmark cosmology export paper of the shell program: it identifies a narrow tensor branch that is mathematically viable, observationally exportable, and structurally chained to the same saturation law whose strong-field descendant is already exposed by the shell benchmark line.

2. FCLET Background Architecture in the Early Universe

2.1 Capacity-Limited Cosmological Background

We begin from a spatially homogeneous and isotropic Friedmann–Lemaître–Robertson–Walker background,

$$ds^2 = -dt^2 + a^2(t)\,\delta_{ij}dx^i dx^j,$$

with scale factor $a(t)$ and Hubble parameter

$$H \equiv \frac{\dot{a}}{a}.$$

In the finite-capacity latency–erasure theory, this cosmological background is not determined solely by matter density and geometric curvature. It is controlled by a finite-capacity substrate

whose local and global load fraction regulates the effective transport properties of the background. The central background variables are the burden fraction I, the latency response χ, the moderated overwrite or erasure contribution Y, and the effective thermodynamic transport scale T_{eff}. The bounded-load structure implies that the cosmological background cannot be treated as an arbitrarily extensible continuum with unlimited local update capacity. The background itself carries a finite effective load budget, and the universe evolves by redistributing and dissipating burden rather than by merely expanding geometrically. This is the conceptual and mathematical source of the moderated-erasure branch.

The early universe is the maximally important regime because there the load fraction is highest,

$$I \to 1^{-},$$

with the approach to unity regulated by the moderated-erasure architecture that prevents uncontrolled blow-up. The precise high-load regime is not a singular infinite-density pathology in the FCLET picture. It is a capacity-limited state in which latency response and overwrite moderation dominate the transport law. This is the background regime on which the primordial tensor branch must be built.

2.2 Latency Background and Moderated-Erasure Cosmology

The cosmological latency field is spatially homogeneous at background level,

$$\chi = \chi(t).$$

Its background dynamics are controlled by the same burden-to-latency structure used throughout the program. Depending on branch representation, one may write a rational branch

$$\chi = \frac{I}{1 - I},$$

or, in the logarithmic normalization used by the benchmark branch,

$$\chi(I) = -\ln(1 - I).$$

The structural facts are decisive:

$$\chi \to 0 \text{as} I \to 0, \chi \to \infty \text{as} I \to 1^{-}.$$

The background cosmological evolution then includes not only the usual matter and radiation sectors, but also the latency contribution and the moderated overwrite sector. At schematic level the Friedmann branch may be written as

$$3M_{\mathrm{Pl}}^2 H^2 = \rho_{\mathrm{std}} + \rho_\chi + \rho_Y,$$

while the effective continuity structure contains the moderated erasure source

$$\dot{\rho}_Y + 3H(\rho_Y + p_Y) = \Gamma_{\mathrm{ov}}(Y).$$

Earlier cosmological FCLET work established that the overwrite source is not arbitrary. It must be moderated so that the high-load universe does not blow up into an uncontrolled background pathology. The generic branch is therefore

$$\Gamma_{\mathrm{ov}}(Y) \propto Y(1-Y)e^{-\sigma Y},$$

for an appropriate normalized load variable Y and suppression parameter σ. This structure stabilizes the high-load cosmological regime and makes a controlled primordial tensor sector possible.

2.3 Effective Tensor-Relevant Transport Variables

The tensor sector does not couple only to background expansion. In FCLET it also couples to the transport law of the substrate. For that reason, four effective variables are especially important:

the effective load fraction I,

the latency background χ,

the effective tensor transport speed c_T,

the effective tensor friction coefficient ν_T.

These are not introduced by hand. They are the tensor-sector projections of the background burden-latency system. The theory therefore predicts that primordial tensor modes propagate on a background whose update and transport structure is not identical to that of a purely geometric passive FLRW stage. At the regime level, their origin is fixed:

$$I \longrightarrow \chi(I) \longrightarrow (Q_T, c_T^2, \nu_T, m_T^2).$$

The entire primordial tensor problem is therefore reorganized by one fact: tensor propagation takes place on a capacity-limited transport background.

2.4 Early-Universe Saturation Regime

The high-load early universe is the first saturation regime of the theory. It is not identical to compact-object shell saturation, but it is governed by the same control logic. In the primordial case, the relevant phenomenon is not local shell formation but transport freeze-out. Modes cease to remain in full dynamical communication with the evolving background once the effective transport scale and expansion scale decouple sufficiently.

This regime is controlled by a cosmological saturation parameter that can be written schematically as

$$\Xi_{\cos}(k) = \frac{c_T(k/a)}{H_{\text{eff}}},$$

where $c_T k/a$ is the effective tensor propagation scale and H_{eff} is the background transport or freeze-out scale.

When

$$\Xi_{\cos} \gg 1,$$

the mode remains dynamically coupled and oscillatory.

When

$$\Xi_{\cos} \sim 1,$$

the mode enters the freeze-out regime.

This freeze-out condition is the cosmological counterpart of shell approach in the late strong-field sector. It is not the same equation, but it is the same type of event: the burden-latency architecture reaches a regime in which ordinary transport no longer continues in its low-load form.

3. Primordial Tensor Perturbations in a Capacity-Limited Universe

3.1 Tensor Perturbation Ansatz

To construct the primordial gravitational-wave sector, consider transverse-traceless tensor perturbations h_{ij} on the FCLET cosmological background,

$$ds^2 = -dt^2 + a^2(t)(\delta_{ij} + h_{ij})dx^i dx^j,$$

with

$$\partial_i h_{ij} = 0, h^i_{\ i} = 0.$$

Decomposing into Fourier modes and polarization states,

$$h_{ij}(\mathbf{x},t) = \sum_{\lambda=+,\times} \int \frac{d^3k}{(2\pi)^3}\, h_{\lambda,k}(t)\, e_{ij}^{(\lambda)}(\hat{\mathbf{k}})\, e^{i\mathbf{k}\cdot\mathbf{x}}.$$

In standard cosmology, the mode equation is determined primarily by Hubble friction and the background scale factor. In FCLET, the tensor sector inherits additional structure from the burden-latency system. The mode amplitude therefore evolves not on a purely geometric background, but through a transport equation modified by the finite-capacity substrate.

3.2 Covariant Tensor Reduction of the FCLET Sector

The tensor perturbation equation follows from the second-order action for the transverse-traceless sector on the FCLET background. At schematic level the quadratic tensor action takes the form

$$S_T^{(2)} = \frac{1}{8}\int d^3x\, dt\, a^3 \left[Q_T\, \dot{h}_{ij}^2 - Q_T c_T^2 \frac{(\nabla h_{ij})^2}{a^2} - Q_T m_T^2 h_{ij}^2 \right],$$

where

Q_T is the effective tensor normalization,

c_T is the effective tensor propagation speed,

m_T^2 is an effective mass-like or transport-shift term.

In a low-load branch consistent with late-time gravitational-wave propagation constraints, one must recover

$$Q_T \to 1, c_T^2 \to 1$$

at low burden. But in the primordial high-load regime these quantities inherit controlled dependence on I, χ, and the overwrite sector.

The tensor equation of motion is therefore

$$\ddot{h}_{\lambda,k} + (3H + \nu_T)\dot{h}_{\lambda,k} + \left(c_T^2 \frac{k^2}{a^2} + m_T^2 \right) h_{\lambda,k} = 0.$$

This is the central primordial tensor equation of FCLET. Every observational and conceptual output of the paper follows from this background-controlled propagation law.

3.3 Canonical Normalization and Conformal-Time Form

Introduce conformal time η by

$$d\eta = \frac{dt}{a}.$$

Define the canonically normalized tensor mode

$$v_{\lambda,k} = z_T\, h_{\lambda,k}, z_T \equiv \frac{a\sqrt{Q_T}}{2}.$$

Then the mode equation becomes

$$v''_{\lambda,k} + \left(c_T^2 k^2 + a^2 m_T^2 - \frac{z_T''}{z_T}\right) v_{\lambda,k} = 0.$$

This form makes the freeze-out structure explicit. The quantity z_T''/z_T plays the role of an effective background potential, while $c_T^2 k^2 + a^2 m_T^2$ plays the role of the propagation sector. The transition between oscillatory propagation and freeze-out occurs when these become comparable:

$$c_T^2 k^2 + a^2 m_T^2 \sim \frac{z_T''}{z_T}.$$

This is the tensor-sector horizon-crossing condition in the FCLET background. It is not identical to the standard $k \sim aH$ criterion, because both c_T and z_T carry capacity-limited background information.

3.4 Primordial Tensor Freeze-Out in the FCLET Regime

The primordial tensor freeze-out condition is the transition from transport-dominated evolution to background-dominated freezing. In FCLET this condition can be written as

$$\Xi_{\cos}(k) \sim 1.$$

When

$$\Xi_{\cos} \gg 1,$$

the tensor mode oscillates and remains dynamically coupled. When

$$\Xi_{\cos} \ll 1,$$

the mode enters the frozen or super-background regime. The freeze-out amplitude is then inherited by the relic primordial tensor spectrum.

The crucial FCLET point is that freeze-out occurs in a background that is itself controlled by the capacity-limited burden-latency architecture. Therefore the tensor relic amplitude is not merely a record of geometric expansion; it is a record of a saturation-regulated transport regime. This is the first side of the shell–cosmology bridge.

3.5 Mathematical Viability of the Tensor Sector: Saturation Without Catastrophe

A capacity-limited theory is scientifically serious only if the high-load regime remains dynamically stable. Saturation must not be confused with pathology. In the present framework, the approach to the high-load regime does not signal the collapse of the tensor perturbation sector. It signals the controlled breakdown of ordinary transport while the perturbation theory itself remains well posed.

To make this exact, the quadratic tensor action must satisfy two non-negotiable conditions throughout the admissible cosmological branch:

$$Q_T > 0, c_T^2 > 0.$$

The first prevents ghost instability. The second prevents gradient instability. These conditions must hold not merely in the low-load branch, but all the way to the early high-load freeze-out regime.

We therefore impose a positivity-preserving tensor closure of the form

$$Q_T = Q_T(I, \chi, Y) > 0,$$

and

$$c_T^2 = c_T^2(I, \chi, Y) > 0,$$

with coefficients and branch restrictions chosen so that positivity is preserved across the admissible saturation regime.

The tensor sector therefore remains strictly ghost-free and gradient-stable throughout the admissible branch, including the high-load saturation regime. Saturation in FCLET is not a perturbative catastrophe. It is a transport threshold. This branch is not merely mathematically acceptable. It is the benchmark saturation branch to be exported to first-pass confrontation.

3.6 Low-Load Luminal Attractor

A viable tensor theory must not only survive the early high-load regime. It must also recover the observationally required low-load late-universe behavior. In FCLET this recovery is not assumed. It is built into the burden-latency architecture itself.

At low load,

$$I \ll 1.$$

Using the logarithmic branch

$$\chi(I) = -\ln(1 - I),$$

one finds

$$\chi(I) = I + \mathcal{O}(I^2).$$

Hence

$$c_T^2 = 1 + \mathcal{O}(I^2).$$

This establishes the low-load attractor:

$$c_T \to 1 \text{as} I \to 0,$$

with quadratic or faster convergence. Once the burden fraction becomes small, the capacity-limited corrections to tensor transport collapse rapidly, and the late-universe propagation law returns smoothly to the luminal branch.

This is the correct FCLET response to the late-universe tensor-speed constraint: the low-load branch is an attractor, not a coincidence. It is one of the acceptance gates of the benchmark tensor branch.

3.7 Physical Meaning of Viability: Stable Freeze-Out Rather than Explosive Transport Failure

The combined result of Sections 3.5 and 3.6 is decisive. The FCLET tensor branch does not use the high-load regime as a place where dynamics becomes singular or uncontrollable. It uses the high-load regime as a place where ordinary transport stops being low-load while the perturbation sector itself remains positive-definite.

The theory therefore predicts freeze-out without ghosting, suppression without gradient blow-up, and late-universe luminality without post hoc repair. Saturation is a transport threshold, not a catastrophe. That is the exact viability meaning of the tensor branch.

4. Primordial Tensor Spectrum, Saturation Consistency, and the Early-Universe Saturation Map

4.1 Power Spectrum Definition

The primordial tensor power spectrum is defined by

$$\langle h_{\lambda,\mathbf{k}} h_{\lambda',\mathbf{k}'} \rangle = (2\pi)^3 \delta_{\lambda\lambda'} \delta^{(3)}(\mathbf{k}+\mathbf{k}') \frac{2\pi^2}{k^3} P_T(k).$$

Using the canonical variable $v_{\lambda,k}$, the freeze-out spectrum is

$$P_T(k) = \frac{2k^3}{\pi^2} \left| \frac{v_k}{z_T} \right|^2_{\eta=\eta_*(k)},$$

where $\eta_*(k)$ denotes the freeze-out time of mode k.

In standard treatments, the scale dependence is governed primarily by the expansion history. In FCLET, the scale dependence is jointly controlled by the background capacity architecture through Q_T, c_T, z_T, and the saturation-regulated evolution of $\Upsilon_*(k)$.

4.2 Capacity-Limited Tilt and Amplitude Modulation

The FCLET primordial tensor spectrum need not be a purely scale-invariant or inflation-derived relic. Its amplitude and tilt inherit direct sensitivity to the burden-latency background. One may write

$$P_T(k) = P_T^{(0)}(k)\, S_T(k),$$

where $P_T^{(0)}(k)$ is the reference low-load form and $S_T(k)$ is the capacity-limited modulation factor.

At leading order this factor depends on the freeze-out values of the transport variables:

$$S_T(k) = S_T(I_*(k), \chi_*(k), Y_*(k)).$$

In the benchmark logarithmic branch, the explicit suppression law is

$$S_T(k) = \exp[-\beta_T \Upsilon_*(k)] = (1 - I_*(k))^{\beta_T}.$$

This immediately implies that the tensor tilt and amplitude become diagnostics of the early-universe capacity regime. The tensor spectrum is not merely a relic of scale-factor evolution. It is a relic of the saturation-regulated transport structure itself.

4.3 Horizon-Scale Suppression and Moderated Freeze-Out

One of the most important consequences of the moderated-erasure background is horizon-scale suppression. In the scalar sector, earlier work already showed that the largest modes can be naturally depleted when freeze-out occurs under a moderated high-load regime. The same logic now extends to tensors.

For sufficiently large scales, freeze-out occurs earlier in the capacity-dominated branch, where overwrite moderation and latency amplification are strongest. This can generate a suppression factor of the form

$$S_T^{\mathrm{low-k}} = \exp[-\beta_T \Upsilon_*(k)].$$

Then the full primordial tensor spectrum may be written schematically as

$$P_T(k) = P_T^{(0)}(k)\, S_T^{\mathrm{low-k}}(k).$$

FCLET therefore does not merely allow a primordial tensor spectrum. It predicts that the largest tensor scales are especially sensitive to capacity-limited saturation and moderated freeze-out. This is the first observable export object of the benchmark branch: a CMB-facing large-scale tensor suppression class.

4.4 Saturation Consistency Relation Between Scalar Tilt and Tensor Suppression

A capacity-limited theory is not permitted to suppress the tensor sector arbitrarily while treating the scalar sector independently. In FCLET, scalar and tensor freeze-out are governed by the same burden-latency background and therefore by the same saturation history. This forces a consistency relation between scalar tilt and tensor suppression.

Let the scalar and tensor spectra be written as

$$P_S(k) = P_S^{(0)}(k)\, S_S(k), P_T(k) = P_T^{(0)}(k)\, S_T(k).$$

Define the scalar and tensor suppression factors

$$S_S(k) = \exp[-\beta_S \Upsilon_*(k)], S_T(k) = \exp[-\beta_T \Upsilon_*(k)].$$

Then

$$\ln S_T = \frac{\beta_T}{\beta_S} \ln S_S.$$

Taking logarithmic derivatives with respect to scale gives

$$n_s - 1 = (n_s^{(0)} - 1) - \beta_S \frac{d\Upsilon_*}{d\ln k},$$
$$n_T = n_T^{(0)} - \beta_T \frac{d\Upsilon_*}{d\ln k}.$$

Eliminating the common factor $d\Upsilon_*/d\ln k$, one obtains the FCLET modified consistency relation:

$$n_T - n_T^{(0)} = \frac{\beta_T}{\beta_S}[(n_s - 1) - (n_s^{(0)} - 1)].$$

In the benchmark-unified branch, the same saturation coordinate drives both sectors, so the strongest and cleanest closure is

$$\frac{\beta_T}{\beta_S} = 1.$$

The consistency relation therefore reduces to

$$n_T - n_T^{(0)} = (n_s - 1) - (n_s^{(0)} - 1).$$

In the nearly scale-invariant reference branch

$$n_s^{(0)} \simeq 1,$$

this becomes

$$\Delta n_T \equiv n_T - n_T^{(0)} \simeq n_s - 1.$$

Using the benchmark scalar input

$$n_s - 1 \simeq -0.04,$$

the resulting tensor displacement is

$$\Delta n_T \simeq -0.04.$$

This numerical value belongs specifically to the benchmark reference branch. If a nontrivial low-load reference branch is adopted, the full relation remains valid but the numerical displacement changes accordingly. This caveat is part of the final statement and is not optional.

4.5 Tensor-to-Scalar Ratio in the Benchmark Branch

The tensor-to-scalar ratio is

$$r(k) = \frac{P_T(k)}{P_S(k)}.$$

Using the common saturation structure,

$$r(k) = r^{(0)}(k)\exp[-(\beta_T - \beta_S)\Upsilon_*(k)].$$

Equivalently,

$$r(k) = r^{(0)}(k)\,(1 - I_*(k))^{\beta_T - \beta_S}.$$

Therefore the FCLET tensor-to-scalar ratio is not an independent phenomenological dial. It is tied to the same saturation physics that sets the scalar tilt and scalar suppression structure. In the benchmark-unified closure $\beta_T/\beta_S = 1$, the leading suppression enters through the common tilt and source-object modification rather than through an arbitrary independent tensor ratio. Once the scalar branch is fixed, the tensor branch is already under pressure. That is exactly why the benchmark branch is scientifically sharper than a generic modified-gravity tensor ansatz.

4.6 Universal Saturation Coordinate and the Shell–Cosmology Bridge

We now reach the central unifying structure of the article.

In the early universe, the relevant saturation phenomenon is tensor freeze-out on a high-load capacity-limited background. In the late strong-field regime, the relevant saturation phenomenon is local shell formation under extreme burden accumulation. These are different kinematic realizations of one control hierarchy.

The bridge is made exact by introducing one universal saturation coordinate:

$$\Upsilon(I) \equiv -\ln(1 - I).$$

In the cosmological branch it is evaluated at horizon crossing,

$$\Upsilon_*(k) = -\ln(1 - I_*(k)),$$

and controls primordial freeze-out.

In the strong-field branch it is evaluated locally,

$$\Upsilon_{\mathrm{loc}} = -\ln(1 - I_{\mathrm{loc}}),$$

and controls shell onset through the local threshold condition

$$\Upsilon_{\mathrm{loc}} \sim \Xi_{\mathrm{crit}}.$$

The shell–cosmology bridge is therefore the statement that these are not independent constructions but regime projections of one saturation architecture. The same logarithmic branch that appears in the background latency sector as

$$\chi(I) = -\ln(1 - I)$$

is here re-read as the universal saturation coordinate Υ. There are not two different functions. There is one logarithmic exhaustion law serving two roles: latency response in the background branch and threshold geometry in the bridge branch.

This allows the first benchmark regime map of the theory:

Table 4.1. Benchmark Closure of the Primordial Saturation Branch

Quantity	**Benchmark-unified value**	**Meaning**
$\Upsilon(I)$	$-\ln(1 - I)$	universal capacity-exhaustion functional
$S_T(k)$	$\exp[-\beta_T \Upsilon_*(k)]$	tensor suppression factor
$S_S(k)$	$\exp[-\beta_S \Upsilon_*(k)]$	scalar suppression factor
β_T/β_S	1	unified scalar–tensor response ratio
consistency relation	$\Delta n_T \simeq n_s - 1$ in benchmark branch	numerical prediction map
benchmark tensor displacement	$\Delta n_T \simeq -0.04$	tensor-tilt shift for $n_s^{(0)} \simeq 1$

Table 4.2. Universal Saturation Coordinate and Its Regime Projections

Regime	Saturation coordinate	Threshold object	Observable descendants
Cosmology	$\Upsilon_*(k)$	freeze-out threshold at horizon crossing	$P_T(k)$, $S_T(k)$, n_T, large-scale tensor suppression
Strong field	Υ_{loc}	shell onset threshold at Ξ_{crit}	ϵ, Λ_s, shell delay, mode deformation

Table note. The cosmological and strong-field observables are not numerically identical. The correct statement is stronger and more precise: they descend from one saturation coordinate through different regime projections.

4.7 Strong-Field Descendants of the Local Saturation Threshold

Once the universal saturation coordinate is fixed, the shell benchmark parameters are not independent laws. They are descendant calibrations of Ξ_{crit}:

$$\epsilon = \epsilon(\Xi_{\mathrm{crit}}), \Lambda_s = \Lambda_s(\Xi_{\mathrm{crit}}).$$

A full microphysical inversion is not claimed at this stage. The correct explicit statement is a leading-order local calibration about the benchmark point:

$$\epsilon - \epsilon_{\mathrm{bench}} \simeq \frac{d\epsilon}{d\Xi_{\mathrm{crit}}}\Big|_{\mathrm{bench}} (\Xi_{\mathrm{crit}} - \Xi_{\mathrm{crit}}^{\mathrm{bench}}),$$
$$\Lambda_s - \Lambda_{s,\mathrm{bench}} \simeq \frac{d\Lambda_s}{d\Xi_{\mathrm{crit}}}\Big|_{\mathrm{bench}} (\Xi_{\mathrm{crit}} - \Xi_{\mathrm{crit}}^{\mathrm{bench}}).$$

This is explicit enough to prevent the bridge from floating free, but honest enough not to pretend that a full microphysical inversion has already been completed.

The detector-facing strong-field benchmark of Article 83 — in particular the continuation-stabilized $(2, 0)$ real-sector anchor

$$\frac{\delta \mathrm{Re}\omega}{\mathrm{Re}\omega} \approx +2.6\%$$

at the benchmark shell point $\epsilon = 0.10$ — is therefore interpreted as the detector descendant of the benchmark local threshold point

$$\Xi_{\mathrm{crit}}^{\mathrm{bench}}.$$

This is the correct bridge statement. It links the cosmology paper to the strong-field benchmark without inventing a false exact inversion formula. It also turns Article 86 into an export paper rather than a merely structural bridge: the cosmological tensor branch now knows which strong-field benchmark line it descends into.

5. Observational Transfer: CMB Tensors, Stochastic Background Structure, and Regime-Linked Signatures

The shell–cosmology bridge acquires full scientific force only when it produces observational transfer structure. A unifying paper that remains at the level of internal formal analogy is incomplete. The present section therefore translates the primordial tensor sector of FCLET into its cosmology-facing and gravitational-wave-facing observable consequence classes. The goal is not merely to state that primordial tensors exist in the theory. The goal is to determine what their capacity-limited origin implies for observables across vastly separated scales.

5.1 Transfer of the Primordial Tensor Spectrum to Late Observables

The primordial tensor power spectrum derived in the previous section,

$$P_T(k) = P_T^{(0)}(k)\, S_T(k),$$

is not observed directly. It is propagated to late observables through cosmological transfer weighted by the FCLET-modified background history. Let

$$\mathcal{T}_T(k, \eta_0)$$

denote the late-time tensor transfer function evaluated at the present epoch η_0. Then the present tensor amplitude is

$$h_T(k, \eta_0) \sim \mathcal{T}_T(k, \eta_0)\, P_T^{1/2}(k).$$

At the level of energy density per logarithmic interval, the corresponding stochastic gravitational-wave background may be written schematically as

$$\Omega_{\mathrm{GW}}(f) \propto f^2\, \mathcal{T}_T^2(f)\, P_T(f).$$

In FCLET, both ingredients in this expression carry theory content. The primordial spectrum is modified by high-load capacity-limited freeze-out, and the transfer function is propagated on a background whose expansion and transport history already depart from a purely standard low-load cosmology in the moderated-erasure regime. The observational content of the theory is therefore inherently two-layered:

primordial saturation history ⟶ late transfer history ⟶ observable tensor window.

This matters because the tensor sector is not grafted onto an otherwise standard background. The full late observable remembers both the primordial and transfer-level FCLET structure.

5.1.1 Benchmark Observable Export Structure

The benchmark-unified saturation branch exports three principal observable objects:

a **primordial tensor source object**

$$P_T^{\mathrm{prim}}(k) = P_T^{(0)}(k)\,\exp[-\beta_T \Upsilon_*(k)],$$

a **large-scale tensor suppression class**

$$S_T^{\mathrm{low-k}}(k) = \exp[-\beta_T \Upsilon_*(k)],$$

a **relic stochastic-background descendant**

$$\Omega_{\mathrm{GW}}(f) \propto f^2\,\mathcal{T}_T^2(f)\,P_T^{\mathrm{prim}}(f).$$

This is the first-fit export structure of the benchmark tensor branch. It is not a loose promise of future confrontation. It is the minimal observable package by which the branch may later be tested against CMB and low-frequency stochastic windows. The PTA branch is therefore not an independent phenomenological sector. It is the relic descendant of the same primordial tensor history that the CMB branch probes closer to its freeze-out origin.

5.2 CMB Tensor Signatures and Large-Scale Suppression

The largest-scale observational interface of the primordial tensor sector is the cosmic microwave background tensor contribution, especially through large-angle polarization structure. In the standard language, the relevant observables are sourced by the primordial tensor spectrum and its transfer into the last-scattering and reionization windows.

The decisive FCLET feature is horizon-scale suppression. Because the largest tensor modes freeze out deepest in the high-load, strongly moderated transport regime, the function

$$S_T^{\mathrm{low-k}}(k) = \exp[-\beta_T \Upsilon_*(k)]$$

is expected to produce the strongest departure from standard expectations at the lowest k. Therefore the tensor contribution to the CMB should not be characterized merely by a global amplitude shift. It should carry a scale-dependent suppression architecture:

$$P_T(k) \simeq P_T^{(0)}(k)\,S_T^{\mathrm{low-k}}(k).$$

This immediately implies a qualitative prediction: the largest tensor scales are the most direct CMB test of the high-load saturation branch. FCLET therefore does not generically predict a featureless rescaling of the primordial tensor sector. It predicts regime-dependent tensor

depletion or modulation that is strongest where freeze-out is most deeply embedded in the high-load branch.

A useful benchmark summary is therefore

largest-scale CMB tensors ⟷ earliest and deepest saturation-sensitive freeze-out.

5.3 Primordial-to-Relic Transfer and Stochastic Gravitational-Wave Background Structure

The second observational interface is the relic low-frequency stochastic gravitational-wave background. Once propagated to late times, the primordial tensor spectrum produces a present-day background whose shape is sensitive to both the freeze-out architecture and the later cosmological transfer history.

The correct transfer statement is

$$k = 2\pi a_0 f,$$

where f is the present-day observed frequency. Thus every PTA frequency bin is the relic descendant of a definite primordial tensor mode.

In a standard scale-free background, one expects a relatively smooth spectral shape once the standard transfer factors are accounted for. In FCLET, the early high-load regime can imprint a nontrivial low-frequency turnover or suppression family through the primordial factor S_T, while the moderated-erasure history can further modify the transfer envelope through $\mathcal{T}_T$. A schematic FCLET prediction is therefore

$$\Omega_{\mathrm{GW}}(f) = \Omega_{\mathrm{GW}}^{(0)}(f)\, S_T^{\mathrm{low-f}}(f)\, \mathcal{T}_T^{\mathrm{FCLET}}(f).$$

This predicts that the relic stochastic background is not generically a single-tilt power law. It is a burden-structured spectrum with a low-frequency sensitivity to early saturation and a potentially nontrivial transfer curvature inherited from the background branch.

The effective low-frequency slope satisfies

$$n_{\mathrm{GW}}^{\mathrm{eff}}(f) = \frac{d\ln \Omega_{\mathrm{GW}}}{d\ln f}.$$

A transferred saturation turnover may then be defined by the condition that the inherited suppression term becomes order-relevant relative to the low-load relic background. This defines a turnover scale

$$f_{\mathrm{turn}},$$

the relic frequency at which the primordial saturation factor ceases to be a weak renormalization and begins to reshape the stochastic envelope. The explicit computation of f_{turn} is deferred to Article 88, where the transferred low-frequency envelope is confronted jointly across the CMB, PTA, LISA, and LVK windows. That deferment is not a gap in the present paper. It is the correct export boundary between the benchmark tensor-branch construction here and the multi-window synthesis there.

5.4 Observational Meaning of the Saturation Consistency Relation

The modified consistency relation derived in the tensor sector has immediate interpretive significance. It means that the FCLET tensor suppression factor cannot be inserted phenomenologically after the fact. Once the scalar sector is fixed, the tensor sector is already constrained.

If the scalar spectrum exhibits a red tilt

$$n_s - 1 < 0$$

because the freeze-out branch samples a nontrivial saturation gradient

$$\frac{d\Upsilon_*}{d\ln k} \neq 0,$$

then the tensor tilt and tensor suppression are forced to respond according to

$$n_T - n_T^{(0)} = \frac{\beta_T}{\beta_S}[(n_s - 1) - (n_s^{(0)} - 1)].$$

In the benchmark-unified branch,

$$\frac{\beta_T}{\beta_S} = 1,$$

and therefore

$$\Delta n_T \simeq n_s - 1$$

in the benchmark reference branch $n_s^{(0)} \simeq 1$.

Thus the same capacity-limited mechanism that bends the scalar spectrum also bends or suppresses the tensor spectrum. The bridge is therefore dynamical, not ornamental. The early-universe tensor branch is mathematically chained to the scalar FCLET branch. This is exactly why the benchmark tensor branch is scientifically harder than a free tensor-suppression phenomenology.

5.5 Regime-Linked Signatures: From Frozen Primordial Tensors to Delayed Shell Spectra

The most powerful observational implication of the present paper is not any single spectrum taken in isolation. It is the existence of regime-linked signatures across early and late sectors.

The early-universe tensor branch predicts:

horizon-scale tensor suppression,

capacity-sensitive tensor tilt modulation,

structured stochastic-background departures from featureless scale-free behavior.

The late strong-field shell branch predicts:

delayed shell-response structure,

mode-branch deformation,

shell reflectivity signatures,

nontrivial excitation hierarchy.

These are not independent phenomenological curiosities. They are the early and late manifestations of one propagation principle: capacity-limited transport ceases to behave like unconstrained standard propagation when the burden-latency system approaches saturation. This yields a unified observational statement:

early freeze-out saturation ⟷ late shell-onset saturation.

The observational signature families are linked by mechanism, not by coincidence.

Table 5.1. Forecastable Signatures of the Benchmark-Unified Saturation Branch

Window	Source object	Principal benchmark signature	Secondary signature
CMB	$P_T^{\mathrm{prim}}(k)$	effective tensor-tilt displacement Δn_T	large-scale tensor attenuation / low-k suppression
PTA	$\Omega_{\mathrm{GW}}(f)$	modified low-frequency slope $n_{\mathrm{GW}}^{\mathrm{eff}}$	transferred saturation turnover f_{turn}
Strong field	Υ_{loc} descendant branch	shell-threshold continuity with detector-facing shell benchmark	descendant shell-response family

Table note. The cosmological and strong-field observables are not numerically identical. The correct statement is stronger and more precise: they descend from one saturation coordinate through different regime projections.

5.6 Why the Shell–Cosmology Bridge Is Observationally Nontrivial

A referee could incorrectly claim that early-universe tensor structure and compact-object shell structure are too remote from one another to form a real joint prediction program. That claim fails for one reason: the present bridge does not rely on common symbolism. It relies on common transport-breakdown structure.

In the early universe, tensor modes freeze out because the mode ceases to remain in full transport contact with the rapidly evolving high-load background. In the compact-remnant regime, the signal acquires shell-delayed structure because propagation ceases to remain purely Kerr-like once local burden approaches saturation and the shell boundary emerges. In both cases, the theory predicts that the largest deviations appear where standard low-load transport fails.

That common statement is physically sharp. It makes the early and late branches observationally continuous. It also hardens the entire FCLET program: the cosmological tensor branch and the strong-field shell branch are no longer allowed to shelter one another as disconnected sectors.

6. Strong-Field Continuity and the Shell-Regime Map

The cosmological tensor sector and the compact-object shell sector now stand side by side. This section shows that they are not merely parallel branches, but continuously connected regime projections of one saturation law.

6.0 One Function, Two Regime Roles

A notation point must be fixed permanently before the regime map is interpreted. In the original background construction, the logarithmic latency branch is

$$\chi(I) = -\ln(1 - I).$$

In the present bridge language, the same function is written as

$$\Upsilon(I) = -\ln(1 - I)$$

when it is used as the universal saturation coordinate. There are not two different functions here. There is one logarithmic exhaustion law serving two roles: latency response in the background branch and threshold geometry in the bridge branch.

This distinction is one of role, not of form. Fixing that point prevents the bridge from looking like a symbolic relabeling trick. It is not. It is the same law performing two different theoretical jobs.

6.1 Two Saturation Regimes of One Burden–Latency System

The FCLET program now contains two mathematically explicit saturation phenomena.

The first is cosmological tensor saturation, realized as high-load background freeze-out:

$$\Xi_{\cos}(k) \sim 1.$$

The second is strong-field shell saturation, realized as local burden-threshold shell onset:

$$\Upsilon_{\mathrm{loc}} \sim \Xi_{\mathrm{crit}}.$$

These are not the same equation because the background symmetries and observables differ. But they are the same class of event. In both cases, the burden-latency system enters a regime in which ordinary transport ceases to continue in its low-load form.

It is therefore natural to define a unified saturation indicator Υ, where the kinematic sector changes but the control hierarchy does not.

6.2 Mapping Cosmological Freeze-Out to Shell Onset

The shell–cosmology bridge becomes explicit when one writes the corresponding threshold conditions side by side.

For primordial tensors, freeze-out occurs when the effective propagation sector and background sector become comparable:

$$c_T^2 k^2 + a^2 m_T^2 \sim \frac{z_T''}{z_T}.$$

For compact-object shell formation, shell onset occurs when local burden reaches the threshold set by the capacity-limited saturation condition:

$$\Upsilon_{\mathrm{loc}} \sim \Xi_{\mathrm{crit}}.$$

These conditions are different in form but identical in function. Each marks the boundary between an ordinary transport regime and a saturation-governed regime. This allows a regime map whose meaning is not that one observation numerically predicts the other directly, but that both must be compatible with one underlying saturation law.

6.3 Early-Universe Transport Failure and Late-Time Horizon-Completion Failure

A deeper continuity emerges when one compares what fails in each regime.

In the early universe, what fails is not geometry itself, but unconstrained tensor transport. The mode no longer continues to oscillate as if the background were a passive low-load medium.

In the strong-field regime, what fails is not merely Schwarzschild or Kerr perturbation theory in the abstract. What fails is the completion of ordinary horizon formation as if the local substrate had unlimited burden capacity.

These are two versions of one principle:

ordinary low-load transport fails at saturation.

In the cosmological case, the outcome is relic freeze-out. In the strong-field case, the outcome is shell formation. This is the central theorem of the shell–cosmology bridge.

6.4 Unified Source Hierarchy Across Early and Late Tensor Sectors

The bridge becomes even sharper once the source hierarchy is written in unified form. The same source architecture that controls the late strong-field sector also appears, in regime-adapted form, in the early tensor background:

$$(I, \chi, Y, T_{\mathrm{eff}}) \longrightarrow \text{regime-specific tensor or shell observables.}$$

In cosmology, this source determines Q_T, c_T^2, m_T^2, and the freeze-out history. In compact remnants, it determines ϵ, shell location, reflectivity structure, and spectral deformation.

A genuine unification paper must do more than juxtapose equations. It must show common source closure. The present paper does exactly that.

6.5 Shell-Regime Map in Theory Space

The continuity between early and late sectors can be represented as a theory-space map with three principal regions:

Low-load transport regime

$$I \ll 1, \Upsilon \ll 1,$$

with luminal tensor propagation and no shell onset.

Cosmological freeze-out regime

$$I \lesssim 1, \Upsilon_*(k) \text{ large enough to modify primordial tensor transport.}$$

Strong-field shell regime

$$I_{\mathrm{loc}} \lesssim 1, \Upsilon_{\mathrm{loc}} \sim \Xi_{\mathrm{crit}},$$

with local saturation and shell formation.

The program's unification claim is then

one universal saturation coordinate ⟶ multiple regime descendants.

This is the formal shell-regime map of the theory. It is also the point at which the bridge stops being purely conceptual and becomes exportable to later multi-window confrontation.

6.5.1 Strong-Field Descendant Calibration of the Benchmark Saturation Branch

The shell-regime map becomes empirically meaningful only when the strong-field descendant is tied to a recognizable benchmark line. That link is provided by the detector-facing shell benchmark of Article 83 and the identifiability atlas of Article 84.

The correct statement is not that the cosmological tensor observable and the strong-field shell observable are numerically identical. The correct statement is stronger and more precise: the strong-field benchmark is the detector descendant calibration of the same local saturation-threshold family.

Thus the continuation-stabilized strong-field anchor

$$\frac{\delta \mathrm{Re}\omega}{\mathrm{Re}\omega} \approx +2.6\%$$

at the benchmark shell point is the local detector descendant of the same threshold family that the cosmology branch samples through $\Upsilon_*(k)$. This is why the benchmark tensor branch is no longer a floating cosmological construction. It is the cosmology-facing export of the same universal saturation law already exposed in the shell sector.

7. Unified Predictions, Empirical Stakes, and Falsification Structure

A paper that unifies the early-universe tensor sector with the compact-object shell sector becomes scientifically valuable only if it sharpens empirical stakes. This section states those stakes without dilution.

7.1 Unified Prediction Class I: Correlated Saturation Signatures Across Scales

The first prediction class is qualitative but exact: the same theory that predicts delayed shell structure in compact remnants also predicts capacity-sensitive departures in primordial tensor structure.

In practical terms, this means:

- a theory point with a strong shell branch cannot simultaneously require a completely structureless primordial tensor sector without justification,
- a theory point with a nontrivial early-universe high-load tensor branch cannot leave the strong-field shell sector fully inert without justification.

The bridge therefore converts what would otherwise be isolated tolerances into cross-sector consistency conditions.

7.2 Unified Prediction Class II: Low-k Tensor Suppression and Strong-Field Shell Activity

The second prediction class is stronger. Because the largest primordial tensor scales are most sensitive to high-load freeze-out, while the strongest compact-object departures are most sensitive to local saturation, the theory predicts that the most capacity-sensitive early and late signatures lie at opposite ends of the same saturation ladder.

Schematically,

$$\text{deeper primordial saturation sensitivity} \Leftrightarrow \text{stronger shell-threshold activity},$$

not as a trivial one-parameter identity, but as a non-separable common-law constraint.

This implies that the two sectors cannot be varied independently once the bridge is taken seriously. The theory is no longer free to keep cosmology quiet while activating strong-field shells, or vice versa, without paying a consistency cost.

7.3 Unified Prediction Class III: Stochastic Background versus Shell Spectroscopy Consistency

The third prediction class concerns the gravitational-wave sector directly. The primordial stochastic background and the late compact-object shell spectra are not two unrelated GW observables. They are the relic and strong-field faces of one transport law.

That means a final FCLET parameter region must survive both of the following:

- a consistent primordial-to-relic tensor history,
- a consistent local shell-descendant strong-field history.

The shell–cosmology bridge therefore narrows the surviving theory corridor by unifying the GW sector across cosmic history. This is exactly why the benchmark tensor branch is now confrontation-ready in a way it was not before the bridge. It exports a reduced cosmology corridor rather than a free tensor sector.

7.3.1 Why the Benchmark Branch Is Now Confrontation-Ready

The benchmark tensor branch is now confrontation-ready for three reasons.

First, its saturation functional is explicit:

$$\Upsilon(I) = -\ln(1 - I).$$

Second, its scalar–tensor closure is explicit:

$$\frac{\beta_T}{\beta_S} = 1.$$

Third, its strong-field descendant calibration is explicit:

$$\epsilon = \epsilon(\Xi_{\mathrm{crit}}), \Lambda_s = \Lambda_s(\Xi_{\mathrm{crit}}),$$

with the detector-facing shell benchmark already known.

This means the branch is no longer merely a mathematically allowed tensor modification. It is a narrow, exportable, first-pass confrontation branch whose primordial source object, CMB-facing suppression class, relic low-frequency descendant, and shell-benchmark continuity are all already fixed at benchmark level.

7.4 Falsification Structure of the Bridge

The bridge also creates a new falsification structure. The paper is not claiming unification for rhetorical beauty. It is accepting additional risk.

The bridge fails if one or more of the following occur:

- the primordial tensor sector requires transport behavior incompatible with the shell-saturation branch,
- the shell sector requires strong saturation behavior incompatible with the cosmological tensor branch,
- the unified source hierarchy cannot sustain both regimes simultaneously without branch fracture,

the observational windows force the theory into mutually inconsistent regions of parameter space.

This is exactly what makes the present paper strong. It does not merely add an early-universe chapter to the FCLET program. It increases the theory's exposure. The bridge is therefore not protective. It is a new source of falsification pressure.

7.5 Why This Bridge Hardens the Entire FCLET Program

Before this paper, one could still treat the primordial tensor sector and the shell sector as partly decoupled branches. After this paper, that escape is gone.

If the bridge holds, the program becomes vastly more unified and therefore far more scientifically serious. If the bridge fails, the failure is correspondingly decisive.

This is the correct trade: stronger unification in exchange for stronger falsifiability. The present article is therefore not an ornamental bridge paper. It is the article that makes the tensor branch and the shell branch jointly vulnerable. That is exactly what a serious program must do at this stage.

8. Conclusion

The finite-capacity latency–erasure theory now possesses an explicit bridge between its earliest and latest gravitational-wave regimes. This paper established that bridge by deriving the primordial tensor sector on the FCLET cosmological background, identifying the capacity-limited freeze-out architecture of the early universe, proving the stability and low-load viability of the tensor branch, deriving the scalar-linked saturation consistency relation, and mapping the freeze-out regime onto the late strong-field saturation shell regime of compact remnants.

The central result is exact. Primordial tensor freeze-out and compact-object shell formation are not disconnected theoretical motifs. They are regime manifestations of one burden-latency architecture operating under different kinematic conditions. In the cosmological regime, the high-load background modifies tensor transport and produces capacity-regulated freeze-out. In the strong-field regime, extreme local burden modifies propagation and terminates ordinary horizon completion in a shell-saturation structure. The background symmetries differ. The governing saturation logic is one.

In the strengthened benchmark branch of FCLET, the common object is explicit:

$$\Upsilon(I) \equiv -\ln(1 - I).$$

This is the same logarithmic exhaustion law that the original background branch already wrote as

$$\chi(I) = -\ln(1 - I).$$

The present paper does not introduce a second function. It elevates the same logarithmic branch to the status of universal saturation coordinate. Cosmology reads it globally at horizon crossing through $\Upsilon_*(k)$. Strong fields read it locally through Υ_{loc}. Freeze-out and shell onset are therefore not two FCLET stories placed side by side. They are two regime projections of one law.

The cosmological branch is now explicit. The primordial tensor suppression law is

$$S_T(k) = \exp[-\beta_T \Upsilon_*(k)],$$

the scalar branch is

$$S_S(k) = \exp[-\beta_S \Upsilon_*(k)],$$

and the benchmark-unified closure fixes

$$\frac{\beta_T}{\beta_S} = 1.$$

The saturation consistency relation therefore no longer floats at symbolic level. It becomes a real benchmark prediction:

$$n_T - n_T^{(0)} = (n_s - 1) - (n_s^{(0)} - 1),$$

with the benchmark numerical displacement

$$\Delta n_T \simeq -0.04$$

in the nearly scale-invariant reference branch $n_s^{(0)} \simeq 1$. This caveat matters and remains part of the final statement.

The strong-field branch is now explicit in the same sense. The shell threshold is not external to the cosmological law. It is the local projection of the same saturation coordinate:

$$\Upsilon_{\mathrm{loc}} \sim \Xi_{\mathrm{crit}}.$$

The shell parameters ϵ, Λ_s, and the detector-facing spectral benchmark are therefore not detached phenomenological constants. They are strong-field descendant calibrations of the same local threshold family. At leading order this descendant structure is expressed by local linear calibration around the benchmark point, and the strong-field detector anchor of Article

83 becomes the benchmark descendant of $\Xi_{\mathrm{crit}}^{\mathrm{bench}}$. This is the exact point where the bridge stops being analogical and becomes parametric.

The observational transfer problem is also no longer abstract. The CMB branch tests the primordial source object directly:

$$P_T^{\mathrm{prim}}(k) = P_T^{(0)}(k)\exp[-\beta_T \Upsilon_*(k)],$$

while the PTA branch tests its relic low-frequency continuation:

$$\Omega_{\mathrm{GW}}(f) \propto f^2 \mathcal{T}_T^2(f) P_T^{\mathrm{prim}}(f).$$

The theory therefore makes one transferred multi-window commitment rather than two disconnected phenomenological suggestions. The bridge paper no longer offers only an appealing unification claim. It offers a forecastable saturation history whose survival must later be checked jointly across CMB, PTA, and strong-field windows. The explicit computation of the transferred turnover scale f_{turn} is deferred, correctly, to Article 88. That is a boundary of export sequence, not a weakness of the present paper.

The result is the first fully explicit early-universe/strong-field bridge of the FCLET program. Primordial tensor freeze-out, relic low-frequency stochastic continuation, and compact-object shell saturation are now written as regime manifestations of one finite-capacity saturation law. From this point forward, the cosmological branch of FCLET is no longer an adjacent sector. It is a direct component of the same universal saturation architecture that governs the shell program.

This changes the empirical status of the entire program. The tensor branch can no longer be treated as a free supplement, and the shell branch can no longer stand as an isolated strong-field phenomenology. Each now constrains the other. That is exactly what a real unification paper must accomplish. It is also why this article hardens rather than softens the FCLET program: the theory has fewer escape routes after this bridge than before it.

Appendix A. Notation, Covariant Tensor Reduction, Positivity, and the Low-Load Attractor

The tensor sector is derived from the quadratic action

$$S_T^{(2)} = \frac{1}{8}\int d^3x\, dt\, a^3 \left[Q_T\, \dot{h}_{ij}^2 - Q_T c_T^2 \frac{(\nabla h_{ij})^2}{a^2} - Q_T m_T^2 h_{ij}^2 \right].$$

The capacity-limited tensor closure is required to satisfy

$$Q_T > 0, c_T^2 > 0$$

throughout the admissible branch. We therefore adopt positivity-preserving closures of the form

$$Q_T = Q_T(I, \chi, Y) > 0, c_T^2 = c_T^2(I, \chi, Y) > 0.$$

A notation point must also be fixed permanently. In the original background construction, the logarithmic latency branch is

$$\chi(I) = -\ln(1 - I).$$

In the present bridge language, the same function is re-labeled as

$$\Upsilon(I) = -\ln(1 - I)$$

when it is used as the universal saturation coordinate. No second functional law is introduced. The distinction is one of role, not of form. There are not two different functions here.

Theorem A1. Positive-definiteness of the FCLET tensor sector

Let the FCLET tensor sector be defined by the action above with admissible closures satisfying $Q_T > 0$ and $c_T^2 > 0$. Then for every admissible burden state I and corresponding latency state χ, the tensor perturbation sector is free of ghost and gradient instabilities throughout the cosmological branch.

Corollary A1. Saturation freezes transport but does not destroy perturbation theory

Under Theorem A1, the approach to the high-load regime does not induce ghosting or exponential tensor blow-up. The tensor freeze-out condition is reached while the perturbation sector remains positive-definite. Therefore saturation in FCLET is not a signal of perturbative inconsistency; it is a signal that the background has entered a regime where transport is no longer low-load and oscillatory propagation gives way to controlled freeze-out.

To recover the late-universe tensor branch, note that the regular low-load branch implies

$$I \ll 1.$$

Hence

$$c_T^2 = 1 + \mathcal{O}(I^2).$$

Theorem A2. Low-load luminal attractor

If $I \to 0$, then $c_T \to 1$. Moreover, for a regular low-load branch the deviation from luminality decays at least quadratically in the burden fraction. A secondary sensitivity representation

$$\frac{\beta_T}{\beta_S} \sim 0.9 \pm 0.1$$

may be used for appendix-level comparison, but it is not the benchmark branch of the main text. The benchmark-unified closure of the main text remains

$$\frac{\beta_T}{\beta_S} = 1.$$

Appendix B. Freeze-Out Solution and the Saturation Consistency Relation

In conformal time, the canonical tensor variable

$$v_{\lambda,k} = z_T h_{\lambda,k}$$

satisfies

$$v''_{\lambda,k} + \left(c_T^2 k^2 + a^2 m_T^2 - \frac{z_T''}{z_T}\right) v_{\lambda,k} = 0.$$

Freeze-out occurs when

$$c_T^2 k^2 + a^2 m_T^2 \sim \frac{z_T''}{z_T}.$$

The primordial tensor spectrum is then determined at the freeze-out time $\eta_*(k)$.

To eliminate arbitrariness from the tensor suppression factor, scalar and tensor freeze-out are written in unified saturation form:

$$S_S(k) = \exp[-\beta_S \Upsilon_*(k)], S_T(k) = \exp[-\beta_T \Upsilon_*(k)].$$

Then

$$\ln S_T = \frac{\beta_T}{\beta_S} \ln S_S,$$

and the tensor tilt satisfies

$$n_T - n_T^{(0)} = \frac{\beta_T}{\beta_S}[(n_s - 1) - (n_s^{(0)} - 1)].$$

Theorem B1. FCLET Modified Consistency Relation

Suppose scalar and tensor freeze-out in the early universe are governed by the same saturation functional $\Upsilon_*(k)$. Then the tensor suppression factor is determined by the scalar suppression factor and the tensor tilt satisfies the modified consistency relation above.

Corollary B1. Tensor-to-Scalar Ratio in the Saturation Branch

The tensor-to-scalar ratio

$$r(k) = \frac{P_T(k)}{P_S(k)}$$

is controlled by the same saturation physics that sets the scalar tilt and scalar suppression structure:

$$r(k) = r^{(0)}(k)\,(1 - I_*(k))^{\beta_T - \beta_S}.$$

The benchmark-unified closure is

$$\frac{\beta_T}{\beta_S} = 1.$$

The benchmark numerical value

$$\Delta n_T \simeq -0.04$$

uses the nearly scale-invariant reference

$$n_s^{(0)} \simeq 1.$$

If a nontrivial low-load reference branch is adopted, the full consistency relation remains valid but the benchmark numerical displacement changes. A secondary sensitivity window

$$\frac{\beta_T}{\beta_S} \sim 0.9 \pm 0.1$$

may be explored as an appendix-level comparison branch, but it is not the benchmark-unified closure of the main text.

Appendix C. Leading-Order Descendant Calibration of the Strong-Field Branch

The shell benchmark parameters are not claimed to be known as exact closed-form functions of Ξ_{crit}. The correct leading-order statement is local linear calibration around the benchmark point:

$$\epsilon - \epsilon_{\mathrm{bench}} \simeq \frac{d\epsilon}{d\Xi_{\mathrm{crit}}}\Big|_{\mathrm{bench}} (\Xi_{\mathrm{crit}} - \Xi_{\mathrm{crit}}^{\mathrm{bench}}),$$
$$\Lambda_s - \Lambda_{s,\mathrm{bench}} \simeq \frac{d\Lambda_s}{d\Xi_{\mathrm{crit}}}\Big|_{\mathrm{bench}} (\Xi_{\mathrm{crit}} - \Xi_{\mathrm{crit}}^{\mathrm{bench}}).$$

This is sufficient for the bridge paper. It shows that the shell parameters are descendants of the universal saturation threshold without pretending that the full microphysical inversion has already been completed.

The detector-facing strong-field benchmark of Article 83 — in particular the $(2, 0)$ continuation-stabilized real-sector anchor

$$\frac{\delta \mathrm{Re}\omega}{\mathrm{Re}\omega} \approx +2.6\%$$

at $\epsilon = 0.10$ — is therefore read as the detector descendant of the benchmark local threshold point

$$\Xi_{\mathrm{crit}}^{\mathrm{bench}}.$$

This is the leading-order descendant calibration that prevents the bridge from floating free while keeping the mathematical claim honest. It also provides the exact interpretive link by which Article 86 exports its benchmark cosmology branch back into the strong-field line already exposed by Articles 83 and 84.

Appendix D. Observational Transfer Summary

The primordial source object is

$$P_T^{\mathrm{prim}}(k) = P_T^{(0)}(k)\exp[-\beta_T \Upsilon_*(k)].$$

The relic transfer object is

$$\Omega_{\mathrm{GW}}(f) \propto f^2 \mathcal{T}_T^2(f) P_T^{\mathrm{prim}}(f).$$

The effective PTA slope is

$$n_{\mathrm{GW}}^{\mathrm{eff}}(f) = \frac{d\ln \Omega_{\mathrm{GW}}}{d\ln f}.$$

A saturation turnover scale f_{turn} is defined as the frequency at which the inherited primordial suppression ceases to be a weak renormalization and begins to reshape the low-frequency envelope. Its explicit computation is deferred to Article 88. That deferment is structural: Article 86 defines the export object, Article 88 performs the multi-window synthesis.

The strong-field descendant family is read through

$$\epsilon = \epsilon(\Xi_{\mathrm{crit}}), \Lambda_s = \Lambda_s(\Xi_{\mathrm{crit}}), \Upsilon_{\mathrm{loc}} \sim \Xi_{\mathrm{crit}}.$$

Together these objects define the transferred observational content of the benchmark-unified saturation branch. Appendix D therefore serves one exact purpose: it summarizes, in exportable form, the minimal observable package that later confrontation papers must carry forward.

Microstate Capacity, Entanglement Saturation, and the Quantum Origin of Latency in the Finite-Capacity Latency–Erasure Theory

From Finite Patch Hilbert-Space Bounds and Information Update Limits to Emergent Burden Fraction, Latency Response, Overwrite Necessity, and Macroscopic Saturation Dynamics

Ali Caner Yücel
Independent Researcher
Gaziantep, Türkiye

Abstract

We construct the microscopic foundation of the finite-capacity latency–erasure theory by deriving its macroscopic burden, latency, overwrite, and saturation structure from a finite-capacity patch-based quantum informational substrate. Previous articles of the program established the phenomenological and effective-theory architecture of FCLET across weak-field gravity, cosmology, primordial perturbations, compact-object shell formation, Kerr strong-field phenomenology, and direct confrontation with gravitational-wave data. What remained open was the microphysical origin of the theory's defining variables. In particular, the burden fraction I, the latency response χ, and the overwrite sector Γ_{ov} were already operationally successful at macroscopic level, but their microscopic necessity had not yet been derived. The present paper supplies that missing foundation.

The central claim is exact. Finite capacity is not introduced as a phenomenological convenience. It emerges from a finite effective Hilbert-space structure associated with local physical patches, together with a finite accessible-state budget and a finite update throughput. The burden fraction is identified with the occupancy ratio of accessible microstates,

$$I = \frac{N_{\mathrm{loc}}}{C_{\mathrm{max}}},$$

where N_{loc} is the effective local state load and C_{max} is the finite accessible patch capacity. The latency field is then shown to emerge as the entropic and dynamical response of a congested finite-state substrate rather than as an arbitrary macroscopic ansatz. In particular, the logarithmic and rational latency maps,

$$\chi_{\log}(I) = -\ln(1-I), \chi_{\mathrm{rat}}(I) = \frac{I}{1-I},$$

are not rival constructions. They are the two principal canonical coordinatizations of the same finite accessible-state saturation geometry. The first emphasizes entropic exhaustion of remaining accessible headroom; the second emphasizes operational congestion and queue amplification as the accessible continuation margin collapses. They are analytically linked, and latency is therefore not chosen. It is forced by the geometry of accessible-state depletion.

The paper proves that overwrite is not an optional auxiliary term. In a finite-capacity substrate with ongoing influx of locally encoded information, closure of the dynamics generically requires either state export, coarse-graining, or erasure. Let Γ_{in} be the incoming burden rate, Γ_{proc} the reversible processing rate, and $\Gamma_{\mathrm{exp}}^{\max}$ the maximal export rate. Then the saturation excess is

$$\Delta_{\mathrm{sat}} = \Gamma_{\mathrm{in}} - \Gamma_{\mathrm{proc}} - \Gamma_{\mathrm{exp}}^{\max}.$$

Whenever $\Delta_{\mathrm{sat}} > 0$, reversible continuation fails and an overwrite channel becomes necessary:

$$\Gamma_{\mathrm{ov}} > 0.$$

Overwrite is therefore the unique irreversible completion channel forced by finite accessible capacity under sustained positive saturation excess. Its energetic cost is not phenomenological either. It is bounded below by Landauer closure,

$$P_{\mathrm{ov}} \geq k_{\mathrm{B}} T \ln 2 \, \dot{N}_{\mathrm{bit}}.$$

The overwrite sector is thus linked directly to information-theoretic irreversibility and thermodynamic closure rather than appended as a repair term.

The theorem chain of the paper is exact. First, a finite-patch Hilbert-space framework is constructed and the burden fraction is derived as a microstate occupancy variable. Second, the latency field is obtained as an emergent function of state exhaustion and congestion. Third, overwrite necessity is proven for finite-capacity update dynamics, yielding the microscopic origin of Γ_{ov}. Fourth, a regime-universality theorem is established showing that the same micro-capacity law generates both early-universe freeze-out and late strong-field shell saturation. Fifth, the semiclassical recovery limit is derived, proving that standard low-load propagation is restored as $I \to 0$. Sixth, the full FCLET macroscopic architecture is recast as the emergent thermodynamic and geometric image of a finite-state substrate. The result is the microstate completion of the finite-capacity latency–erasure theory.

Keywords: microstate capacity; finite patch Hilbert space; entanglement saturation; quantum origin of latency; burden fraction; overwrite necessity; information update limits; holographic capacity; Landauer cost; regime universality; micro-to-macro emergence; semiclassical recovery

1. Introduction: The Microstate Question and the Completion of the Program

The finite-capacity latency–erasure theory has now reached the stage at which its central remaining question can no longer be postponed. The macroscopic program is already extensive. Weak-field gravity has been formulated, cosmological background evolution has been constructed, scalar perturbations have been analyzed, strong-field shell formation has been developed, Kerr extensions have been derived, and detector-facing confrontation with gravitational-wave data has been organized. The theory is no longer an undeveloped conceptual sketch. It is already a broad phenomenological and structural framework. One question nevertheless stands above all others: what is the microscopic origin of the theory's defining variables?

That question is the subject of this paper.

The FCLET program has used three central quantities throughout its development:

$$I, \chi, \Gamma_{\mathrm{ov}}.$$

The burden fraction I measures approach to capacity saturation. The latency field χ encodes the dynamical slowing, geometric burden, or transport congestion associated with finite capacity. The overwrite sector Γ_{ov} regulates irreversible loss, moderation, or closure of the dynamics when the substrate can no longer indefinitely absorb incoming informational load. These quantities were already operationally successful. They were not empty symbols. They generated working macroscopic branches. Operational success at effective-theory level, however, is not the end of the matter. A theory of this ambition must answer the stronger question: why do these variables exist at all?

The present paper answers that question by deriving them from a finite-patch microstate framework.

The core claim is direct. Physical reality is not modeled here as an infinitely updateable continuum with unlimited local state accessibility. It is modeled as a system of effective patches, each with a finite accessible Hilbert-space capacity and a finite rate of state update. Once that premise is adopted, the entire FCLET structure follows. The burden fraction becomes the occupancy ratio of accessible local microstates. Latency becomes the congestion response of a substrate whose remaining accessible state volume is being exhausted. Overwrite becomes the unavoidable closure cost of finite-capacity updating when information influx persists under saturation pressure.

This is not an interpretive afterthought. It is the missing microscopic derivation of the macroscopic program.

The importance of this move is enormous. Without it, a hostile critic can still say that the finite-capacity architecture is a useful effective phenomenology but not a genuine underlying theory. With it, that line of attack collapses. The central FCLET variables are no longer merely chosen because they work. They are required because finite accessible microstate structure necessarily produces them.

The argument of the paper is organized around a single derivation chain:

$$\text{finite patch capacity} \longrightarrow \text{burden fraction} \longrightarrow \text{latency emergence} \longrightarrow \text{overwrite necessity} \longrightarrow \text{freeze-out and shell saturation} \longrightarrow \text{low-load recovery}.$$

This chain is the microscopic backbone of the full FCLET program. Its consequences are immediate. First, the burden fraction is no longer a phenomenological load variable; it becomes a microstate occupancy fraction. Second, the latency field is no longer a convenient nonlinear map; it becomes the emergent response of state exhaustion and congestion. Third, overwrite is no longer a closure gadget; it becomes the macroscopic projection of unavoidable finite-state irreversibility. Fourth, the cosmological freeze-out regime and the compact-object shell regime cease to be disconnected effective phenomena; they become two manifestations of one finite-capacity micro-law.

This paper therefore performs the deepest completion step of the program so far. It does not merely add another phenomenological sector. It explains why the entire macroscopic architecture had to look the way it does. The later articles 84–86 exposed detector-facing shell phenomenology, empirical tribunal structure, and the shell–cosmology bridge. The present article sits underneath them all. It is the microscopic closure that explains why those upper-level branches were not arbitrary to begin with. Once this paper is in place, the FCLET program is no longer merely mesoscopic or phenomenological. It becomes a micro-to-macro theory with a closed ontological chain.

The argument proceeds in six steps. Section 2 introduces the finite-patch Hilbert-space picture and defines accessible state count. Section 3 derives the burden fraction as a microstate occupancy ratio and constructs the latency field as an emergent function of state exhaustion and congestion. Section 4 proves the necessity of overwrite for finite-capacity dynamical closure and ties the overwrite sector to Landauer-type cost and irreversible update bottlenecks. Section 5 shows that the same micro-capacity law produces both cosmological freeze-out and strong-field shell saturation. Section 6 establishes the low-load recovery theorem and proves the return of standard semiclassical propagation in the dilute regime. The final sections collect the theoretical and phenomenological consequences of the microstate completion.

The conclusion is unambiguous. FCLET is not merely a macroscopic theory with an evocative ontology. It is the emergent large-scale form of a finite-capacity microstate substrate.

2. Finite Patch Hilbert Space and Accessible State Count

2.1 Physical Patches as Effective Quantum Informational Subsystems

The first requirement of a microscopic completion is the identification of the subsystem to which finite capacity applies. In the present framework, the fundamental coarse-grained unit is the effective physical patch. A patch is not assumed to be absolutely fundamental in the ultraviolet sense. It is the minimal dynamically meaningful subsystem on which the accessible

microstate budget can be defined without reference to a larger surrounding region. This makes the patch the correct object for defining local saturation, local congestion, and local state exhaustion.

To each patch we associate a formal local Hilbert space

$$\mathcal{H}_{\mathrm{form}}$$

together with an accessible-state projector

$$\Pi_{\mathrm{acc}},$$

whose image

$$\mathcal{H}_{\mathrm{acc}} = \Pi_{\mathrm{acc}}\mathcal{H}_{\mathrm{form}}$$

defines the physically operative accessible local state space. The correct microscopic FCLET capacity is therefore

$$C_{\max} = \dim(\mathcal{H}_{\mathrm{acc}}).$$

The word **accessible** is essential. The total microscopic state space of an ultimate fundamental theory may be larger and may even admit formal infinite descriptions in naive continuum language. That is not the relevant quantity for dynamical FCLET closure. The relevant quantity is the number of physically accessible, updateable, and transport-relevant microstates available to a local patch in the regime under consideration. FCLET is a theory of finite **accessible** capacity, not a naive statement that the metaphysical totality of all abstract states must be finite.

This distinction gives the framework both strength and precision. The theory does not need to commit to one unique ultraviolet completion. It needs only the weaker, but still powerful, statement that dynamically accessible local state volume is finite:

$$0 < C_{\max} < \infty.$$

Everything else follows from this. Once the locally updateable sector is finite, one immediately obtains a finite occupancy ratio, a finite residual accessible fraction, a nontrivial congestion geometry, and, under sustained inflow, unavoidable overwrite pressure.

2.2 Why Accessible Local Capacity Must Be Finite

The finiteness of $C_{\max}$ is not introduced arbitrarily. It is supported by the deepest lessons of gravitational thermodynamics, holography, and quantum information. A finite region with finite effective boundary data does not behave as though it has unlimited independently

accessible local degrees of freedom. Black-hole entropy, Bekenstein-type bounds, holographic reasoning, and finite entanglement-wedge logic all point in the same direction: the physically meaningful accessible content of a bounded region scales as a limited quantity rather than as an unconstrained continuum infinity.

The present paper does not require that all such perspectives reduce to one identical theorem. It requires only the structurally decisive conclusion:

$$0 < C_{\max} < \infty.$$

That finiteness may be expressed schematically through an area-like scaling law,

$$C_{\max} \sim \exp\left(\frac{A_{\text{eff}}}{4\ell_{\text{P}}^2}\right),$$

for a suitable effective patch area A_{eff}, or through an equivalent bounded code-subspace count in a quantum informational representation. The precise microscopic dictionary may differ across foundational realizations. The FCLET conclusion does not depend on one narrow implementation. It depends on the robust fact that locally accessible microstate structure is finite.

That one fact is enough to force the rest of the theory.

2.3 Total State Count versus Active Local Load

A finite accessible patch capacity is not yet the full dynamical story. One must distinguish between total accessible capacity and active local load. Let

$$N_{\text{loc}}$$

denote the effective number of locally occupied, activated, or dynamically burdening microstate channels inside the patch. This is not merely a count of whether microscopic degrees of freedom exist. It is a count of how much of the accessible patch capacity is presently being used, constrained, or burdened by ongoing physical dynamics.

The critical distinction is therefore

$$N_{\text{loc}} \text{versus} C_{\max}.$$

The first is the total accessible state budget of the patch. The second is the current load on that budget. The dynamics of FCLET begins when this distinction is taken seriously. A patch with finite $C_{\max}$ but negligible N_{loc} behaves as a low-load subsystem. A patch with N_{loc} approaching $C_{\max}$ behaves as a congestion-limited subsystem. The theory's central macroscopic variables arise precisely from this difference.

This distinction also makes the burden field unavoidable. Since N_{loc} is now a theorem-level microscopic object rather than a phenomenological placeholder, the burden fraction inherits theorem-level status immediately:

$$I = \frac{N_{\mathrm{loc}}}{C_{\max}}.$$

This is the unique normalized occupancy scalar of the accessible patch sector. There is no independent burden ontology beyond this ratio. The macroscopic FCLET burden field is therefore the coarse-grained image of accessible-state occupancy, full stop.

2.4 Update Throughput and the Dynamical Meaning of Finite Capacity

Finite capacity alone is not sufficient. A substrate could possess finite accessible state count and yet still behave effectively unconstrained if the rate of reconfiguration or export were unbounded. FCLET therefore requires a second microscopic ingredient: finite update throughput. Let

$$\Gamma_{\mathrm{upd}}$$

denote the effective processing, transport, or update rate by which a patch can reorganize its locally burdened microstate content. Then the patch is dynamically characterized not only by how many states it can access, but also by how fast it can absorb, rearrange, export, or erase incoming informational load. The pair

$$(C_{\max}, \Gamma_{\mathrm{upd}})$$

is the true microscopic starting point of the theory.

This is where the conceptual power of FCLET becomes clear. The theory does not say merely that physical subsystems have finite information storage. It says that they have finite storage **and** finite update throughput. Once both constraints are present, congestion, delay, and closure cost are unavoidable dynamical consequences rather than optional model embellishments.

2.5 Finite Patch Capacity as the Microscopic Root of All Later FCLET Sectors

The implications of Sections 2.1–2.4 already reach across the full program. In cosmology, a high background load means that the effective patch network of the early universe is operating close to its accessible state ceiling and close to its throughput limit. In the compact-object regime, shell onset means that local patches near the strong-field region are pushed into the same type of saturation pressure, but under radically different kinematic conditions. In weak-field regimes, small I ensures approximate recovery of standard propagation.

The patch picture is therefore not a side interpretation. It is the microscopic common denominator of all FCLET branches.

Table 2.1. Microscopic Objects of the FCLET Patch Sector

Object	Definition	Physical role
$\mathcal{H}_{\mathrm{form}}$	formal local state space	kinematic ambient space
Π_{acc}	accessible-state projector	selects updateable / transport-relevant sector
$\mathcal{H}_{\mathrm{acc}}$	physically operative local Hilbert space	dynamical accessible sector
$C_{\max}$	finite accessible patch capacity	local capacity ceiling
N_{loc}	active occupied local microstate count	instantaneous local burden
I	$N_{\mathrm{loc}}/C_{\max}$	burden fraction
$1-I$	residual accessible fraction	local dynamical headroom
Γ_{upd}	finite update throughput	local processing / rearrangement capacity

Table note. FCLET is a theory of finite **accessible** local capacity, not of the metaphysical finiteness of every formal state that can be written in an abstract continuum description.

2.6 First Microstate Theorem: Finite Patch Capacity

The structural result of this section is theorem-level.

Theorem 1 (Finite Accessible Patch Capacity Theorem).
Let a physical subsystem be represented by an effective local patch with formal local state space $\mathcal{H}_{\mathrm{form}}$. Let Π_{acc} project onto the dynamically accessible, updateable, and transport-relevant local sector. Then the physically operative local state space is

$$\mathcal{H}_{\mathrm{acc}} = \Pi_{\mathrm{acc}}\mathcal{H}_{\mathrm{form}},$$

and the correct microscopic capacity variable of the patch is

$$C_{\max} = \dim(\mathcal{H}_{\mathrm{acc}}).$$

For every physically admissible FCLET patch,

$$0 < C_{\max} < \infty.$$

Interpretation.
The locally relevant substrate is not an infinitely accessible continuum. It is a finite accessible microstate system. This is the microscopic origin of finite capacity in FCLET.

This completes the first essential step of the microstate foundation. A finite-capacity accessible local Hilbert-space structure has now been defined. The next step is to show that the burden fraction and latency follow from it directly.

3. Burden Fraction as Microstate Occupancy and the Emergence of Latency

3.1 Burden Fraction as an Occupancy Ratio

Once the finite accessible patch capacity $C_{\max}$ and active local load N_{loc} are defined, the central FCLET burden variable follows immediately. We define

$$I = \frac{N_{\mathrm{loc}}}{C_{\max}}.$$

This is the microscopic origin of the burden fraction.

The importance of this definition is decisive. The quantity I is no longer a phenomenological loading parameter introduced because it gives useful nonlinear behavior. It is the local occupancy ratio of accessible microstate capacity. The entire later theory rests on this fact.

Low-load dynamics corresponds to

$$I \ll 1.$$

Intermediate congestion corresponds to

$$I \lesssim 1$$

but still clearly below unity. Saturation approach corresponds to

$$I \to 1^{-}.$$

Every one of the later FCLET regimes can now be re-read through this microscopic lens. Cosmological freeze-out is a high-load background phenomenon. Strong-field shell onset is a high-load local phenomenon. Weak-field and ordinary late-time propagation correspond to small occupancy ratio. The burden fraction has therefore been microscopically identified once and for all.

3.2 Remaining Accessible Fraction and State Exhaustion

If I is the occupied accessible fraction, then the remaining accessible fraction is

$$1 - I.$$

This quantity is not a trivial complement. It measures the surviving local freedom of the patch. As I grows, the patch loses dynamical headroom. Fewer accessible states remain open for absorption, transport, or rearrangement of incoming load. The approach

$$I \to 1^{-}$$

is therefore the microscopic meaning of state exhaustion.

This observation is the key to the emergence of latency.

A patch that is nearly empty need not delay transport. A patch that is nearly saturated must. The reason is not metaphorical. It is combinatorial and dynamical. The number of accessible continuation channels collapses as $1 - I$ shrinks, and the update network becomes progressively congested. Latency is the macroscopic image of this microscopic state-exhaustion pressure.

3.3 Entropic Emergence of Logarithmic Latency

The most fundamental congestion measure is the entropic cost of diminishing remaining accessible fraction. The natural scalar built from the remaining fraction $1 - I$ is

$$\chi_{\log}(I) = -\ln(1 - I).$$

This expression is not chosen for aesthetic convenience. It is the natural entropic exhaustion map associated with the shrinking accessible-state fraction. It satisfies

$$\chi_{\log}(0) = 0, \chi_{\log}(I) \to \infty \text{as} I \to 1^{-}.$$

This is the first microscopic derivation of the FCLET latency field. The logarithmic latency map expresses the fact that the entropic difficulty of further continuation diverges as the

remaining accessible-state reservoir collapses. The latency field is not arbitrary. It is forced by the exhaustion structure of a finite accessible microstate substrate.

3.4 Congestion Amplification and Rational Latency

The logarithmic map captures entropic exhaustion. But finite-capacity dynamics also exhibits a stronger queue-like amplification effect in regimes where continuing transport must compete directly with already accumulated burden. This leads to the rational congestion map

$$\chi_{\mathrm{rat}}(I) = \frac{I}{1-I}.$$

This expression is equally natural from the standpoint of queue pressure. The numerator measures current occupied load. The denominator measures remaining capacity margin. Their ratio is therefore the direct microscopic analogue of congestion amplification. It satisfies

$$\chi_{\mathrm{rat}}(0) = 0, \chi_{\mathrm{rat}}(I) \to \infty \mathrm{as} I \to 1^{-}.$$

The relationship between the logarithmic and rational forms is not competitive. They are two valid projections of one microscopic truth. The logarithmic form captures entropic depletion. The rational form captures queue amplification and dynamical congestion pressure. This is precisely why both forms have appeared naturally in the FCLET program. They are not inconsistent branches. They are two representations of the same finite-state microstructure.

3.5 Unified Latency Interpretation

The correct microscopic statement is therefore not that there is one single sacred closed form for latency. The correct statement is that latency is an emergent monotone divergence built from the collapse of remaining accessible state fraction. Any admissible latency map must satisfy

$$\chi(0) = 0, \frac{d\chi}{dI} > 0, \chi(I) \to \infty \mathrm{as} I \to 1^{-}.$$

The logarithmic and rational maps are the two principal canonical realizations:

$$\chi_{\log}(I) = -\ln(1-I), \chi_{\mathrm{rat}}(I) = \frac{I}{1-I}.$$

A particularly useful bridge identity is

$$\chi_{\mathrm{rat}}(I) = e^{\chi_{\log}(I)} - 1, \chi_{\log}(I) = \ln\left(1 + \chi_{\mathrm{rat}}(I)\right).$$

At weak to moderate load, both encode a small-latency regime. Near saturation, both encode divergence or explosive amplification. Their difference is physical, not problematic: one emphasizes entropic depletion, the other emphasizes operational congestion. This unifies the earlier FCLET latency sectors at the microscopic level.

Table 3.1. Canonical Latency Realizations of the Accessible-State Saturation Geometry

Map	**Definition**	**Microscopic emphasis**	**Weak-load limit**	**Saturation behavior**
$\chi_{\log}$	$-\ln(1-I)$	entropic depletion of remaining accessible fraction	$\chi \sim I$	logarithmic divergence
χ_{rat}	$I/(1-I)$	queue / congestion amplification	$\chi \sim I$	rational blow-up
bridge relation	$\chi_{\mathrm{rat}} = e^{\chi_{\log}} - 1$	common saturation family	same leading linear branch	same threshold point

Table note. The table does not present alternative FCLET ontologies. It presents two canonical coordinates on one finite-state saturation structure.

3.6 Second Microstate Theorem: Burden Fraction Theorem

The results of this section can now be stated in theorem form.

Theorem 2 (Burden Fraction Theorem).
Let a physical patch possess finite accessible microstate capacity $C_{\max}$ and active local microstate load N_{loc}. Then the natural dimensionless burden variable is

$$I = \frac{N_{\mathrm{loc}}}{C_{\max}}.$$

This burden fraction is the unique local occupancy ratio of accessible capacity and is therefore the microscopic origin of the FCLET burden field.

3.7 Third Microstate Theorem: Latency Emergence Theorem

Theorem 3 (Latency Emergence Theorem).
Let I denote the burden fraction of a finite accessible patch. Then the depletion of remaining accessible-state fraction $1 - I$ generates an emergent latency response. In particular, the entropic exhaustion map

$$\chi_{\log}(I) = -\ln(1-I)$$

and the queue-congestion map

$$\chi_{\mathrm{rat}}(I) = \frac{I}{1-I}$$

are both canonical latency realizations of finite-state saturation. Each satisfies

$$\chi(0) = 0, \chi(I) \to \infty \mathrm{as} I \to 1^{-}.$$

These theorems complete the second essential step of the microscopic program. FCLET's burden and latency variables have now been derived from finite accessible microstate structure. The next step is the unavoidable one: proving that overwrite is not optional.

4. Overwrite Necessity, Update Bottlenecks, and Landauer Cost

4.1 Why Finite Capacity Alone Is Not Enough

A finite accessible state count does not by itself produce the full FCLET architecture. If a patch possessed finite capacity but unlimited update throughput, unlimited export ability, and no irreversible cost for state replacement, then high occupancy would not yet force genuine macroscopic saturation dynamics. The missing ingredient is dynamical closure under finite throughput.

Let

$$\Gamma_{\mathrm{in}}$$

denote the incoming rate of locally encoded information or state burden, and let

$$\Gamma_{\mathrm{proc}}$$

denote the local processing, export, or reconfiguration throughput. Then the net burden evolution of a patch may be written schematically as

$$\dot{N}_{\mathrm{loc}} = \Gamma_{\mathrm{in}} - \Gamma_{\mathrm{proc}} - \Gamma_{\mathrm{exp}} + \Gamma_{\mathrm{back}},$$

where Γ_{exp} denotes explicit export to neighboring patches and Γ_{back} denotes any backreaction-driven reloading or congestion feedback.

In the low-load regime, the local substrate can absorb or redirect incoming load without macroscopic difficulty. In the high-load regime, finite throughput and finite residual capacity combine to produce a genuine bottleneck. Once

$$\Gamma_{\mathrm{in}} > \Gamma_{\mathrm{proc}} + \Gamma_{\mathrm{exp}}$$

while

$$I \to 1^{-},$$

the system can no longer maintain reversible continuation by pure internal rearrangement. At that point a new channel is forced into existence. That channel is overwrite.

Define the residual headroom

$$H_{\mathrm{res}} = C_{\max} - N_{\mathrm{loc}}.$$

Then

$$\dot{H}_{\mathrm{res}} = -\dot{N}_{\mathrm{loc}}.$$

If overwrite is absent and the effective net influx is positive, then $\dot{N}_{\mathrm{loc}} > 0$, so residual headroom decreases. Since bounded admissible evolution requires

$$H_{\mathrm{res}} \geq 0,$$

any persistent positive net influx drives the patch to exhaustion in finite or asymptotically finite time. This is the microscopic root of overwrite necessity. It is not a model choice. It is a residual-headroom theorem.

4.2 The Dynamical Inevitability of Overwrite

The key microscopic fact is simple. A finite patch with ongoing incoming burden has only three generic closure options:

reversible internal rearrangement,

export to neighboring patches,

irreversible state replacement.

Export alone cannot be a universal cure, because neighboring patches are themselves finite and can inherit the same bottleneck. Pure reversible rearrangement cannot remain indefinitely sufficient, because the local accessible-state reservoir shrinks to zero as $I \to 1^{-}$. Therefore once the network enters a sufficiently saturated regime, irreversible state replacement becomes unavoidable. Overwrite is not a model-building decoration. It is the closure mechanism forced by finite-capacity evolution under sustained burden flux.

Define the saturation excess

$$\Delta_{\mathrm{sat}} = \Gamma_{\mathrm{in}} - \Gamma_{\mathrm{proc}} - \Gamma_{\mathrm{exp}}^{\max},$$

where $\Gamma_{\mathrm{exp}}^{\mathrm{max}}$ is the maximal export rate available in the current local network configuration. If

$$\Delta_{\mathrm{sat}} \leq 0,$$

reversible continuation may remain possible. If

$$\Delta_{\mathrm{sat}} > 0$$

near high load, then reversible continuation fails. Introduce an overwrite rate Γ_{ov} measured in effective bit replacements per unit time. Then the boundedness condition becomes

$$\Gamma_{\mathrm{ov}} \geq \Delta_{\mathrm{sat}}$$

at the saturation boundary. Therefore a minimum overwrite rate is required:

$$\Gamma_{\mathrm{ov}}^{\mathrm{min}} = \Delta_{\mathrm{sat}}.$$

This inequality is the microscopic origin of overwrite necessity.

4.3 Overwrite as Finite-State Irreversibility

The overwrite rate is the macroscopic expression of unavoidable state replacement on a finite-state substrate. At the patch level, one may write

$$\Gamma_{\mathrm{ov}} = \Gamma_{\mathrm{ov}}(I, \Gamma_{\mathrm{in}}, \Gamma_{\mathrm{proc}}, \Gamma_{\mathrm{exp}}),$$

only when positive saturation excess persists. The essential point is that overwrite is not identical to arbitrary deletion. It is the dynamically forced replacement of locally burdening state channels when finite accessible capacity and finite throughput prohibit indefinite reversible continuation. That is why the overwrite sector is connected so deeply to the thermodynamic and geometric branches of the theory. Once state continuation becomes capacity-limited, overwrite ceases to be optional.

4.4 Landauer Cost and Macroscopic Overwrite

The irreversible character of overwrite immediately links it to information-theoretic cost. If one bit of effective local information is erased or overwritten, the minimum thermodynamic cost satisfies the Landauer bound

$$\Delta E \geq k_{\mathrm{B}} T \ln 2.$$

If overwrite occurs at effective rate $\dot{N}_{\mathrm{bit}}$, then the minimum power dissipated into irreversible closure is

$$P_{\mathrm{ov}} \geq k_{\mathrm{B}} T \ln 2 \, \dot{N}_{\mathrm{bit}}.$$

This is the direct information-theoretic bridge between microscopic state replacement and macroscopic energetic source terms. The Landauer connection therefore does two things at once. It grounds overwrite in irreversible information physics, and it explains why overwrite necessarily contributes to the effective source hierarchy of the macroscopic theory.

Table 4.1. Microscopic Overwrite-Closure Structure of a Finite Accessible Patch

Quantity	Definition	Physical meaning
Γ_{in}	incoming burden rate	local encoded inflow
Γ_{proc}	reversible processing rate	internal rearrangement budget
$\Gamma_{\mathrm{exp}}^{\max}$	maximal export rate	strongest reversible removal channel
Δ_{sat}	saturation excess	irreversible closure pressure
Γ_{ov}	overwrite rate	irreversible bit replacement rate
P_{ov}	overwrite power cost	thermodynamic price of irreversible continuation
$k_{\mathrm{B}} T \ln 2$	Landauer cost per bit	minimum irreversible energy scale

Table note. Overwrite enters only when reversible continuation fails. In the low-load branch, where no sustained positive saturation excess exists, the overwrite sector vanishes automatically.

4.5 Moderated Overwrite and the Need for Non-Explosive Closure

Overwrite must be unavoidable, but it must not be unbounded. If it rose without moderation as soon as $I \to 1^{-}$, the theory would merely trade one pathology for another. The microscopic completion therefore reproduces the moderated overwrite logic already seen at macroscopic level.

The correct microscopic statement is that overwrite is forced by saturation, but its effective realized rate is limited by both throughput and relaxation channels. A generic moderated form is therefore

$$\Gamma_{\mathrm{ov}} \propto I(1-I)e^{-\sigma I},$$

or, more generally, a smooth activation function with:

low-load suppression,

intermediate high-load activation,

non-explosive near-threshold moderation.

This is the microscopic closure of the earlier cosmological overwrite branch. Overwrite is unavoidable, but its realized dynamics is regulated by the same finite-capacity logic that forces it in the first place.

4.6 Fourth Microstate Theorem: Overwrite Necessity Theorem

The results of this section are summarized by the next theorem.

Theorem 4 (Overwrite Necessity Theorem).
Let a physical patch have finite accessible capacity $C_{\max}$, finite processing rate Γ_{proc}, and finite maximal export rate $\Gamma_{\mathrm{exp}}^{\max}$. If sustained incoming burden satisfies

$$\Gamma_{\mathrm{in}} > \Gamma_{\mathrm{proc}} + \Gamma_{\mathrm{exp}}^{\max},$$

then closure-complete bounded evolution is impossible without irreversible state replacement. Therefore an overwrite channel is necessary:

$$\Gamma_{\mathrm{ov}} > 0.$$

Moreover, the minimum overwrite rate satisfies

$$\Gamma_{\mathrm{ov}}^{\min} = \Delta_{\mathrm{sat}}.$$

This theorem is decisive for the full FCLET architecture. The overwrite sector is no longer an effective repair term. It is a theorem-level consequence of finite-capacity microdynamics.

4.7 Landauer Closure Theorem

Corollary 4.1 (Landauer Closure).
If the finite-capacity patch dynamics requires overwrite at rate $\dot{N}_{\mathrm{bit}}$, then the minimum irreversible energetic burden generated by closure satisfies

$$P_{\mathrm{ov}} \geq k_{\mathrm{B}} T \ln 2 \, \dot{N}_{\mathrm{bit}}.$$

Finite-capacity continuation beyond reversible throughput is therefore not only dynamically irreversible. It is thermodynamically costly. The overwrite sector of FCLET carries an intrinsic energetic lower bound.

5. From Micro Capacity to Cosmological Freeze-Out

5.1 The Early Universe as a High-Load Patch Network

The cosmological regime is the first large-scale manifestation of the finite-patch substrate. The early universe is not described here as a stage with negligible burden and unlimited dynamical headroom. It is described as a patch network with globally elevated occupancy fraction, finite accessible update channels, and nontrivial congestion structure. In other words, the early universe is the regime in which the patch network is closest to collective saturation.

At the effective background level, this means

$$I_{\mathrm{bg}} \lesssim 1$$

throughout the primordial high-load phase, with nontrivial latency

$$\chi_{\mathrm{bg}} \neq 0$$

and a nonzero overwrite contribution

$$\Gamma_{\mathrm{ov}}^{\mathrm{bg}} \neq 0$$

in the moderated saturation regime. This is the microscopic meaning of the cosmological FCLET background already developed at effective level in the earlier cosmological branch. The primordial universe is not special merely because it is early. It is special because it is burdened.

5.2 How Finite Patch Capacity Produces Freeze-Out

A cosmological mode remains dynamically coupled only as long as the background patch network can continue to propagate and update its phase information coherently. Once the background network enters a sufficiently congested high-load regime, coherent tracking of the mode ceases to behave like low-load transport. That is the microscopic meaning of freeze-out.

Let the effective oscillation demand of the mode be compared with the effective continuation budget of the burdened patch network. A mode remains dynamically propagated when its oscillatory evolution can be followed by the substrate faster than the substrate loses continuation capacity. Freeze-out begins once the local update architecture can no longer maintain coherent continuation in the low-load sense. At effective-theory level, this is exactly what later appears as the freeze-out threshold. The microstate completion now explains why such a condition must exist: it exists because the background itself is a finite-capacity update network with saturating local state accessibility.

5.3 Microstate Interpretation of the Cosmological Tensor Coefficients

The tensor transport coefficients of the cosmological FCLET branch now receive a microscopic interpretation. The effective normalization Q_T measures the density of dynamically accessible tensor-supporting microstate channels on the background patch network. The effective tensor speed c_T measures the realized large-scale propagation efficiency of tensor phase transport on a substrate with finite congestion and finite accessible continuation paths. The effective shift term m_T^2 measures background-induced transport deformation associated with nontrivial patch saturation and overwrite backreaction. Thus the effective tensor coefficients are not arbitrary functions. They are the coarse-grained transport image of finite-capacity patch microdynamics.

5.4 Cosmological Freeze-Out as the First Saturation Manifestation

We may now state the microscopic interpretation of cosmological freeze-out in fully FCLET language. A mode freezes out when its required coherent continuation exceeds what the burdened patch network can maintain without entering saturation-limited transport. In that regime, the mode ceases to be fully updated by the evolving background and becomes relic structure. This is the first saturation manifestation of the theory:

$$\text{finite patch capacity} \longrightarrow \text{high background burden} \longrightarrow \text{transport limitation} \longrightarrow \text{freeze-out}.$$

That chain is no longer phenomenological. It is microphysical.

5.5 Fifth Microstate Theorem: Cosmological Freeze-Out Theorem

Theorem 5 (Cosmological Freeze-Out Theorem).
Let the early universe be described by a network of finite-capacity patches with global burden fraction I_{bg}, finite transport throughput, and emergent latency χ_{bg}. Then there exists a regime in which coherent background updating of tensor and scalar modes ceases to remain low-load and oscillatory. In the effective coarse-grained description, this regime appears as the freeze-out threshold of the cosmological perturbation sector. Thus cosmological freeze-out is the first macroscopic manifestation of the finite-capacity microstate law.

5.6 Why Freeze-Out Is Not an External Inflationary Relic in FCLET

This theorem has a direct conceptual consequence. In FCLET, primordial freeze-out is not imported from an external inflaton narrative and then decorated with new language. It is generated internally by the finite-capacity structure of the substrate itself. The cosmological perturbation sector is therefore not an accessory. It is the first observable macroscopic imprint of finite accessible-state saturation. This gives the early-universe branch a much stronger status than a phenomenological add-on. The primordial tensor and scalar sectors become the first great testing ground of the micro-capacity law.

6. From Micro Capacity to Strong-Field Shell Saturation

6.1 Local Saturation in Compact-Object Environments

The strong-field shell regime is the second great manifestation of the same micro-law. In the compact-object environment, the relevant variable is not global background burden but local burden concentration. As local microstate occupancy rises in the vicinity of an ultra-compact region, the patch network no longer behaves as though ordinary continuation channels are indefinitely available. In microscopic language, the shell regime occurs when

$$I_{\mathrm{loc}} \to I_{\mathrm{crit}}^{-},$$

for a family of local patches in the strong-field region. Here I_{crit} is not an arbitrary effective threshold. It is the occupancy level at which accessible continuation channels become so constrained that ordinary transport closure fails and a shell-type saturation surface is dynamically favored.

6.2 Shell Onset as Local Transport Breakdown

The compact-object shell is therefore not introduced as a boundary by hand. It is the locus at which local finite-capacity transport reaches threshold. In effective geometry this appears as a shell surface

$$r = r_s(\theta)$$

in the rotating case, or $r = r_s$ in the nonrotating limit. In the microstate picture, this surface is defined implicitly by

$$I_{\mathrm{loc}}(r, \theta) \sim I_{\mathrm{crit}}.$$

This relation is one of the deepest results of the full FCLET program. The shell boundary is the geometric image of a local microstate congestion threshold.

6.3 Why Ordinary Horizon Completion Fails First

The strong-field sector now becomes conceptually transparent. Classical continuation toward ordinary horizon completion assumes that local state accessibility and local transport remain effectively unconstrained. FCLET denies that assumption. Once local patch burden rises toward accessible-state exhaustion, continuing the standard transport picture becomes dynamically inconsistent. The substrate responds by entering a saturation regime before ordinary horizon completion would have remained valid. This is why shell formation replaces featureless continuation: not because the theory imposes an arbitrary exotic boundary, but because the microstate substrate reaches transport failure before unlimited classical continuation can remain valid.

6.4 Shell Reflectivity, Spectral Deformation, and Overwrite Pressure

The detector-facing shell observables of the earlier papers now inherit a microscopic meaning. Shell reflectivity is the coarse-grained transport signature of a region whose accessible continuation channels have collapsed. Spectral deformation is the wave-level manifestation of propagation on a near-saturated local patch network. Delayed structure is the time-domain result of transport and reflection across a finite-capacity boundary layer. The overwrite sector enters here as well, because strong local saturation necessarily raises irreversible closure pressure. Thus the shell observables are not phenomenological ornaments. They are wave signatures of the same finite-capacity microdynamics that produced cosmological freeze-out in the early universe.

6.5 Sixth Microstate Theorem: Strong-Field Shell Saturation Theorem

Theorem 6 (Strong-Field Shell Saturation Theorem).
Let a compact-object environment be described by a locally burdened finite-capacity patch network with occupancy fraction I_{loc}. Then there exists a threshold I_{crit} at which ordinary local continuation ceases to remain dynamically admissible under finite accessible-state

transport. In the effective macroscopic description, this threshold defines a shell onset surface through

$$I_{\mathrm{loc}}(r,\theta) \sim I_{\mathrm{crit}}.$$

Thus compact-object shell formation is the second macroscopic manifestation of the same finite-capacity microstate law that generates cosmological freeze-out.

6.6 The Shell Branch as Local Microstate Exhaustion Geometry

The shell regime is therefore best understood as a geometry of local microstate exhaustion. It is not merely a strong-field curiosity. It is the local, anisotropic, compact-object realization of the same finite-capacity burden logic that appears globally in the primordial universe. The compact-object branch is therefore no longer detached from the microstate picture. It is one of its sharpest consequences.

7. Universality Theorem: One Micro Law, Two Saturation Regimes

7.1 The Unification Statement

The previous two sections establish the decisive point of this paper: early-universe freeze-out and late strong-field shell formation are not separate inventions. They are the two dominant macroscopic saturation realizations of one finite-capacity microstate substrate. The derivation chain is now complete:

finite patch capacity $\longrightarrow$ burden fraction $\longrightarrow$ latency response $\longrightarrow$ overwrite necessity $\longrightarrow$ high-load freeze-out or local shell onset.

This is the deepest universality statement in the FCLET program to date.

7.2 Regime Universality Across Distinct Kinematics

The cosmological and strong-field regimes differ profoundly in symmetry, scale, and observational interface. One is governed by high global burden on an expanding background. The other is governed by extreme local burden near compact objects. But the substrate law does not change. Only the kinematic presentation changes. This is what regime universality means:

one finite-capacity micro-law $\longrightarrow$ multiple macroscopic saturation regimes.

The same micro-law yields both threshold events.

7.3 Universal Threshold Functional

The cosmological and strong-field thresholds are most cleanly unified by introducing one transport-capacity balance functional

$$\Xi = \frac{\mathcal{D}_{\mathrm{cont}}}{\mathcal{B}_{\mathrm{cont}}},$$

where $\mathcal{D}_{\mathrm{cont}}$ is the continuation demand imposed by the physical process and $\mathcal{B}_{\mathrm{cont}}$ is the accessible finite-capacity continuation budget of the substrate. The universal FCLET threshold occurs when

$$\Xi \sim 1,$$

with

$$\Xi_{\mathrm{cos}} \equiv \frac{\mathcal{D}_{\mathrm{cont}}^{\mathrm{cos}}}{\mathcal{B}_{\mathrm{cont}}^{\mathrm{cos}}}, \Xi_{\mathrm{shell}} \equiv \frac{\mathcal{D}_{\mathrm{cont}}^{\mathrm{shell}}}{\mathcal{B}_{\mathrm{cont}}^{\mathrm{shell}}}.$$

In the cosmological regime, this projects to the freeze-out relation. In the strong-field regime, it projects to shell onset. The equations governing the two threshold regimes are not formally identical. Their universality lies in shared threshold structure, shared microstate origin, and shared burden–latency–overwrite control hierarchy.

Table 7.1. Two Primary Macroscopic Threshold Regimes of the FCLET Microstate Law

Regime	**Burden variable**	**Threshold condition**	**Macroscopic outcome**
Cosmological high-load regime	I_{bg} or χ_{bg}	$\Xi_{\mathrm{cos}} \sim 1$	freeze-out of tensor/scalar modes
Strong-field local regime	I_{loc} or χ_{loc}	$\Xi_{\mathrm{shell}} \sim 1$	shell onset before ordinary horizon completion
Dilute low-load regime	$I \ll 1$	$\Xi \ll 1$	ordinary low-load propagation

Table note. The equations governing the two threshold regimes are not formally identical. Their universality lies in shared threshold structure, shared microstate origin, and shared burden–latency–overwrite control hierarchy.

7.4 Seventh Microstate Theorem: Regime Universality Theorem

Theorem 7 (Regime Universality Theorem).
Let physical reality be described at effective microscopic level by a finite-capacity patch substrate with finite accessible state count, finite update throughput, emergent burden fraction I, emergent latency field χ, and necessary overwrite channel Γ_{ov}. Then the theory admits two and only two primary saturation manifestations at macroscopic level:

a global or background high-load transport threshold, whose coarse-grained signature is cosmological freeze-out;

a local strong-field transport threshold, whose coarse-grained signature is shell onset.

Hence cosmological freeze-out and strong-field shell formation are universal regime projections of one underlying finite-capacity microstate law.

7.5 Why This Theorem Changes the Status of the Whole Program

This theorem is the crown of the paper. It converts the shell–cosmology bridge from a macro-level structural analogy into a true microphysical unification. Once this result is accepted, the early-universe and strong-field sectors can no longer be treated as parallel but independent branches. They become necessary companions. One finite-capacity law governs both. This alters the program's scientific status. FCLET is no longer just a framework with multiple successful effective sectors. It becomes a single micro-to-macro theory whose extreme regimes are linked by theorem rather than by metaphor. The macro bridge built in Article 86 is therefore the coarse-grained regime image of the microstate closure built here.

8. Semiclassical Recovery and the Return of Standard Propagation

8.1 Why the Theory Must Recover Ordinary Low-Load Physics

A successful microscopic completion must do more than generate extreme regimes. It must explain why most observed physics is not extreme. In FCLET this means explaining why the low-load universe behaves approximately like an ordinary propagating continuum even though the underlying substrate is finite-capacity. The answer is that finite capacity matters decisively only when occupancy and throughput pressure become non-negligible. In dilute regimes, those effects collapse perturbatively.

8.2 Dilute Occupancy and Disappearing Congestion

When

$$I \ll 1,$$

the patch has large residual accessible-state fraction

$$1 - I \approx 1.$$

In this regime, the entropic exhaustion map and the rational congestion map both collapse to small values:

$$\chi_{\log}(I) = I + \mathcal{O}(I^2), \chi_{\mathrm{rat}}(I) = I + \mathcal{O}(I^2).$$

Hence the latency response becomes perturbatively small. The substrate no longer behaves as a congested, update-limited system. Overwrite is also suppressed because reversible continuation and export remain sufficient:

$$\Gamma_{\mathrm{ov}} \to 0 \mathrm{as} I \to 0.$$

This is the microscopic origin of low-load ordinary physics in FCLET. Standard propagation is not assumed from outside. It is the natural dilute-capacity limit of the same micro-law that produces saturation elsewhere.

8.3 Emergent Continuum Approximation from Patch Dilution

When local burden is small in every physically relevant patch, the discreteness or bounded accessibility of the underlying substrate ceases to matter at observational level. The patch network behaves effectively as a smooth updateable medium. This is the correct FCLET meaning of the semiclassical or continuum limit. It is not that the underlying finite-capacity law disappears. It is that its saturation-sensitive corrections become negligible.

Schematically, one may write for any effective transport quantity $\mathcal{T}$,

$$\mathcal{T}_{\mathrm{FCLET}} = \mathcal{T}_{\mathrm{std}} + \delta\mathcal{T}(I),$$

with

$$\delta\mathcal{T}(I) \to 0 \mathrm{as} I \to 0.$$

Thus the ordinary low-load universe is not outside the theory. It is a controlled asymptotic branch of the same theory.

8.4 Eighth Microstate Theorem: Low-Load Recovery Theorem

Theorem 8 (Low-Load Recovery Theorem).
Let a physical system be governed by a finite-capacity microstate substrate with burden

fraction I, latency response $\chi(I)$, and overwrite sector Γ_{ov}. If the system evolves in a regime where

$$I \ll 1,$$

then

$$\chi(I) \to 0, \Gamma_{\mathrm{ov}} \to 0,$$

and all finite-capacity transport corrections collapse perturbatively. The effective macroscopic dynamics therefore converges to the ordinary low-load propagation branch.

8.5 Why Recovery Matters for the Full Program

The importance of the low-load theorem is not local to the present paper. It validates the entire upper architecture of the theory. Weak-field viability, late-time gravitational-wave luminality, ordinary cosmological propagation at low load, and the existence of familiar semiclassical behavior all rely on this result. Without it, the microstate completion would be dynamically impressive but phenomenologically dangerous. With it, the microstate completion becomes the exact closure of the full FCLET regime ladder.

9. From Microstate Capacity to the Full FCLET Macro-Architecture

9.1 The Micro-to-Macro Dictionary

The microstate completion provides the following exact identifications.

Finite accessible patch capacity

$$C_{\max} = \dim(\mathcal{H}_{\mathrm{acc}})$$

is the microscopic origin of finite local information budget.

Active local load

$$N_{\mathrm{loc}}$$

is the microscopic origin of local burdening state count.

Burden fraction

$$I = \frac{N_{\mathrm{loc}}}{C_{\max}}$$

is the macroscopic occupancy variable used throughout FCLET.

Latency field

$$\chi(I)$$

is the macroscopic image of state exhaustion and congestion.

Overwrite sector

$$\Gamma_{\mathrm{ov}}$$

is the macroscopic image of unavoidable irreversible closure cost under saturation.

Freeze-out and shell saturation
These are regime-level manifestations of finite-capacity transport breakdown in high-load and local-collapse settings respectively.

This dictionary is the full ontological closure of the program. The upper-level theory did not merely happen to choose the right symbols. Those symbols are the correct macro-variables of a finite accessible microstate substrate.

9.2 Ninth Microstate Theorem: Macro-Architecture Emergence Theorem

Theorem 9 (Macro-Architecture Emergence Theorem).
Let physical reality be described by a finite-capacity patch network with finite accessible Hilbert-space budget, finite update throughput, active local load, and inevitable overwrite under saturation. Then the macroscopic FCLET architecture

$$(I,\ \chi,\ \Gamma_{\mathrm{ov}},\ \text{freeze-out},\ \text{shell saturation})$$

is the emergent large-scale image of that substrate.

This theorem is the real completion theorem of the paper. It says that FCLET is not merely compatible with a finite-capacity substrate. It is the natural emergent macroscopic form of such a substrate.

9.3 Why 87 Sits Under 83–86

The previous late-stage papers of the program already did major work:

83 exposed the strong-field shell benchmark,

84 built the detector-facing identifiability atlas,

85 defined the empirical tribunal of the shell branch,

86 built the shell–cosmology bridge.

The present paper is not parallel to them. It sits beneath them. It explains why those branches were not arbitrary to begin with. In that sense, 87 is not "another article" in the sequence. It is the exact mathematical spine of the microscopic completion. That is why it had to come after the phenomenological branches were mature enough to show what needed explaining, yet before the full global synthesis can claim true closure.

9.4 Tenth Microstate Theorem: Program Closure Theorem

The final result of the paper can now be written as one closing theorem.

Theorem 10 (Program Closure Theorem).
If physical dynamics is governed by a finite accessible microstate substrate with finite capacity, finite update throughput, emergent congestion latency, and unavoidable overwrite under saturation, then the full FCLET macro-architecture is recovered as its large-scale effective form. In that case, weak-field ordinary propagation, early-universe freeze-out, and strong-field shell saturation are not disconnected sectors but asymptotic and high-load regimes of one micro-to-macro theory.

This theorem is the exact mathematical and ontological closure of the paper. It is also the reason 87 is indispensable to the final sequence. Without it, the later program remains powerful but partially effective-theoretic. With it, the program becomes internally closed.

Conclusion

The finite-capacity latency–erasure theory now has its microscopic foundation. This paper has shown that the central variables of the program are not phenomenological conveniences but necessary emergent objects of a finite accessible microstate substrate. The burden fraction

$$I = \frac{N_{\mathrm{loc}}}{C_{\max}}$$

is the occupancy ratio of accessible patch states. The latency field $\chi(I)$ is the emergent response of state exhaustion and congestion. The overwrite sector Γ_{ov} is the unavoidable closure cost of finite-capacity evolution under sustained burden flux. These are not interpretive decorations. They are theorem-level consequences of finite patch capacity and finite update throughput.

The paper has also shown that the same microscopic law generates all major FCLET regimes. In the low-load limit, the theory recovers ordinary propagation. In the high-load cosmological regime, it produces freeze-out. In the strong-field regime, it produces shell saturation. The weak-field branch, the primordial branch, and the shell branch are therefore not adjacent sectors. They are regime projections of one finite-capacity microstate law.

This is the deepest closure step of the program so far. The role of 87 is now exact. Article 83 gave the stabilized shell benchmark. Article 84 turned that branch into a detector-facing identifiability atlas. Article 85 made it answerable to data as a locked empirical tribunal. Article 86 linked the shell branch to the primordial tensor branch through a universal saturation coordinate. The present paper explains why that whole upper architecture had to exist in the first place. It is the microstate completion of the burden–latency–overwrite law. It is the exact mathematical spine of the program's microscopic closure.

The consequence is severe and scientifically healthy. The theory has fewer escape routes after this paper than before it. The central macroscopic sectors can no longer drift independently. They now stand together as the large-scale image of one finite accessible microstate substrate. If that microscopic law survives, the whole program becomes far more coherent. If it fails, the failure is correspondingly decisive. That is the correct price of genuine completion.

The micro-to-macro logic of FCLET is therefore now complete:

$$\text{finite patch capacity} \longrightarrow \text{burden fraction} \longrightarrow \text{latency response} \longrightarrow \text{overwrite necessity} \longrightarrow \text{freeze-out and shell saturation} \longrightarrow \text{low-load recovery.}$$

This chain is not heuristic. It is the theorem structure of the paper. It is also the final reason the program can now be treated as more than a strong phenomenological framework. It is a finite-capacity micro-to-macro theory.

Appendix A. Patch Network Kinematics and Accessible Hilbert-Space Capacity

Each effective physical patch is associated with an accessible Hilbert-space sector

$$\mathcal{H}_{\mathrm{acc}}, C_{\max} = \dim(\mathcal{H}_{\mathrm{acc}}) < \infty.$$

More precisely, one may start from a formal local state space $\mathcal{H}_{\mathrm{form}}$ and define the operative sector through an accessible-state projector:

$$\mathcal{H}_{\mathrm{acc}} = \Pi_{\mathrm{acc}} \mathcal{H}_{\mathrm{form}}.$$

The relevant quantity for FCLET is not the metaphysical total number of all abstract states, but the effective accessible number of locally updateable and transport-relevant states. A patch network is then defined by

$$\mathcal{P} = \{P_\alpha\},$$

with local capacities $C_{\max}$, local loads $N_{\mathrm{loc}}^{(\alpha)}$, and local throughput scales $\Gamma_{\mathrm{upd}}^{(\alpha)}$. The macroscopic burden field arises from coarse-graining this patch network.

Appendix B. Entropic and Congestion Forms of the Latency Map

The canonical latency realizations derived from state exhaustion are

$$\chi_{\log}(I) = -\ln(1-I), \chi_{\mathrm{rat}}(I) = \frac{I}{1-I}.$$

The first is the entropic exhaustion map. The second is the queue-amplification or congestion map. Both satisfy

$$\chi(0) = 0, \chi(I) \to \infty \text{ as } I \to 1^{-}.$$

Their analytic bridge is

$$\chi_{\mathrm{rat}} = e^{\chi_{\log}} - 1, \chi_{\log} = \ln(1 + \chi_{\mathrm{rat}}).$$

The correct microscopic conclusion is not that one of them must erase the other. It is that both are admissible macro-images of the same finite-state exhaustion structure. This appendix records that the earlier FCLET use of both logarithmic and rational forms was not inconsistency. It was already a sign of deeper microscopic dual interpretation.

Appendix C. Overwrite Closure and Landauer Cost

Overwrite activates when incoming burden exceeds reversible local continuation capacity near saturation:

$$\Gamma_{\mathrm{in}} > \Gamma_{\mathrm{proc}} + \Gamma_{\mathrm{exp}}^{\max} \text{with} I \to 1^{-}.$$

Equivalently, the saturation excess

$$\Delta_{\mathrm{sat}} = \Gamma_{\mathrm{in}} - \Gamma_{\mathrm{proc}} - \Gamma_{\mathrm{exp}}^{\max}$$

becomes positive. Then

$$\Gamma_{\mathrm{ov}} > 0$$

is required for closure, with minimum overwrite rate

$$\Gamma_{\mathrm{ov}}^{\min} = \Delta_{\mathrm{sat}}.$$

The irreversible character of overwrite links it to Landauer cost:

$$\Delta E \geq k_{\mathrm{B}} T \ln 2, P_{\mathrm{ov}} \geq k_{\mathrm{B}} T \ln 2 \, \dot{N}_{\mathrm{bit}}.$$

A moderated overwrite law must satisfy

$$\Gamma_{\mathrm{ov}} \to 0 \text{ as } I \to 0,$$

while activating nontrivially in the saturation regime and remaining dynamically controlled against blow-up. This appendix records the microscopic source of the macroscopic overwrite sector used throughout the FCLET program.

Appendix D. Regime Universality Summary

The same microscopic law yields three regime projections:

low-load regime: $I \ll 1$, ordinary propagation recovered,

cosmological high-load regime: network-level transport-limited freeze-out,

strong-field local saturation regime: shell onset and delayed-response structure.

A useful universal balance functional is

$$\Xi = \frac{\mathcal{D}_{\mathrm{cont}}}{\mathcal{B}_{\mathrm{cont}}},$$

with cosmological and strong-field realizations

$$\Xi_{\mathrm{cos}}, \Xi_{\mathrm{shell}}.$$

Thus cosmological freeze-out and shell saturation are not separate inventions. They are the global and local high-load images of one finite-capacity substrate. This appendix is the microstate counterpart of the shell–cosmology bridge later formalized at macroscopic saturation-coordinate level.

Appendix E. Low-Load Recovery and Theorem Chain Summary

The complete theorem chain of the paper is:

Finite Accessible Patch Capacity Theorem

Burden Fraction Theorem

Latency Emergence Theorem

Overwrite Necessity Theorem

Cosmological Freeze-Out Theorem

Strong-Field Shell Saturation Theorem

Regime Universality Theorem

Low-Load Recovery Theorem

Macro-Architecture Emergence Theorem

Program Closure Theorem

This chain is the final mathematical backbone of 87. It is also the clearest summary of the paper's real role inside the full program: 87 is not merely a microscopic addendum. It is the theorem-level closure of the whole FCLET architecture.

Multi-Messenger Observational Synthesis of the Finite-Capacity Latency–Erasure Theory

A Unified Forecast and Falsification Map Across LVK, LISA, Pulsar Timing Arrays, and CMB Tensor Windows from One Micro-Capacity Law

Ali Caner Yücel
Independent Researcher
Gaziantep, Türkiye

Abstract

We construct the multi-messenger observational synthesis of the finite-capacity latency–erasure theory by unifying its detector-facing predictions across stellar-mass compact-binary mergers, massive black-hole inspirals and mergers, pulsar timing array backgrounds, and cosmic microwave background tensor observables. Earlier FCLET analyses established the theoretical architecture of the program from finite-capacity microstate structure and emergent latency to cosmological freeze-out, compact-object shell formation, Kerr strong-field phenomenology, and direct confrontation with gravitational-wave data. What remained open was the global observational synthesis: how the same micro-capacity law projects into all major gravitational and cosmological measurement windows over the next observational era. The present article establishes that synthesis in full.

The central claim is exact. LVK, LISA, PTA, and CMB are not independent external tests attached to separate FCLET submodels. They are frequency-separated and regime-separated measurement windows on the same underlying law. The burden fraction I, the latency response χ, and the overwrite or closure sector Γ_{ov} determine cosmological freeze-out at the largest scales, relic stochastic structure at nanohertz frequencies, massive compact-object shell phenomenology in the millihertz band, and detector-facing post-merger shell signatures in the audio band. The observational program of FCLET is therefore not a collection of unrelated forecasts. It is one hierarchical transport-and-saturation atlas spanning cosmic history.

A unified messenger map is derived in which each window is associated with a distinct saturation regime, observable hierarchy, and sensitivity functional. The CMB probes the largest-scale primordial tensor suppression and saturation consistency relations. PTA observables probe the low-frequency relic tensor background and transfer-modified stochastic structure. LISA probes long-baseline strong-field transport, supermassive shell phenomenology, and the mass-scaled shell-response regime. LVK probes the highest-curvature stellar-mass post-merger shell signatures and immediate detector-level confrontation against Kerr-family alternatives. The theory is then represented by a single

global parameter manifold, projected into messenger-specific observable spaces and combined into a unified survival and falsification geometry.

Five main results are established. First, a messenger-unified observable dictionary is constructed from the FCLET microstate law. Second, window-specific sensitivity directions and degeneracy structures are identified for LVK, LISA, PTA, and CMB. Third, a cross-window consistency system is derived, showing how a theory point that survives one window constrains what must appear in the others. Fourth, a global weighted synthesis framework is built to combine current and future observations into a single survival map. Fifth, decisive falsification routes are identified, showing exactly how the next generation of multi-band gravitational and cosmological measurements can either preserve or eliminate the remaining theory corridor. The result is not an auxiliary outlook paper appended to a completed sequence. It is the final observational constitution of the finite-capacity latency–erasure program.

Keywords: multi-messenger astronomy; observational synthesis; global survival geometry; CMB constraints; PTA constraints; LISA prospects; LVK confrontation; degeneracy breaking; common survival corridor; cross-window consistency; messenger complementarity; global FCLET viability

1. Introduction: From a Microstate Law to the Observable Universe

The finite-capacity latency–erasure theory has reached the only scale of completion that matters for a serious physical program: the scale at which its microphysical law must be distributed across the observable universe. Earlier FCLET analyses established weak-field gravity, the cosmological background sector, primordial perturbations, strong-field shell saturation, Kerr generalization, detector-facing shell phenomenology, and direct confrontation protocols with gravitational-wave data. The microstate completion then derived burden, latency, overwrite, and regime universality from a finite accessible patch structure. Once that chain is in place, one decisive question remains. How does one and the same micro-capacity law appear across the full hierarchy of gravitational and cosmological observation windows?

That question is answered here.

It is no longer sufficient to discuss cosmological tensor suppression in one context, compact-object shell onset in another, and detector-facing ringdown confrontation in a third while leaving their observational coexistence implicit. Once the microstate law is known, the full messenger architecture must be written explicitly. The early universe, the stochastic background, the supermassive strong-field regime, and the stellar-mass post-merger regime must all be treated as windowed projections of one theory.

The central claim is exact. The observable universe does not confront FCLET through one preferred experiment. It confronts it through a hierarchy of messenger windows, each sensitive to a different regime of the same capacity-limited transport law. The largest angular scales of the cosmic microwave background probe the primordial high-load freeze-out branch. Pulsar timing arrays probe the relic low-frequency tensor background shaped by the same early-universe saturation law and its later transfer history. LISA probes long-duration strong-

field transport and shell phenomenology in the massive and supermassive compact-object regime. LVK probes the sharpest post-merger shell signatures and the immediate confrontation of FCLET with Kerr-family alternatives.

These windows are not detached tests of unrelated subtheories. They are observational projections of one micro-to-macro chain:

$$\text{finite patch capacity} \longrightarrow \text{burden fraction} \longrightarrow \text{latency response} \longrightarrow \text{overwrite closure} \longrightarrow \text{freeze-out and shell saturation} \longrightarrow \text{messenger-window observables.}$$

This statement has three immediate consequences.

First, the messenger windows are not interchangeable. Each probes a different saturation regime, frequency domain, and transport history. CMB constrains primordial high-load tensor structure and scalar–tensor consistency. PTA constrains the relic nanohertz continuation of the same tensor sector. LISA constrains the strong-field shell law in the massive and supermassive regime. LVK constrains the sharp stellar-mass confrontation regime in present data. No single window spans the whole theory.

Second, the windows do not merely accumulate evidence independently. They constrain one another. A theory point that survives the CMB cannot arbitrarily choose a PTA background. A theory point that survives LVK cannot arbitrarily choose a different shell law for LISA. A theory point that invokes primordial saturation must remain compatible with the same micro-capacity law that governs strong-field shell formation. The messenger architecture is therefore a consistency system rather than a collection of disconnected forecasts.

Third, the correct language of judgment is survival and falsification, not qualitative promise. FCLET must not be allowed to appear interesting in several windows while retreating into mutually incompatible sectors. The correct object is a global multi-window survival set,

$$\mathfrak{S}_{\text{global}} = \bigcap_{w} \mathfrak{S}_{w} ,$$

obtained by intersecting the messenger-specific allowed regions. If that set remains nonempty and nontrivial, FCLET survives as a genuine multi-messenger theory. If it collapses, the theory is globally falsified. If it survives only by evacuating its own distinctive content, the theory has retreated into null form.

The observational windows themselves differ radically in character.

The CMB is the largest-scale and earliest-time messenger. It is sensitive to primordial tensor structure, low-k saturation effects, and modified scalar–tensor consistency under finite-capacity freeze-out.

PTA is the nanohertz relic messenger. It is sensitive to the low-frequency stochastic tensor background and therefore to the transport and survival of primordial saturation structure into the late universe.

LISA is the millihertz bridge messenger. It is sensitive to the strong-field transport regime of massive and supermassive compact systems, where shell onset, delayed response, and long-baseline mode structure become accessible in a band that no present detector probes.

LVK is the audio-band confrontation messenger. It is sensitive to the sharpest post-merger shell signatures in stellar-mass events and therefore provides the most immediate event-level test against Kerr-family null models.

Each of these windows tests a different slice of the same theory manifold.

The analysis that follows is organized around five tasks. Section 2 constructs a unified observable dictionary mapping the micro-capacity law into window-specific observables. Section 3 identifies the messenger windows as regime projections of the same theory manifold. Section 4 derives cross-window consistency relations that prevent arbitrary independent tuning of different sectors. Section 5 analyzes complementary sensitivity directions and degeneracy breaking. Section 6 builds the global multi-messenger survival map. Section 7 lays out the observational forecast hierarchy of the next two decades. Section 8 identifies decisive falsification routes. The appendices provide operator-level, geometric, and forecast-level formal closure.

The result is not a phenomenological catalog. It is the final observational geometry of the program. It is the paper in which FCLET stops being judged by branch-wise plausibility and starts being judged by the topology of its surviving global corridor.

2. Unified Observable Dictionary from the Micro-Capacity Law

2.1 From Microstate Variables to Observable Structure

The microstate completion of FCLET established that the theory is generated by a finite accessible patch law with central variables

$$I, \chi, \Gamma_{\mathrm{ov}}.$$

The observational synthesis begins by asking how these variables appear in measurable form.

They do not appear directly as abstract microstate counters in experiment. They appear through window-specific effective observables. The same underlying micro-capacity law is therefore mapped into a family of messenger-specific projection operators:

$$\mathcal{O}_w = \Pi_w(\mathcal{M}_{\mathrm{FCLET}}),$$

where w labels the observational window and $\mathcal{M}_{\mathrm{FCLET}}$ denotes the global theory manifold. Each experiment sees not the full microscopic law in its native variables, but one projected observational image of it.

The theory manifold contains the micro-to-macro hierarchy

$$\mathcal{M}_{\mathrm{FCLET}} = \{I, \chi, \Gamma_{\mathrm{ov}}, \Upsilon, \Theta_{\mathrm{shell}}, \Theta_{\mathrm{cos}}, \Theta_{\mathrm{trans}}\},$$

where Υ denotes the universal saturation coordinate, Θ_{shell} the strong-field shell variables, Θ_{cos} the cosmological freeze-out variables, and Θ_{trans} the transfer-level continuation variables. Different windows are sensitive to different directions in this manifold. Messenger windows are therefore not independent parameter domains. They are different observational slices of the same theory coordinates.

2.1.1 Primary and Secondary Observable Classes

For every messenger window w, let

$$\mathbf{O}_w$$

denote the full observable vector. We partition it as

$$\mathbf{O}_w = \mathbf{O}_w^{\mathrm{prim}} \cup \mathbf{O}_w^{\mathrm{sec}}.$$

The interpretation is exact. $\mathbf{O}_w^{\mathrm{prim}}$ contains the quantities that directly determine survival, exclusion, or window-level admissibility. $\mathbf{O}_w^{\mathrm{sec}}$ contains quantities that diagnose transfer structure, sharpen inference, break degeneracies, or classify the form of support without independently deciding the window verdict. This hierarchy is necessary because the messenger atlas is not a symbolic catalog. It is an operational confrontation constitution.

2.2 CMB Observables as Primordial High-Load Projections

In the CMB window, the relevant observables are the largest-scale projections of the primordial freeze-out branch. These include the scalar tilt, tensor tilt, tensor-to-scalar ratio, and low-k tensor suppression structure:

$$\mathbf{O}_{\mathrm{CMB}}^{\mathrm{prim}} = \{n_s, n_T, r, S_T^{\mathrm{low-k}}\}.$$

These observables arise because the primordial high-load universe probes the global background burden fraction and its saturation response. The CMB therefore measures the earliest and largest-scale projection of the micro-capacity law. The same finite accessible-state structure that produced burden and latency at microscopic level appears observationally as modified freeze-out, scale-dependent tensor suppression, and scalar–tensor coupling constraints.

The scalar and tensor primordial spectra are written as

$$P_S(k) = P_S^{(0)}(k)\, S_S(k), P_T(k) = P_T^{(0)}(k)\, S_T(k),$$

with the FCLET saturation consistency relation

$$\ln S_T = \frac{\beta_T}{\beta_S} \ln S_S,$$

and the associated tilt relation

$$n_T - n_T^{(0)} = \frac{\beta_T}{\beta_S}[(n_s - 1) - (n_s^{(0)} - 1)].$$

These equations do not merely define a useful parametrization. They express the observational image of one saturation law acting on both scalar and tensor sectors.

Secondary CMB observables include transfer-sensitive and consistency-sensitive quantities such as

$$\mathbf{O}_{\mathrm{CMB}}^{\mathrm{sec}} = \{\alpha_T^{\mathrm{eff}}, \Delta n_T, \text{large-angle depletion structure}\}.$$

2.3 PTA Observables as Relic Stochastic Projections

In the PTA window, the relevant observables are low-frequency relic tensor background quantities:

$$\mathbf{O}_{\mathrm{PTA}}^{\mathrm{prim}} = \{\Omega_{\mathrm{GW}}(f), n_{\mathrm{GW}}^{\mathrm{eff}}, f_{\mathrm{turn}}\},$$

where $\Omega_{\mathrm{GW}}(f)$ is the stochastic background spectral density, $n_{\mathrm{GW}}^{\mathrm{eff}}$ is the effective low-frequency slope, and f_{turn} is the transferred saturation turnover scale.

The PTA window is therefore the relic continuation of the primordial tensor sector. It is neither identical to the CMB nor independent of it. It probes how the primordial saturation structure survives transport into the late universe at nanohertz frequencies.

At schematic level, the relic background is written as

$$\Omega_{\mathrm{GW}}(f) = \Omega_{\mathrm{GW}}^{(0)}(f)\, \mathcal{T}_{\mathrm{GW}}(f)\, S_T(f),$$

where $\Omega_{\mathrm{GW}}^{(0)}$ is the reference low-load relic spectrum, $\mathcal{T}_{\mathrm{GW}}$ is the transfer deformation induced by FCLET background history, and $S_T(f)$ is the inherited primordial saturation factor evaluated at the comoving scale corresponding to frequency f.

The effective slope is

$$n_{\mathrm{GW}}^{\mathrm{eff}}(f) = \frac{d\ln \Omega_{\mathrm{GW}}}{d\ln f}.$$

Secondary PTA observables include spectral-curvature and transfer-modulation indicators:

$$\mathbf{O}_{\mathrm{PTA}}^{\mathrm{sec}} = \{\kappa_{\mathrm{GW}}, \mathcal{T}_{\mathrm{relic}}^{\mathrm{mod}}, \text{envelope deformation}\}.$$

2.4 LISA Observables as Massive Shell and Long-Baseline Transport Projections

In the LISA window, the relevant observables lie in the massive and supermassive strong-field regime, especially where long-duration transport and delayed shell structure become visible:

$$\mathbf{O}_{\mathrm{LISA}}^{\mathrm{prim}} = \{\Delta t_{\mathrm{shell}}^{\mathrm{LISA}}, \delta\omega_{\mathrm{shell}}^{\mathrm{LISA}}, R_s^{\mathrm{LISA}}, \mathcal{B}_{\mathrm{shell}}^{\mathrm{LISA}}\}.$$

LISA does not merely revisit the same shell physics at lower frequency. It probes the mass-scaled shell law in a different regime of time structure, propagation history, and compact-object hierarchy. It is the long-baseline strong-field transport window of FCLET.

The essential scaling structure takes the form

$$\begin{aligned}
\Delta t_{\mathrm{shell}}^{\mathrm{LISA}} &= \mathcal{S}_t(M_f, a_f)\, \Delta t_{\mathrm{shell}}^{\mathrm{red}}, \\
R_s^{\mathrm{LISA}} &= \mathcal{S}_R(M_f, a_f)\, R_s^{\mathrm{red}}, \\
\delta\omega_{\mathrm{shell}}^{\mathrm{LISA}} &= \mathcal{S}_\omega(M_f, a_f)\, \delta\omega_{\mathrm{shell}}^{\mathrm{red}},
\end{aligned}$$

where M_f and a_f are the final mass and dimensionless spin of the remnant, and $\Theta_{\mathrm{shell}}^{\mathrm{red}}$ denotes the reduced shell parameter set.

Secondary LISA observables include inspiral-to-ringdown transport quantities and extended excitation structure:

$$\mathbf{O}_{\mathrm{LISA}}^{\mathrm{sec}} = \{\mathcal{E}_{\mathrm{shell}}^{\mathrm{massive}}, \Phi_{\mathrm{tr}}^{\mathrm{long}}, \text{massive-band hierarchy}\}.$$

2.5 LVK Observables as Immediate Post-Merger Confrontation Projections

In the LVK window, the observable vector is already sharply detector-facing:

$$\mathbf{O}_{\mathrm{LVK}}^{\mathrm{prim}} = \{\Delta\ln \mathcal{Z}^{\mathrm{FCLET|null}}, \Pi_{\mathrm{DI}}, \mathcal{C}_{\mathrm{null}}, \gamma_{\mathrm{coh}}\}.$$

Here $\Delta\ln \mathcal{Z}^{\mathrm{FCLET|null}}$ is the evidence gap between FCLET and null competitors, Π_{DI} measures support inside decisive regions of theory space, $\mathcal{C}_{\mathrm{null}}$ measures compression toward null-shell behavior, and γ_{coh} measures detector-network coherence of the nonstandard signal.

This is the strongest present confrontation window for the stellar-mass shell branch. The LVK band is the regime in which the micro-capacity law is tested through immediate post-merger shell structure, Kerr mimicry rejection, null-shell compression, and network coherence of delayed transport signatures.

Secondary LVK observables include event-level ablation penalties and start-time/overtone resilience indicators:

$$\mathbf{O}_{\mathrm{LVK}}^{\mathrm{sec}} = \{\Delta_{\mathrm{abl}}^{(a)}, \mathcal{O}^{\mathrm{imm}}, \mathcal{P}^{\mathrm{delay}}\}.$$

2.6 The Messenger Dictionary Is One-to-Many, Not Many-to-Many

The most important structural feature of the observable dictionary is that it is one-to-many rather than many-to-many. One theory manifold generates many window observables. The windows are not assigned separate theory cores. The messenger dictionary is therefore the mathematical assertion that the same micro-capacity law is interrogated under different observational filters.

Theorem 1 (Window Projection Theorem).
Let $\mathcal{M}_{\mathrm{FCLET}}$ denote the global parameter and structure manifold of the finite-capacity latency–erasure theory. Then each observational window

$$w \in \{\mathrm{CMB}, \mathrm{PTA}, \mathrm{LISA}, \mathrm{LVK}\}$$

is represented by a messenger-specific projection operator

$$\Pi_w : \mathcal{M}_{\mathrm{FCLET}} \to \mathbf{O}_w,$$

so that the measurable observables in each window are derived from one and the same underlying theory manifold rather than from independent submodels.

This theorem gives the first pillar of the multi-messenger architecture. The observable universe does not interrogate four loosely connected FCLET branches. It interrogates one theory through four regime-specific readout maps.

3. Messenger Windows as Regime Projections of One Theory Manifold

3.1 Why Messenger Windows Must Be Treated as Regime Projections

A global observational synthesis cannot stop at a dictionary of observables. It must explain why different experiments are sensitive to different subsets of the same theory manifold. Each messenger probes a distinct regime of the capacity-limited transport law. The windows are separated not only by instrumental design, but by physical regime: cosmic time, frequency band, compactness scale, transport history, and degree of saturation all differ from one window to another.

The correct mathematical statement is therefore stronger than

$$\mathbf{O}_w = \Pi_w(\mathcal{M}_{\mathrm{FCLET}}).$$

It is that each window corresponds to a regime projection of the theory manifold:

$$\Pi_w = \mathcal{D}_w \circ \mathcal{R}_w,$$

where the regime projection selects the physically relevant saturation branch and the detector projection maps that branch into measurable observables.

This distinction is crucial. The windows are not merely different instruments looking at the same object from arbitrary angles. They are different regime realizations of the same underlying law.

3.2 The CMB as the Primordial High-Load Regime

The CMB window corresponds to the highest-scale and earliest-time regime of the theory. The relevant branch is the primordial high-load background, where finite accessible-state congestion controls tensor and scalar freeze-out. In regime language, the CMB probes

$$\mathcal{R}_{\mathrm{CMB}}: \mathcal{M}_{\mathrm{FCLET}} \to \mathcal{M}_{\mathrm{prim}}^{\mathrm{high-load}}$$

during the primordial saturation phase.

The corresponding regime projection is

$$\mathcal{D}_{\mathrm{CMB}}: \mathcal{M}_{\mathrm{prim}}^{\mathrm{high-load}} \to \mathbf{O}_{\mathrm{CMB}},$$

with strongest sensitivity to the saturation consistency structure and low-k freeze-out deformation.

This is why the CMB cannot be treated as a vague inflation test external to FCLET. It is the observational regime in which the finite-capacity substrate is read at its largest-scale high-load edge.

3.3 The PTA Window as the Relic Low-Frequency Continuation of the Primordial Branch

The PTA window does not probe primordial freeze-out directly at last scattering. It probes the late-time relic continuation of the same tensor branch after cosmic transfer and redshifting into the nanohertz band. In regime language, PTA is the low-frequency survival test of the primordial tensor sector.

Its regime projection is

$$\mathcal{R}_{\mathrm{PTA}}: \mathcal{M}_{\mathrm{FCLET}} \to \mathcal{M}_{\mathrm{relic}}^{\mathrm{low-f}},$$

with strongest sensitivity to the transferred stochastic envelope and large-scale saturation history.

PTA is therefore not just another stochastic-background experiment. It is the relic continuation window of the primordial burden law. What the CMB sees at freeze-out scale, PTA sees after cosmological transfer and survival into the present universe.

3.4 The LISA Window as the Massive Strong-Field Transport Regime

The LISA window occupies a fundamentally different regime. It does not primarily test the primordial background. It tests the strong-field transport law of massive and supermassive compact systems, where shell onset and delayed response are probed across much longer dynamical baselines than in the stellar-mass band.

Its regime projection is

$$\mathcal{R}_{\mathrm{LISA}}: \mathcal{M}_{\mathrm{FCLET}} \to \mathcal{M}_{\mathrm{shell}}^{\mathrm{massive}}.$$

LISA is therefore the massive-band shell and transport regime. It probes how the same saturation law scales when the compact object, transport timescale, and observable mode structure all move into a different mass hierarchy.

3.5 The LVK Window as the Sharp Stellar-Mass Confrontation Regime

The LVK window corresponds to the most direct present confrontation regime of the shell branch. It is the highest-curvature presently accessible post-merger environment in which the shell law is tested against Kerr-family alternatives with immediate event-level statistical pressure.

Its regime projection is

$$\mathcal{R}_{\mathrm{LVK}}: \mathcal{M}_{\mathrm{FCLET}} \to \mathcal{M}_{\mathrm{shell}}^{\mathrm{stellar}}.$$

LVK is therefore the sharp stellar-mass shell-confrontation regime. It is the observational face of the local saturation law at its most immediate presently accessible scale.

3.6 Regime Projections Imply Structured Complementarity

Once the windows are understood as regime projections, they are complementary by construction. No single window measures the whole law. But no surviving theory point can ignore any window that probes a regime into which the same law necessarily extends. Messenger complementarity is therefore not optional scientific strategy. It is an intrinsic property of the theory.

Theorem 2 (Regime Projection Theorem).
Each observational messenger window of FCLET is a regime-specific projection of the same global theory manifold. In particular, CMB probes the primordial high-load background regime, PTA probes the transferred low-frequency relic tensor regime, LISA probes the massive strong-field transport regime, and LVK probes the stellar-mass sharp post-merger confrontation regime. Hence the messenger windows are complementary regime realizations of one micro-capacity law.

This theorem supplies the second pillar of the synthesis. The four windows are not four detached opportunities for phenomenology. They are four experimentally distinct realizations of regime universality.

3.7 Regime Complementarity as the Observational Image of Universality

The deeper meaning of this theorem is that observational complementarity is the experimental image of theoretical universality. The microstate completion established that one micro-law produces both cosmological freeze-out and strong-field shell saturation. The shell–cosmology bridge established that these are not disconnected effective branches. The multi-messenger structure is the observational counterpart of that same statement.

CMB and PTA probe the cosmological side of the universality theorem. LISA and LVK probe the strong-field side. No messenger stands outside the law. Each is one observational reading of a common finite-capacity substrate.

That is why the messenger system must be treated jointly from the outset rather than assembled retrospectively after separate branch studies have been completed.

4. Cross-Window Consistency Relations

4.1 Why Multi-Messenger Consistency Is Non-Negotiable

Once the messenger windows are recognized as regime projections of one theory manifold, the next consequence is unavoidable: a theory point that survives in one window cannot move arbitrarily in the others. This is the direct implication of the one-law structure. If FCLET is generated by a single finite-capacity microstate law, then all messenger observables must be mutually constrained by that law.

This is the decisive transition from a catalog of signatures to a true global test. A theory that fits one window but requires incompatible behavior in another has not survived multi-messenger confrontation. It has fractured.

The general consistency statement is

$$\mathcal{T}_{u\to v}: \mathbf{O}_u \to \mathbf{O}_v$$

for any pair of messenger windows u, v.

4.2 CMB-to-PTA Consistency: Primordial Suppression Must Survive Transfer

The most immediate consistency relation links the primordial tensor window to the relic stochastic window. If the CMB branch requires a nontrivial tensor suppression structure

$$S_T^{\mathrm{low-k}}(k)$$

or a specific modified consistency relation between scalar and tensor sectors, then the relic nanohertz background cannot be arbitrary. The primordial branch and the PTA branch are separated by transfer, not by different laws.

This means that

$$\mathbf{O}_{\mathrm{PTA}} \subset \mathcal{T}_{\mathrm{CMB}\to\mathrm{PTA}}(\mathbf{O}_{\mathrm{CMB}})$$

through the cosmological transfer map. A theory point that predicts strong large-scale primordial suppression but leaves no corresponding low-frequency relic signature, turnover, or structured envelope in the PTA band is internally inconsistent unless a precise transfer mechanism inside the same theory point enforces it.

This can be stated more sharply. The cosmological branch does not permit a primordial solution and a separate late-time relic solution. It permits one transferred tensor history.

4.3 CMB-to-PTA Consistency in Parameter Language

Let the primordial tensor structure be controlled by

$$\Theta_{\mathrm{prim}} = \{\Upsilon_*, \beta_T, \beta_S, n_s, n_T, r\},$$

so that the CMB window constrains

$$\Theta_{\mathrm{prim}} \in \mathfrak{S}_{\mathrm{CMB}}.$$

Then the same theory coordinates determine the relic stochastic background after propagation:

$$\Omega_{\mathrm{GW}}(f) = \mathcal{T}_{\mathrm{relic}}[\Theta_{\mathrm{prim}}],$$

with $\mathcal{T}_{\mathrm{relic}}$ fixed by the same background branch rather than chosen independently.

The effective low-frequency slope

$$n_{\mathrm{GW}}^{\mathrm{eff}}(f) = \frac{d\ln \Omega_{\mathrm{GW}}}{d\ln f}$$

therefore carries direct memory of the primordial saturation structure:

$$n_{\mathrm{GW}}^{\mathrm{eff}} = n_{\mathrm{GW}}^{\mathrm{eff}}(\Theta_{\mathrm{prim}}, \Theta_{\mathrm{trans}}).$$

The turnover scale f_{turn} is equally constrained by the same transfer chain. The PTA window is therefore not a loose phenomenological add-on to CMB tensor physics. It is the nanohertz continuation of the same underlying tensor source object.

4.4 LISA-to-LVK Consistency: One Shell Law, Two Mass Scales

The second great consistency system links the strong-field windows. If the shell sector is governed by one local saturation law and one micro-capacity architecture, then stellar-mass and supermassive compact objects cannot be assigned unrelated shell phenomenologies.

Let the shell observables be controlled by

$$\Theta_{\mathrm{shell}} = \{\epsilon, \Lambda_s, \Delta t_{\mathrm{shell}}, R_s, \delta\omega_{\mathrm{shell}}, \mathcal{B}_{\mathrm{shell}}\}.$$

Then the same shell law that governs LVK events also governs LISA-band strong-field systems, after mass, spin, and timescale scaling are accounted for:

$$\mathbf{O}_{\mathrm{LISA}} \subset \mathcal{T}_{\mathrm{LVK}\to\mathrm{LISA}}(\mathbf{O}_{\mathrm{LVK}}), \mathbf{O}_{\mathrm{LVK}} \subset \mathcal{T}_{\mathrm{LISA}\to\mathrm{LVK}}(\mathbf{O}_{\mathrm{LISA}}).$$

This is not a loose similarity statement. It is a mass-scaled identity of law.

4.5 LISA-to-LVK Consistency in Scaling Form

The practical implication is that shell delays, reflectivities, and mode-branch structures must scale coherently between the audio and millihertz bands:

$$\begin{aligned}
\Delta t_{\mathrm{shell}}^{\mathrm{LISA}} &= \mathcal{S}_t(M_f, a_f)\, \Delta t_{\mathrm{shell}}^{\mathrm{LVK}}, \\
R_s^{\mathrm{LISA}} &= \mathcal{S}_R(M_f, a_f)\, R_s^{\mathrm{LVK}}, \\
\delta\omega_{\mathrm{shell}}^{\mathrm{LISA}} &= \mathcal{S}_\omega(M_f, a_f)\, \delta\omega_{\mathrm{shell}}^{\mathrm{LVK}}.
\end{aligned}$$

If the LVK window favors a shell structure of one type, the LISA window cannot favor a qualitatively unrelated shell law unless the theory is broken. The two windows differ in scale, not in ontology.

4.6 Primordial-to-Shell Continuity

The deepest consistency relation is inherited from the microstate completion and the shell–cosmology bridge: the early-universe freeze-out branch and the late-time shell branch arise from one saturation law. Therefore a theory point that requires strong primordial saturation but no meaningful shell branch, or vice versa, is not automatically admissible.

Schematically,

$$\mathcal{T}_{\mathrm{prim}\to\mathrm{shell}}:\Theta_{\mathrm{prim}}\to\Theta_{\mathrm{shell}},$$

because all four windows read the same burden–latency substrate.

The cosmological and strong-field sectors are therefore not merely adjacent. They are mutually constraining.

4.7 Cross-Window Consistency Theorem

Theorem 3 (Cross-Window Consistency Theorem).
Let $\mathcal{M}_{\mathrm{FCLET}}$ be the global parameter manifold of FCLET, and let $\mathfrak{S}_w$ denote the survival set of messenger window w. Then survival in any one messenger window imposes nontrivial restrictions on the observables and survival geometry of the others:

$$\mathfrak{S}_v \subset \mathcal{T}_{u\to v}(\mathfrak{S}_u)$$

for all relevant window pairs u, v. In particular, CMB constrains PTA through transferred primordial tensor structure, and LVK constrains LISA through the common shell scaling law. Hence no surviving FCLET theory point can be tuned independently across different messenger windows.

This theorem is where multi-messenger synthesis becomes mathematically serious. The windows no longer merely coexist. They bind.

5. Sensitivity Directions and Degeneracy Breaking

5.1 Why the Messenger Windows Are Not Redundant

Each messenger window is sensitive to a different direction in the global theory manifold. The power of multi-messenger synthesis therefore lies not in repetition, but in structured complementarity. Each messenger eliminates some regions of theory space that others leave only weakly constrained, and each messenger leaves some directions partially degenerate that others can collapse.

Let

$$\mathcal{M}_{\mathrm{FCLET}}$$

be the global manifold of theory variables and emergent effective quantities. For each messenger window w, define a local sensitivity functional

$$\mathcal{S}_w : \mathcal{M}_{\mathrm{FCLET}} \to \mathbb{R}^+,$$

which measures how sharply observable predictions respond to displacement along different theory directions. The geometry of the multi-messenger problem is therefore not described only by survival sets, but by a family of messenger-dependent sensitivity structures.

This is the correct language for understanding degeneracy breaking.

5.2 CMB Sensitivity Directions

The CMB is most sensitive to the primordial high-load branch. Its strongest directions are

$$\{n_s, n_T, r, S_T^{\mathrm{low-k}}, \mathcal{C}_{ST}\},$$

where $\mathcal{C}_{ST}$ denotes the scalar–tensor consistency structure.

These observables measure how strongly tensor suppression is linked to scalar suppression, how the finite-capacity law deforms the largest primordial scales, and how the primordial branch departs from standard low-load tensor history. What the CMB does not determine sharply is the detailed compact-object shell law in its detector-facing form. The CMB therefore constrains primordial saturation coordinates while leaving substantial degeneracy along some strong-field directions.

5.3 PTA Sensitivity Directions

PTA is most sensitive to the relic continuation of the primordial tensor branch. Its dominant sensitivity directions are

$$\{\Omega_{\mathrm{GW}}(f), n_{\mathrm{GW}}^{\mathrm{eff}}, f_{\mathrm{turn}}, \kappa_{\mathrm{GW}}\}.$$

These observables respond most strongly to the survival of primordial suppression structure under transfer and to low-frequency relic envelope deformation. PTA therefore probes the nanohertz continuation of the cosmological sector. It does not directly determine the full compact-object shell geometry, but it constrains how much primordial tensor structure can remain hidden once cosmic transfer is taken seriously.

In that sense, PTA breaks a class of cosmological degeneracies that the CMB alone can leave only partially open.

5.4 LISA Sensitivity Directions

LISA is most sensitive to the large-mass strong-field transport regime. The dominant theory directions in this band include

$$\{\Delta t_{\mathrm{shell}}^{\mathrm{LISA}}, \delta\omega_{\mathrm{shell}}^{\mathrm{LISA}}, R_s^{\mathrm{LISA}}, \mathcal{B}_{\mathrm{shell}}^{\mathrm{LISA}}, \Theta_{\mathrm{shell}}^{\mathrm{red}}\},$$

evaluated in the massive and supermassive regime.

This means that LISA probes long-baseline shell transport, mass-scaled delay structure, strong-field mode deformation, and the large-mass realization of the same shell law confronted in the audio band by LVK. LISA is therefore the decisive bridge band between immediate detector-level post-merger confrontation and broad strong-field transport phenomenology. It breaks scaling degeneracies that LVK alone cannot eliminate because the stellar-mass branch does not fully determine how the same shell law behaves over many decades in mass and timescale.

5.5 LVK Sensitivity Directions

LVK is most sensitive to the sharpest presently accessible post-merger confrontation quantities:

$$\{\Delta\ln \mathcal{Z}^{\mathrm{FCLET|null}}, \Pi_{\mathrm{DI}}, \mathcal{C}_{\mathrm{null}}, \gamma_{\mathrm{coh}}, \Delta_{\mathrm{abl}}^{(a)}\}.$$

This means that LVK measures whether shell structure outperforms Kerr-family null models, whether support lies in decisive islands rather than in mimicry-prone zones, whether the shell branch is compressed toward null-shell space, and whether delayed transport signatures are detector-network coherent.

LVK therefore provides the most aggressive near-term falsification channel for the stellar-mass shell regime. It is not the broadest messenger, but it is the sharpest immediate confrontation messenger.

5.6 Degeneracy Structure of the Global Manifold

Each window leaves some directions unresolved. The CMB can constrain primordial saturation while leaving relic-transfer ambiguities. PTA can constrain relic low-frequency structure without uniquely isolating the full primordial origin. LVK can constrain the stellar-mass shell branch without fully determining how the same shell law scales into the massive regime. LISA can constrain the large-mass shell branch while remaining less decisive about the primordial tensor sector.

This is why the global theory corridor cannot be inferred from any single messenger.

Let

$$\mathfrak{D}_w$$

denote the degeneracy submanifold left unresolved by messenger window w. The correct strategy of multi-messenger synthesis is therefore not to minimize each degeneracy separately, but to examine the global intersection

$$\mathfrak{D}_{\text{global}} = \bigcap_w \mathfrak{D}_w .$$

If this global degeneracy intersection is narrow, then the theory has been sharply localized by messenger complementarity. If it remains broad, then the theory still possesses substantial global freedom even if individual windows appear informative.

5.7 Degeneracy-Breaking Theorem

Theorem 4 (Degeneracy-Breaking Theorem).
Let $\mathfrak{D}_w$ denote the parameter directions left unresolved by messenger window w. Then the multi-messenger system breaks theory degeneracies through complementary regime sensitivity:

$$\mathfrak{D}_{\text{global}} = \bigcap_w \mathfrak{D}_w .$$

If the messenger windows probe sufficiently complementary saturation directions, this intersection is strictly narrower than any single-window degeneracy manifold. Hence multi-messenger synthesis yields a more restrictive FCLET survival corridor than any single observation band alone.

5.8 Why the Messenger System Is Stronger than the Sum of Its Parts

The deeper implication is that the messenger system is not additive in a naive sense. Its strength lies in non-parallelity. The windows do not merely contribute evidence independently; they rotate and intersect theory space. What looks weak in one window can become decisive when cut transversely by another. This is the observational image of the one-law structure already established at microphysical level.

6. Global Multi-Messenger Survival Map

6.1 Messenger-Specific Survival and Exclusion Sets

Each messenger window defines its own allowed and excluded regions. Let

$$\mathfrak{S}_w$$

denote the messenger-specific survival sets, and let

$$\mathfrak{E}_w = \mathcal{M}_{\mathrm{FCLET}} \setminus \mathfrak{S}_w$$

denote the corresponding exclusion sets.

These sets live in the same global FCLET manifold. They do not describe different theories. They describe different observational cuts through one theory.

6.2 Definition of the Global Survival Region

The global multi-messenger survival region is

$$\mathfrak{S}_{\mathrm{global}} = \bigcap_w \mathfrak{S}_w \,.$$

This is the central object of the paper. It is the part of theory space that survives the full multi-window observational universe.

The corresponding global exclusion region is

$$\mathfrak{E}_{\mathrm{global}} = \bigcup_w \mathfrak{E}_w \,.$$

A theory that survives only in isolated single-window slices but not in the full intersection has not survived globally. It has merely delayed elimination.

6.3 Weighted Global Synthesis

Not all windows carry equal present authority. Some are already sharp confrontation tools, some are broad relic-structure constraints, and some are future decisive probes. The global synthesis should therefore be represented both as a strict set intersection and as a weighted confrontation score.

Let

$$W_w$$

denote the authority weight of messenger window w, normalized so that

$$\sum_w W_w = 1.$$

Then define a global survival score

$$\Sigma_{\mathrm{global}} = \sum_{w} W_w \; \Xi_w,$$

where Ξ_w measures the survival strength or positive content of FCLET in messenger window w. This scalar summary does not replace the survival set intersection. The set decides whether the theory survives globally; the score indicates how strongly and where.

6.3.1 Benchmark Messenger Authority Hierarchy

The weights themselves must be read historically. In the near-term benchmark epoch, the correct authority ordering is dominated by already active or rapidly maturing windows:

$$W_{\mathrm{LVK}}^{\mathrm{near}} \sim W_{\mathrm{PTA}}^{\mathrm{near}} \sim W_{\mathrm{CMB}}^{\mathrm{near}} > W_{\mathrm{LISA}}^{\mathrm{near}}.$$

In the mid-term benchmark epoch, LISA becomes decisive and the hierarchy changes:

$$W_{\mathrm{LISA}}^{\mathrm{mid}} \sim W_{\mathrm{LVK}}^{\mathrm{mid}} \sim W_{\mathrm{PTA}}^{\mathrm{mid}} \sim W_{\mathrm{CMB}}^{\mathrm{mid}}.$$

In the long-term benchmark epoch, the weights flatten because the theory must survive the full observational universe:

$$W_{\mathrm{LVK}}^{\mathrm{long}} \sim W_{\mathrm{LISA}}^{\mathrm{long}} \sim W_{\mathrm{PTA}}^{\mathrm{long}} \sim W_{\mathrm{CMB}}^{\mathrm{long}}.$$

These are not decorative choices. They are the benchmark authority hierarchy implied by the forecast logic of the manifesto.

6.4 Nontrivial Survival versus Trivial Retreat

A nonempty intersection is not automatically impressive. The surviving set may still be physically trivial. The correct distinction is therefore between nontrivial multi-window survival, in which the surviving region preserves real predictive and detector-facing content across the messenger system, and trivial or near-null retreat, in which the surviving region remains nonempty only because the theory has collapsed into effectively standard or observationally inert sectors.

We write

$$\mathfrak{S}_{\mathrm{global}} = \mathfrak{S}_{\mathrm{nt}} \cup \mathfrak{S}_{\mathrm{tr}},$$

where $\mathfrak{S}_{\mathrm{nt}}$ contains theory points that preserve real predictive and detector-facing content across multiple windows, while $\mathfrak{S}_{\mathrm{tr}}$ contains theory points that survive only by collapsing into observationally inert, null-mimicking, or effectively standard sectors.

Define the null-retreat region

$$\mathcal{C}_{\text{retreat}}$$

and the retreat compression functional

$$\mathcal{C}_{\text{retreat}} = \frac{\mu(\mathfrak{S}_{\text{tr}})}{\mu(\mathfrak{S}_{\text{global}}) + \varepsilon},$$

where μ is a chosen measure on the theory manifold. High $\mathcal{C}_{\text{retreat}}$ indicates that shell, primordial saturation, and cross-window nonstandard structure are being compressed toward trivial limits. High retreat is therefore not acceptable survival. It is survival by self-evacuation.

6.5 Window Hierarchy Inside the Global Survival Geometry

The structure of $\mathfrak{S}_{\text{global}}$ is rarely uniform. Some portions may be constrained primarily by cosmological windows, others by strong-field windows. Some may survive only because one messenger has not yet fully opened observationally. This means that the global survival set should be foliated by messenger dominance sectors. Let

$$\mathfrak{S}_{\text{dom}}^{(w)}$$

denote the region whose persistence is most strongly limited by messenger w. Then one may decompose the surviving corridor into a hierarchy of messenger-boundary regimes.

This decomposition matters because it identifies where future observational pressure is likely to strike first.

6.6 Global Multi-Messenger Survival Theorem

Theorem 5 (Global Multi-Messenger Survival Theorem).
Let $\mathfrak{S}_w$ denote the survival set of messenger window w. Then the globally surviving FCLET theory corridor is

$$\mathfrak{S}_{\text{global}} = \bigcap_{w} \mathfrak{S}_w \,.$$

FCLET survives as a genuine multi-messenger theory only if

$$\mathfrak{S}_{\text{global}} \neq \emptyset$$

and the surviving region remains nontrivial in predictive content, i.e.

$$\mathfrak{S}_{\mathrm{nt}} \neq \emptyset.$$

If the intersection is empty, the theory is globally falsified. If the intersection is nonempty but only trivial or observationally inert, the theory survives only in retreat form.

6.7 Why the Global Survival Map Is the Correct Final Language

At this stage of the program, branch-by-branch language is no longer sufficient. FCLET is not to be judged by isolated local successes. It is to be judged by whether one theory point, or at least one coherent theory corridor, survives the whole messenger system. That is why the global survival map is not a helpful summary. It is the actual object of judgment.

7. Forecast Hierarchy for the Next 20 Years

7.1 Why Future Hierarchy Matters

A serious observational manifesto must do more than identify tests. It must state in what order the theory is likely to come under pressure. The next twenty years will not constrain all windows equally or simultaneously. The synthesis must therefore be time-ordered. Let observational epoch be denoted by t. Then the messenger-specific survival regions evolve:

$$\mathfrak{S}_w = \mathfrak{S}_w(t),$$

and hence

$$\mathfrak{S}_{\mathrm{global}} = \mathfrak{S}_{\mathrm{global}}(t).$$

The basic monotonicity expectation is

$$\mathfrak{S}_{\mathrm{global}}(t_2) \subseteq \mathfrak{S}_{\mathrm{global}}(t_1) \text{for } t_2 > t_1,$$

provided data quality and cross-window coverage improve. This is the mathematical expression of the pressure cascade emphasized in the main text.

7.2 Near-Term Hierarchy

In the near term, the sharpest pressure will come from the windows already active:

deeper LVK catalogs and improved post-merger inference,

PTA refinement of stochastic-background shape and turnover structure,

continued cosmological tightening of tensor-sector constraints.

This is the stage in which current messenger windows begin to narrow the broadest FCLET corridors. In particular, the strongest immediate pressure is likely to fall on the sharp post-merger shell sector and on low-frequency relic-background shape.

7.3 Mid-Term Hierarchy

In the mid term, LISA becomes decisive. The millihertz band opens the supermassive and long-baseline shell frontier. This is likely to be the first window that can truly test whether the shell law scales coherently beyond the stellar-mass regime.

At this stage the most important combined tests become:

LVK–LISA shell scaling consistency,

CMB–PTA primordial relic continuity,

and emerging cross-window degeneracy collapse.

The mid-term era is therefore the era in which FCLET stops being a two-window theory and becomes a genuine four-window theory.

7.4 Long-Term Hierarchy

In the longer term, the full global synthesis becomes possible:

refined CMB tensor sensitivity,

improved PTA low-frequency structure,

mature LISA strong-field transport constraints,

deeper LVK catalogs with better event-level shell confrontation.

At that point the theory can no longer live in messenger-specific partial corridors. It must survive the full intersection geometry.

7.5 Forecast Hierarchy as a Pressure Cascade

The messenger system should therefore be understood as a pressure cascade. Near-term windows narrow local branches. Mid-term windows test scaling and inter-window law continuity. Long-term synthesis decides whether a global corridor survives at all.

In schematic form:

$$\mathfrak{S}^{\mathrm{near}}_{\mathrm{global}} \supseteq \mathfrak{S}^{\mathrm{mid}}_{\mathrm{global}} \supseteq \mathfrak{S}^{\mathrm{long}}_{\mathrm{global}}.$$

This is the correct temporal grammar of the observational manifesto.

7.6 The Importance of Staged Falsification

A theory with multiple messenger windows should not be expected to die all at once. It should be expected to lose territory in stages. The value of the present forecast hierarchy is that it predicts where those losses should occur first if the theory is wrong. This is scientifically much stronger than presenting a timeless list of possible future measurements.

8. Decisive Falsification Routes

8.1 Why the Theory Must Specify How It Fails

A global observational program is scientifically serious only if it states how it can fail. The multi-messenger system is therefore a landscape of decisive eliminations as well as opportunities.

8.2 Channel 1: Primordial Fracture

The first decisive route is primordial inconsistency. If the CMB window requires a specific tensor suppression structure or saturation history that fails to produce an admissible PTA relic background after transfer, then the primordial branch fractures:

$$\mathfrak{S}_{\mathrm{CMB}} \cap \mathfrak{S}_{\mathrm{PTA}} = \emptyset$$

within the cosmological tensor submanifold.

This is the route by which the early-universe branch can fail even before strong-field windows reach final precision.

8.3 Channel 2: Strong-Field Mass-Scaling Fracture

The second decisive route is strong-field scaling failure. If the stellar-mass shell law tolerated or favored by LVK cannot be scaled into an admissible supermassive shell law in the LISA band, or vice versa, then the shell branch fractures across mass hierarchy:

$$\mathfrak{S}_{\mathrm{LVK}} \cap \mathfrak{S}_{\mathrm{LISA}} = \emptyset$$

within the shell-law scaling submanifold.

This kills the shell law as one law across compact-object hierarchy. The strong-field branch would then no longer be one branch, but an inconsistent set of band-specific phenomenologies. That is decisive failure.

8.4 Channel 3: Null-Retreat Domination

The third decisive route is null retreat. Let

$$\mathcal{C}_{\text{retreat}}$$

denote the null-retreat region. If

$$\mathfrak{S}_{\text{global}} \subseteq \mathcal{C}_{\text{retreat}},$$

then the theory survives only by evacuating its own content. This is falsification by evacuation of content rather than by direct contradiction. It matters because a theory can look superficially alive while losing everything that made it distinctive. Null-retreat domination is not acceptable survival. It is observational death in trivialized form.

8.5 Channel 4: Full Global Fracture

The fourth and strictest route is full cross-window incompatibility:

$$\mathfrak{S}_{\text{global}} = \emptyset.$$

This is the final falsification route. The theory is then not merely pressured, weakened, or partially fractured. It is globally incompatible with the observational universe. This is the exact reason the global survival map is the final judge of the manifesto.

8.6 Falsification Severity Ordering

Not every negative result has the same significance. The correct severity ordering is

$$\text{primordial fracture} < \text{strong-field mass-scaling fracture} < \text{null-retreat domination} < \text{full global fracture.}$$

The interpretation is exact:

primordial fracture kills one major branch of the theory,

strong-field mass-scaling fracture kills the shell law across hierarchy,

null-retreat domination kills the theory's distinct physical content,

full global fracture kills the entire program.

This ranking prevents all negative outcomes from being rhetorically flattened into one flat notion of failure. The theory can lose a branch, lose its content, or lose the whole observable universe. Those are not the same event.

Table 8.1. Forecast Hierarchy and Falsification Channels of FCLET

Stage / channel	Main pressure source	What it tests	Failure meaning
Near-term	LVK + PTA + CMB	immediate shell confrontation, relic shape, broad primordial admissibility	early narrowing of broad corridors
Mid-term	LISA + LVK/PTA/CMB bridges	shell mass scaling, primordial relic continuity	branch fracture becomes decisive
Long-term	full four-window synthesis	global corridor survival	final global verdict
Primordial fracture	CMB–PTA mismatch	cosmological branch continuity	primordial messenger system broken
Strong-field mass-scaling fracture	LVK–LISA mismatch	shell-law coherence across mass hierarchy	strong-field branch broken
Null-retreat domination	global retreat to inert sectors	preservation of nontrivial content	theory survives only by self-evacuation
Full global fracture	empty global intersection	compatibility with full observational universe	whole program falsified

Table note. The hierarchy is not merely chronological. It is also judicial: each stage opens different kinds of eliminations, and each elimination carries different severity.

8.7 Forecast Hierarchy and Falsification Theorem

Theorem 6 (Forecast Hierarchy and Falsification Channels Theorem).
Let $\mathfrak{S}_{\mathrm{global}}(t)$ denote the time-dependent global survival set of FCLET. Then observational progress narrows the admissible corridor through a staged hierarchy:

near-term windows narrow broad local branches,

mid-term bridge windows test scaling and inter-window continuity,

long-term synthesis decides whether a global corridor survives at all.

Moreover, FCLET may be eliminated through four decisive channels:

primordial fracture,

strong-field mass-scaling fracture,

null-retreat domination,

full global fracture.

Hence the observational future of FCLET is a structured pressure cascade rather than an undifferentiated collection of tests, and its negative outcomes carry an internal severity hierarchy rather than one flat notion of failure.

9. From Branch Defense to Global Judgment

The observational synthesis now stands complete in principle. FCLET is no longer a theory that happens to have several phenomenological branches. It is a theory whose micro-capacity law distributes itself across the observable universe through a structured hierarchy of messenger windows.

That is the true meaning of this article.

CMB does not stand outside the theory as a cosmological add-on. PTA does not stand outside it as a relic background curiosity. LISA does not stand outside it as a future optional shell band. LVK does not stand outside it as a present data-analysis niche. All four are part of one observational atlas. The messenger system is the experimental image of the microstate law.

This means that the scientific status of FCLET has changed again. Earlier work turned it from ontology into effective phenomenology, from effective phenomenology into detector-facing confrontation, and from macroscopic theory into microstate completion. The present article performs the final observational step. It turns FCLET into a globally distributed program of falsifiable measurement.

The most important practical consequence is this: FCLET is no longer to be defended one branch at a time. It is no longer enough to say that the primordial tensor sector looks interesting, or that the shell sector produces novel ringdown structure, or that a given messenger leaves room for nontrivial behavior. Those arguments belong to an earlier stage of theory development.

From this point onward, the theory must survive globally:

$$\mathfrak{S}_{\mathrm{global}} \neq \emptyset, \mathfrak{S}_{\mathrm{nt}} \neq \emptyset.$$

The messenger windows form one tribunal, not four unrelated audiences. Each asks a different question, but each asks it of the same law. CMB asks how the micro-capacity law behaved when the universe was globally burdened. PTA asks what relic tensor structure survived. LISA asks how the shell law scales in the massive band. LVK asks whether the strongest presently accessible post-merger signals prefer the shell branch over Kerr-family null recovery.

Together they do not merely test FCLET. They define what it means for FCLET to survive the observable universe.

10. Conclusion

The finite-capacity latency–erasure theory now possesses a unified observational synthesis across the principal gravitational and cosmological messenger windows. LVK, LISA, PTA, and CMB are not detached tests of loosely related submodels, but regime-separated observational projections of one micro-capacity law.

A unified observable dictionary has been constructed, the messenger windows have been identified as regime projections of the same theory manifold, cross-window consistency relations have been derived, complementary sensitivity directions and degeneracy breaking have been analyzed, the global multi-messenger survival set has been defined, and decisive falsification routes have been formalized. The result is a full observational atlas of FCLET across cosmic history.

The theory can no longer be judged only by isolated branch successes. It must now survive the global intersection

$$\mathfrak{S}_{\text{global}} = \bigcap_{w} \mathfrak{S}_{w} .$$

If that corridor survives as a nontrivial set, FCLET stands as a genuine multi-messenger theory. If it collapses, or survives only in trivial retreat form, the program is observationally defeated.

A serious theory does not ask to be admired window by window. It asks to survive the observable universe as a whole.

Final Observational Constitution Theorem

Theorem 7 (Final Observational Constitution Theorem).
Let $\mathcal{M}_{\text{FCLET}}$ denote the global theory manifold of the finite-capacity latency–erasure theory, and let $\{\mathfrak{S}_w\}$ denote the messenger-specific survival sets induced by CMB, PTA, LISA, and LVK. Then the only final observational status of FCLET is determined by the geometry of

$$\mathfrak{S}_{\text{global}} = \bigcap_{w} \mathfrak{S}_{w} .$$

FCLET is observationally alive only if this global corridor is nonempty and nontrivial. It is observationally dead either if the intersection is empty or if all surviving points are compressed into null-retreat form. Therefore FCLET is judged globally or not at all.

Appendix A. Unified Observable Dictionary

The messenger windows are associated with the following primary and secondary observable sets.

For the CMB:

$$\mathbf{O}_{\mathrm{CMB}}^{\mathrm{prim}} = \{n_s, n_T, r, S_T^{\mathrm{low-k}}\}, \mathbf{O}_{\mathrm{CMB}}^{\mathrm{sec}} = \{\alpha_T^{\mathrm{eff}}, \Delta n_T, \text{large-angle depletion structure}\}.$$

For PTA:

$$\mathbf{O}_{\mathrm{PTA}}^{\mathrm{prim}} = \{\Omega_{\mathrm{GW}}(f), n_{\mathrm{GW}}^{\mathrm{eff}}, f_{\mathrm{turn}}\}, \mathbf{O}_{\mathrm{PTA}}^{\mathrm{sec}} = \{\kappa_{\mathrm{GW}}, \mathcal{T}_{\mathrm{relic}}^{\mathrm{mod}}, \text{envelope deformation}\}.$$

For LISA:

$$\mathbf{O}_{\mathrm{LISA}}^{\mathrm{prim}} = \{\Delta t_{\mathrm{shell}}^{\mathrm{LISA}}, \delta\omega_{\mathrm{shell}}^{\mathrm{LISA}}, R_s^{\mathrm{LISA}}, \mathcal{B}_{\mathrm{shell}}^{\mathrm{LISA}}\},$$
$$\mathbf{O}_{\mathrm{LISA}}^{\mathrm{sec}} = \{\mathcal{E}_{\mathrm{shell}}^{\mathrm{massive}}, \Phi_{\mathrm{tr}}^{\mathrm{long}}, \text{massive-band hierarchy}\}.$$

For LVK:

$$\mathbf{O}_{\mathrm{LVK}}^{\mathrm{prim}} = \{\Delta \ln \mathcal{Z}^{\mathrm{FCLET|null}}, \Pi_{\mathrm{DI}}, \mathcal{C}_{\mathrm{null}}, \gamma_{\mathrm{coh}}\}, \mathbf{O}_{\mathrm{LVK}}^{\mathrm{sec}} = \{\Delta_{\mathrm{abl}}^{(a)}, \mathcal{O}^{\mathrm{imm}}, \mathcal{P}^{\mathrm{delay}}\}.$$

The point of this appendix is not taxonomy alone. It records exactly which observables carry judgment force in each messenger window and which serve as interpretive refinement.

Appendix B. Regime Projection Operators

Each messenger window is represented by a regime selection $\mathcal{R}_w$ and a detector projection $\mathcal{D}_w$:

$$\Pi_w = \mathcal{D}_w \circ \mathcal{R}_w.$$

The principal regime projections are:

$$\mathcal{R}_{\mathrm{CMB}}: \mathcal{M}_{\mathrm{FCLET}} \to \mathcal{M}_{\mathrm{prim}}^{\mathrm{high-load}},$$
$$\mathcal{R}_{\mathrm{PTA}}: \mathcal{M}_{\mathrm{FCLET}} \to \mathcal{M}_{\mathrm{relic}}^{\mathrm{low-f}},$$

$$\mathcal{R}_{\mathrm{LISA}}: \mathcal{M}_{\mathrm{FCLET}} \to \mathcal{M}_{\mathrm{shell}}^{\mathrm{massive}},$$
$$\mathcal{R}_{\mathrm{LVK}}: \mathcal{M}_{\mathrm{FCLET}} \to \mathcal{M}_{\mathrm{shell}}^{\mathrm{stellar}}.$$

This appendix formalizes the statement that messenger windows are regime projections of one theory manifold, not independent submodels.

Appendix C. Cross-Window Consistency Operators

The principal consistency operators are:

$$\mathcal{T}_{\mathrm{CMB}\to\mathrm{PTA}}: \mathbf{O}_{\mathrm{CMB}} \to \mathbf{O}_{\mathrm{PTA}},$$

encoding primordial-to-relic transfer,

$$\mathcal{T}_{\mathrm{LVK}\to\mathrm{LISA}}: \mathbf{O}_{\mathrm{LVK}} \to \mathbf{O}_{\mathrm{LISA}},$$

encoding strong-field shell scaling across mass hierarchy,

and the deeper continuity operator

$$\mathcal{T}_{\mathrm{prim}\to\mathrm{shell}}: \Theta_{\mathrm{prim}} \to \Theta_{\mathrm{shell}},$$

encoding universality of the micro-capacity law between cosmological freeze-out and shell saturation.

This appendix makes explicit that survival in one window induces nontrivial allowed-shape restrictions in the others.

Appendix D. Global Survival Geometry

The global survival and exclusion sets are

$$\mathfrak{S}_{\mathrm{global}} = \bigcap_{w} \mathfrak{S}_{w}\,, \mathfrak{E}_{\mathrm{global}} = \bigcup_{w} \mathfrak{E}_{w}\,.$$

The nontrivial and retreat regions are

$$\mathfrak{S}_{\mathrm{nt}} = \mathfrak{S}_{\mathrm{global}} \setminus \mathcal{C}_{\mathrm{retreat}}, \mathfrak{S}_{\mathrm{tr}} = \mathfrak{S}_{\mathrm{global}} \cap \mathcal{C}_{\mathrm{retreat}}.$$

The retreat compression functional is

$$\mathcal{C}_{\mathrm{retreat}} = \frac{\mu(\mathfrak{S}_{\mathrm{tr}})}{\mu(\mathfrak{S}_{\mathrm{global}}) + \varepsilon}.$$

The weighted synthesis scalar is

$$\Sigma_{\mathrm{global}} = \sum_{w} W_w \; \Xi_w.$$

The global survival set may also be decomposed into messenger-dominance sectors

$$\mathfrak{S}_{\mathrm{global}} = \bigcup_{w} \mathfrak{S}_{\mathrm{dom}}^{(w)},$$

where $\mathfrak{S}_{\mathrm{dom}}^{(w)}$ denotes the region whose persistence is most strongly limited by messenger w.

This appendix records the exact objects by which FCLET is now judged globally rather than one branch at a time.

Appendix E. Forecast Hierarchy and Falsification Channels

The global survival set is time-dependent:

$$\mathfrak{S}_{\mathrm{global}} = \mathfrak{S}_{\mathrm{global}}(t),$$

with staged narrowing

$$\mathfrak{S}_{\mathrm{global}}^{\mathrm{near}} \supseteq \mathfrak{S}_{\mathrm{global}}^{\mathrm{mid}} \supseteq \mathfrak{S}_{\mathrm{global}}^{\mathrm{long}}.$$

Near-term pressure is dominated by currently active or rapidly maturing windows:

$$\mathcal{W}_{\mathrm{near}} = \{\mathrm{LVK}, \mathrm{PTA}, \mathrm{CMB}\}.$$

Mid-term pressure becomes dominated by LISA bridge tests:

$$\mathcal{W}_{\mathrm{mid}} = \{\mathrm{LVK}, \mathrm{PTA}, \mathrm{CMB}, \mathrm{LISA}\}.$$

Long-term pressure is the full intersectional verdict of the messenger system.

Define the contraction functional

$$\mathcal{C}_{\mathrm{contr}}(t_1 \to t_2) = 1 - \frac{\mathrm{Vol}[\mathfrak{S}_{\mathrm{global}}(t_2)]}{\mathrm{Vol}[\mathfrak{S}_{\mathrm{global}}(t_1)]}.$$

The four decisive falsification channels are:

Channel 1. Primordial fracture

$$\mathfrak{S}_{\mathrm{CMB}} \cap \mathfrak{S}_{\mathrm{PTA}} = \emptyset$$

in the cosmological tensor submanifold.

Channel 2. Strong-field mass-scaling fracture

$$\mathfrak{S}_{\mathrm{LVK}} \cap \mathfrak{S}_{\mathrm{LISA}} = \emptyset$$

in the reduced shell-law manifold.

Channel 3. Null-retreat domination

$$\mathfrak{S}_{\mathrm{global}} \subseteq \mathcal{C}_{\mathrm{retreat}}.$$

Channel 4. Full global fracture

$$\mathfrak{S}_{\mathrm{global}} = \emptyset.$$

The severity ordering is

$$\text{primordial fracture} < \text{strong-field mass-scaling fracture} < \text{null-retreat domination} < \text{full global fracture.}$$

This appendix gives 88 its time-axis and severity-axis at once: the future of FCLET is a structured pressure cascade rather than an undifferentiated collection of tests.

Global Confrontation, Hubble Interface, and Acoustic Completion

Global Survival Geometry, Reduced Contraction, and True One-Parameter Bridge Viability in the Finite-Capacity Latency–Erasure Theory

From Strong-Field Shell Benchmarks and Cosmological Tensor Corridors to a Quantitative Global Viability Map, Bridge-Slope Falsification, and Time-Dependent Contraction of the FCLET Benchmark Program

Article 89

Abstract

We construct the first quantitative global viability analysis of the finite-capacity latency–erasure theory by coupling its strong-field shell benchmark corridor to its cosmological tensor corridor within a unified survival-geometry framework. Previous stages of the FCLET program established the rotating shell benchmark and detector-facing identifiability structure in the strong-field sector, the locked empirical tribunal for real-event confrontation, the shell–cosmology bridge, the microstate completion of the burden–latency–overwrite architecture, and the multi-messenger global judgment framework. What remained open was the first explicit quantitative test of whether the strong-field and cosmological benchmark branches admit a common global survival structure once written in coupled form. The present article provides that construction.

The analysis proceeds in three exact stages. First, we define the reduced global corridor as the Cartesian compatibility product of the admissible strong-field interval and the admissible cosmological interval. We show that this reduced set is nonempty and physically nontrivial: the strong-field branch retains a non-null detector-facing spectral-deformation sector, while the cosmology branch retains a non-inert tensor corridor compatible with benchmark FCLET closure. Second, we construct the reduced contraction dynamics of this two-parameter survival region through an explicit area-normalized contraction functional $K(\tau)$, together with a benchmark robustness functional and a reduced falsification ladder distinguishing benchmark death, reduced retreat, and full reduced fracture. Third, we eliminate the residual independence of the reduced variables by constructing a continuous benchmark-anchored bridge law $\beta_S(\xi)$, thereby replacing reduced compatibility by a true one-parameter global survival set.

The resulting one-parameter global corridor is shown to be nonempty under the minimal physical conditions of continuity and benchmark anchoring. For a linear benchmark bridge

family, the true corridor length is obtained analytically, the true contraction functional $K_{\mathrm{true}}(\tau)$ is defined, and a new coupled failure mode appears: bridge-slope falsification, in which the strong-field and cosmological windows remain separately nonempty but no single continuous one-parameter FCLET continuation law survives both simultaneously. This yields the first explicit quantitative proof that the benchmark FCLET program is not merely branch-wise compatible, but globally viable at the first nontrivial continuous coupling level.

The paper therefore does not add a new phenomenological sector. It does something more decisive. It converts the late-stage FCLET architecture into a quantitative global viability problem with explicit survival sets, contraction functionals, benchmark death conditions, and bridge-slope failure criteria. In this sense, Article 89 is the first mathematical global-survival paper of the FCLET program.

Keywords

Finite-Capacity Latency–Erasure Theory; FCLET; global survival geometry; reduced contraction functional; strong-field shell benchmark; cosmological tensor corridor; one-parameter bridge map; benchmark robustness; bridge-slope falsification; global viability

1. Introduction: Why a Quantitative Global Survival Paper Is Necessary

The finite-capacity latency–erasure theory has now reached the stage at which structural completeness alone is no longer sufficient. The program already possesses a broad and internally organized architecture. The strong-field sector has been developed from detector-facing shell benchmarks to identifiability maps and locked empirical confrontation logic. The cosmological sector has been developed from background saturation to primordial tensor structure and shell–cosmology continuity. The microstate sector has established a finite-capacity substrate beneath both. The multi-messenger sector has already stated the final standard by which the theory must ultimately be judged: not branch by branch, but through a global survival geometry spanning the observable universe. What remained missing was one precise step between these achievements and the final observational constitution. That step is the subject of the present paper.

The missing step is quantitative global viability.

It is one thing to have a viable strong-field shell branch. It is another to have a viable cosmological tensor branch. It is stronger still to argue that the two should be regarded as regime projections of one underlying burden–latency architecture. But none of that yet proves that the branches survive jointly once written in a common mathematical language and forced into quantitative relation. The question that now has to be answered is exact:

Can the benchmark strong-field corridor and the benchmark cosmological corridor survive simultaneously as one global FCLET structure?

Article 89 is written to answer that question and nothing else.

This is why the paper must be quantitative rather than merely conceptual. Earlier articles were required to build the strong-field branch, the cosmological branch, the microstate closure, and the observational constitution. The present article is required to determine whether those achievements actually fit together at benchmark level once reduced to explicit admissible intervals and coupled through a common survival analysis. In other words, this paper does not introduce a new physical sector. It determines whether the already existing late-stage sectors admit a mathematically nonempty, physically nontrivial, and globally interpretable joint corridor.

The strongest reason such a paper is now necessary is that the program has become too advanced to remain satisfied with parallel branch success. Once the FCLET architecture includes a detector-facing strong-field shell branch, a cosmological tensor branch, a microstate completion, and a global multi-messenger judgment standard, a new burden falls on the theory. It must demonstrate that these are not merely successful neighboring constructions. They must be shown to possess a common viability geometry. If they do not, then the program remains impressive but only partially assembled. If they do, then the program takes its first truly global mathematical step beyond branch coexistence.

This is the precise intellectual role of Article 89.

The problem must be staged carefully. At first, the strong-field and cosmological sectors do not live in the same parameter coordinate. The strong-field benchmark corridor is naturally written in terms of a threshold coordinate

$$\xi \equiv \Xi_{\mathrm{crit}},$$

while the cosmology corridor is naturally written in terms of the scalar saturation parameter

$$\beta_S.$$

The first admissibility question is therefore reduced rather than fully unified. One asks whether the strong-field interval in ξ and the cosmological interval in β_S are simultaneously nonempty and mutually compatible in the benchmark architecture. This yields the reduced global object

$$S_{\mathrm{global}}^{\mathrm{red}} = S_{\mathrm{sf}}^{\xi} \times S_{\mathrm{cos}}^{\beta}.$$

The first result of the paper is that this reduced set is nonempty and physically nontrivial.

But this is not yet the final result. A reduced Cartesian compatibility region, while important, is not the same as a truly global coupled theory corridor. It shows joint admissibility of two windows, but not yet a single continuation law. The next step is therefore to transform the reduced corridor into a contraction problem. If the reduced corridor exists, then it must be possible to ask how that corridor shrinks under future pressure from stronger strong-field

constraints and tighter cosmological constraints. That question is answered by the reduced contraction functional

$$K(\tau),$$

which tracks how much of the benchmark reduced compatibility region remains at observational epoch τ.

This already produces a nontrivial conclusion. The benchmark survives in the reduced corridor, but its margin structure is asymmetric. In the cosmological direction the benchmark sits comfortably in the interior of the admissible interval. In the strong-field direction it sits exactly on the lower boundary. This means that reduced survival exists, but benchmark robustness is already one-sided. The corridor is alive, but its first pressure point is visible. That alone is a significant result, because it identifies where the earliest plausible benchmark failure is expected to arise.

The paper then proceeds to the decisive step: replacing reduced compatibility by true one-parameter coupling. This is done by introducing a continuous benchmark-anchored bridge law

$$\beta_S = \beta_S(\xi), \beta_S(\xi_{\mathrm{bench}}) = 1.$$

Once this is done, the reduced Cartesian product is no longer the correct global object. The theory now possesses a true one-parameter global set

$$S_{\mathrm{global}} = \{\xi : \xi \in S_{\mathrm{sf}}^{\xi}, \beta_S(\xi) \in S_{\mathrm{cos}}^{\beta}\}.$$

This is the real mathematical core of Article 89. It is the first point in the FCLET program at which the strong-field and cosmological benchmark sectors are no longer merely jointly admissible in a reduced product space, but are explicitly tested as manifestations of one continuous coupled structure.

The significance of this step is substantial. A reduced compatibility result says that two branches can live side by side. A true bridge result says that one underlying continuation law can traverse both. The former is valuable. The latter is a much stronger statement of global viability. It is therefore not enough for Article 89 merely to state that a bridge can be imagined. It must prove that under physically meaningful assumptions—continuity and benchmark anchoring—the coupled global set is actually nonempty.

That proof is one of the paper's central results.

Once the true one-parameter set is defined, a second and even sharper problem appears. A coupled theory can fail in a new way that a reduced theory cannot. Even if the strong-field and cosmological windows remain separately admissible, the coupled one-parameter corridor may still collapse if the bridge law is too steep. This is the origin of bridge-slope falsification. It is one of the most important conceptual innovations of the paper. It shows that global

viability is not exhausted by separate window survival. It also depends on the geometry of the law that couples them.

This is why Article 89 is not simply a technical note on parameter matching. It is the first global viability paper of the FCLET program.

The structure of the paper follows this logic exactly. Section 2 constructs the reduced global compatibility region and establishes its nonemptiness. Section 3 defines the reduced contraction functional and the benchmark robustness functional. Section 4 places this reduced corridor on a time axis and develops the near-term, mid-term, and long-term pressure map. Section 5 defines the reduced falsification ladder, distinguishing benchmark death, reduced retreat, and full reduced fracture. Section 6 then replaces reduced compatibility by a true one-parameter bridge law and proves nonempty coupled survival. Section 7 introduces the true contraction functional

$$K_{\mathrm{true}}(\tau)$$

and the new coupled failure mode of bridge-slope collapse. Section 8 closes the paper by stating the final viability theorem: FCLET is not merely reduced-compatible; it is globally viable at the first continuous one-parameter coupling level.

This final point must be stated clearly. The present paper does not claim that the full FCLET program has already survived all future observational pressure. It does not replace the later empirical confrontation papers. It does not announce a final universal victory. What it does prove is more precise: once written in explicit quantitative form, the strong-field benchmark branch and the cosmological benchmark branch admit both a reduced nontrivial survival region and a genuinely coupled one-parameter global corridor. This is exactly the step the program needed. It is the step that converts branch coexistence into explicit global viability.

That is why Article 89 is necessary, and that is what it proves.

2. Reduced Global Compatibility and the Benchmark Corridor

The first task of a quantitative global viability paper is to determine whether the late strong-field branch and the cosmological branch are even jointly admissible at benchmark level before one attempts a fully coupled one-parameter bridge. This is the correct point of departure for Article 89. A theory cannot be declared globally viable merely because two branches look individually healthy in separate articles. It must first be shown that the corresponding admissible regions are simultaneously nonempty when written in a common reduced survival language.

At the present stage of the FCLET program, the strong-field sector and the cosmology sector do not yet live on one explicitly unified master coordinate. The strong-field benchmark branch is naturally written in terms of a threshold variable

$$\xi \equiv \Xi_{\mathrm{crit}},$$

which controls the onset and admissible range of the detector-facing shell sector. The cosmological branch is naturally written in terms of the scalar saturation coupling

$$\beta_S,$$

which governs the admissible primordial tensor correction structure under the benchmark scalar–tensor closure. The first global problem is therefore a **reduced** problem rather than a fully coupled one. One asks whether the admissible strong-field interval in ξ and the admissible cosmology interval in β_S are simultaneously nonempty and whether their benchmark representatives are mutually compatible inside one reduced survival geometry.

This reduced question is already scientifically meaningful. If the reduced compatibility region were empty, the program would fail before any true bridge map could even be attempted. If it is nonempty and physically nontrivial, then a true bridge construction becomes mathematically worthwhile and physically motivated. The present section establishes exactly this first result.

2.1 Strong-Field Reduced Corridor

The detector-facing strong-field branch emerging from the rotating shell sector is summarized, at reduced benchmark level, by an admissible threshold interval

$$S_{\mathrm{sf}}^{\xi} = [\xi_{\min}, \xi_{\max}].$$

At the benchmark stage reached by the strong-field sequence, the admissible interval is taken to be

$$S_{\mathrm{sf}}^{\xi} = [0.300, 0.800].$$

This interval is not an arbitrary convenience interval. It encodes the reduced detector-facing admissibility of the shell sector after the benchmark anchoring, the identifiability structure, and the confrontation logic of the previous late-stage articles have already been imposed. In reduced language, ξ represents the effective local threshold coordinate governing the nontrivial strong-field shell branch.

The corresponding detector-facing observable in the simplest reduced representation is the dominant real-sector spectral displacement

$$\frac{\delta \mathrm{Re}\,\omega}{\mathrm{Re}\,\omega} = \alpha_{\mathrm{sf}}\,\xi.$$

The strong-field benchmark anchor is fixed by

$$\frac{\delta \mathrm{Re}\,\omega}{\mathrm{Re}\,\omega}\Big|_{\mathrm{bench}} \approx +2.6\% \text{at} \xi_{\mathrm{bench}} = 0.300.$$

This immediately fixes the reduced strong-field proportionality constant:

$$\alpha_{\mathrm{sf}} = \frac{2.6\%}{0.300} \approx 8.667\% \text{ per unit } \xi.$$

Therefore the reduced strong-field admissible observable range becomes

$$\frac{\delta \mathrm{Re}\,\omega}{\mathrm{Re}\,\omega} \in [8.667\% \times 0.300, 8.667\% \times 0.800],$$

that is,

$$\frac{\delta \mathrm{Re}\,\omega}{\mathrm{Re}\,\omega} \in [+2.6\%, +6.9\%].$$

This is the first decisive point of the reduced global analysis. The strong-field admissible branch is manifestly non-null. It is not compressed into an inert shell-free or detector-invisible limit. Even before any coupling to cosmology is attempted, the reduced strong-field corridor already carries genuine detector-facing nontriviality.

2.2 Cosmology Reduced Corridor

The cosmology sector is represented, at reduced benchmark level, by an admissible interval for the scalar saturation coupling:

$$S_{\mathrm{cos}}^{\beta} = [\beta_{\mathrm{min}}, \beta_{\mathrm{max}}].$$

Under the benchmark closure and the current reduced admissibility assumptions, this interval is

$$S_{\mathrm{cos}}^{\beta} = [0.761, 1.239].$$

This corridor is not chosen arbitrarily. It represents the admissible benchmark cosmology branch after imposing the FCLET scalar–tensor benchmark closure together with the current reduced cosmological admissibility assumptions. In reduced form, β_S controls the size of the cosmological saturation response inherited by the tensor sector through the benchmark relation

$$\frac{\beta_T}{\beta_S} = 1.$$

The benchmark cosmological representative is

$$\beta_{S,\mathrm{bench}} = 1.$$

This is the natural closure point because it corresponds to the canonical benchmark branch already singled out in the late cosmological sector.

Under this benchmark closure, the cosmological tensor correction remains nontrivial. The reduced benchmark branch carries

$$\Delta n_T \approx -0.035,$$

and the tensor-to-scalar ratio remains in the admissible benchmark interval

$$r_{\mathrm{FCLET}} \in [0.007, 0.020].$$

Thus the reduced cosmology corridor is likewise non-inert. It is not a vanishing-correction branch hidden inside observational irrelevance. The cosmological reduced survival set therefore already satisfies the same minimal nontriviality requirement as the strong-field branch.

2.3 Definition of the Reduced Global Survival Set

Because the strong-field and cosmology sectors are still parameterized by different reduced variables, the correct first global object is the Cartesian product of their admissible intervals:

$$S^{\mathrm{red}}_{\mathrm{global}} = S^{\xi}_{\mathrm{sf}} \times S^{\beta}_{\mathrm{cos}}.$$

Substituting the benchmark intervals gives

$$S^{\mathrm{red}}_{\mathrm{global}} = [0.300, 0.800] \times [0.761, 1.239].$$

The first global verdict is therefore immediate:

$$S^{\mathrm{red}}_{\mathrm{global}} \neq \emptyset.$$

This statement is exact and load-bearing. It means that the detector-facing strong-field branch and the benchmark cosmology branch are jointly admissible at reduced level. The late FCLET architecture does not collapse into immediate numerical incompatibility as soon as both sectors are written side by side in one survival geometry.

This is the first quantitative global result of the paper.

It is important to state precisely what this result does and does not mean.

It **does** mean that there exists a nonempty reduced compatibility region in which the strong-field threshold variable and the cosmological saturation variable are simultaneously admissible.

It **does not yet** mean that one and the same master parameter generates both through a true bridge law. That stronger claim belongs to the later one-parameter bridge analysis. The present result is reduced compatibility, not yet fully coupled global viability.

That distinction is mathematically necessary and conceptually clean.

2.4 Reduced Global Area

To quantify the size of the reduced compatibility corridor, define its measure by the standard area functional:

$$A_0 = \mu(S_{\mathrm{global}}^{\mathrm{red}}).$$

Since the reduced set is rectangular at this stage,

$$A_0 = (\xi_{\max} - \xi_{\min})(\beta_{\max} - \beta_{\min}).$$

Substituting the benchmark bounds yields

$$A_0 = (0.800 - 0.300)(1.239 - 0.761) = 0.500 \times 0.478 = 0.239.$$

This number is the natural normalization constant for all later reduced contraction analysis. It measures the size of the benchmark reduced global corridor before any future tightening is imposed. In that sense, it plays the same role for the reduced global problem that a benchmark survival volume plays in a standard constrained parameter study.

It is also already informative. The reduced compatibility region is not a barely surviving zero-measure coincidence. It has positive finite area:

$$A_0 = 0.239 > 0.$$

Therefore the reduced global survival result is not topological in the weakest possible sense. It is geometrically substantive.

2.5 Benchmark Point Inside the Reduced Corridor

A global reduced corridor can be nonempty without containing the preferred benchmark representative of the theory. That possibility must be excluded explicitly. The benchmark point is

$$(\xi_{\mathrm{bench}}, \beta_{S,\mathrm{bench}}) = (0.300, 1.000).$$

The strong-field coordinate satisfies

$$0.300 \in [0.300, 0.800],$$

and the cosmology coordinate satisfies

$$1.000 \in [0.761, 1.239].$$

Hence

$$(\xi_{\text{bench}}, \beta_{S,\text{bench}}) \in S^{\text{red}}_{\text{global}}.$$

This is the second major result of the section. The benchmark FCLET point does not merely coexist abstractly with a nonempty reduced compatibility region. It lies inside it.

But its position is geometrically asymmetric. In the cosmology direction, the benchmark is strictly interior:

$$0.761 < 1.000 < 1.239.$$

In the strong-field direction, the benchmark lies exactly on the lower boundary:

$$0.300 = \xi_{\min}.$$

This asymmetry is not a technical curiosity. It is the first signal of how future contraction pressure is likely to act on the reduced benchmark corridor. The cosmology branch currently leaves interior room around the benchmark. The strong-field branch does not. The benchmark survives, but not with symmetric robustness.

This observation will become decisive in the later contraction and falsification sections.

2.6 Reduced Margin Structure

To make the geometric status of the benchmark precise, define the directional margins:

$$m_\xi^- = \xi_{\text{bench}} - \xi_{\min}, m_\xi^+ = \xi_{\max} - \xi_{\text{bench}},$$
$$m_\beta^- = \beta_{S,\text{bench}} - \beta_{\min}, m_\beta^+ = \beta_{\max} - \beta_{S,\text{bench}}.$$

At the benchmark epoch one finds

$$m_\xi^- = 0.300 - 0.300 = 0, m_\xi^+ = 0.800 - 0.300 = 0.500,$$
$$m_\beta^- = 1.000 - 0.761 = 0.239, m_\beta^+ = 1.239 - 1.000 = 0.239.$$

Thus the benchmark point is one-sidedly supported in strong field and symmetrically interior-supported in cosmology.

This is already enough to state the first benchmark-robustness fact:

The benchmark reduced corridor is alive, but its first fragility lies at the lower strong-field boundary.

That fact is not interpretive rhetoric. It follows directly from the current reduced margin structure.

2.7 Reduced Nontriviality

Nonemptiness alone is not enough. A survival set can be formally nonempty while containing only trivial or observationally inert theory points. The reduced corridor of Article 89 is stronger than that.

In the strong-field direction, the reduced survival range carries

$$\frac{\delta \mathrm{Re}\ \omega}{\mathrm{Re}\ \omega} \in [+2.6\%, +6.9\%],$$

which is manifestly nonzero and detector-facing.

In the cosmology direction, the reduced branch carries benchmark tensor content:

$$\Delta n_T \approx -0.035, r_{\mathrm{FCLET}} \in [0.007, 0.020].$$

Therefore the reduced global corridor is not merely a mathematical coexistence set. It remains nontrivial in both observational sectors. This justifies the stronger statement:

Reduced nontrivial survival is established.

That is the correct verdict of Stage 1.

2.8 Reduced Compatibility Theorem

The results of this section can now be summarized in theorem form.

Theorem 1 (Reduced Global Compatibility Theorem).
Let the reduced strong-field benchmark corridor be

$$S_{\mathrm{sf}}^{\xi} = [0.300, 0.800],$$

and let the reduced cosmology benchmark corridor be

$$S_{\mathrm{cos}}^{\beta} = [0.761, 1.239].$$

Then the reduced global FCLET survival region

$$S_{\mathrm{global}}^{\mathrm{red}} = S_{\mathrm{sf}}^{\xi} \times S_{\mathrm{cos}}^{\beta}$$

is nonempty and has positive finite area

$$A_0 = 0.239.$$

Moreover, the benchmark point

$$(\xi_{\mathrm{bench}}, \beta_{S,\mathrm{bench}}) = (0.300, 1.000)$$

lies inside this reduced global corridor.

This theorem establishes the first quantitative global viability result of the FCLET program: the late strong-field shell branch and the benchmark cosmological tensor branch are jointly admissible at reduced level.

2.9 Corollary: Reduced Nontrivial Survival

Corollary 1 (Reduced Nontrivial Survival Corollary).
Under the same assumptions, the reduced global corridor is not observationally inert. In the strong-field sector it retains the non-null detector-facing deformation range

$$\frac{\delta \mathrm{Re}\ \omega}{\mathrm{Re}\ \omega} \in [+2.6\%, +6.9\%],$$

and in the cosmology sector it retains non-inert tensor content characterized at benchmark level by

$$\Delta n_T \approx -0.035, r_{\mathrm{FCLET}} \in [0.007, 0.020].$$

Hence

$$S_{\mathrm{global}}^{\mathrm{red}}$$

is not merely nonempty. It is physically nontrivial.

2.10 What This Section Achieves

This section resolves the first indispensable global question of Article 89. It shows that the late FCLET architecture is not immediately incompatible when the detector-facing strong-field branch and the benchmark cosmological branch are placed in one quantitative survival geometry. It also shows that the benchmark point itself remains admissible and that the reduced global corridor carries nontrivial physical content in both windows.

At the same time, the section reveals the first important asymmetry of the benchmark branch: strong-field survival is boundary-supported, while cosmology survival is interior-supported. This means that the reduced corridor is alive, but it is not equally robust in all directions.

That asymmetry is the correct starting point for the next stage of the paper.

The reduced global corridor has now been shown to exist. The next task is to determine how it contracts under future pressure. That is the role of the reduced contraction functional

$$K(\tau),$$

which is introduced in the next section.

3. Reduced Global Contraction Functional and Benchmark Robustness

The reduced compatibility result established in the previous section is already significant. The strong-field benchmark corridor and the cosmological benchmark corridor are jointly admissible, the reduced global set is nonempty, and the benchmark point lies inside it. But a static nonemptiness result is not yet enough for a real global viability analysis. Once a reduced corridor exists, the next question is immediate:

How does this corridor contract under future observational pressure?

This is the exact purpose of the present section.

The reduced global problem is still two-parameter at this stage. The strong-field sector is parameterized by the threshold coordinate

$$\xi \equiv \Xi_{\mathrm{crit}},$$

while the cosmology sector is parameterized by

$$\beta_S.$$

Accordingly, the correct global object remains

$$S_{\mathrm{global}}^{\mathrm{red}}(\tau) = S_{\mathrm{sf}}(\tau) \times S_{\mathrm{cos}}(\tau),$$

where the admissible intervals are now written explicitly as functions of the observational epoch τ:

$$S_{\mathrm{sf}}(\tau) = [\xi_{\mathrm{min}}(\tau), \xi_{\mathrm{max}}(\tau)], S_{\mathrm{cos}}(\tau) = [\beta_{\mathrm{min}}(\tau), \beta_{\mathrm{max}}(\tau)].$$

The purpose of Section 3 is to convert this reduced global corridor into a contraction problem with explicit benchmark-normalized dynamics, and to identify the exact robustness structure of the benchmark point within that corridor.

3.1 Reduced Global Area

Because the reduced survival set is rectangular at this stage, its measure is the ordinary product area

$$A(\tau) = \mu\left(S^{\mathrm{red}}_{\mathrm{global}}(\tau)\right) = [\xi_{\max}(\tau) - \xi_{\min}(\tau)][\beta_{\max}(\tau) - \beta_{\min}(\tau)].$$

At the benchmark epoch τ_0, the reduced admissible intervals are

$$S_{\mathrm{sf}}(\tau_0) = [0.300,0.800], S_{\cos}(\tau_0) = [0.761,1.239].$$

Hence the benchmark reduced area is

$$A_0 = A(\tau_0) = (0.800 - 0.300)(1.239 - 0.761) = 0.500 \times 0.478 = 0.239.$$

This area is the natural normalization constant of the reduced global contraction problem. It is the size of the benchmark reduced corridor before any future tightening has been imposed.

The fact that

$$A_0 = 0.239 > 0$$

already matters. The reduced survival problem is not topologically trivial and not sustained by a measure-zero coincidence. It begins with a finite benchmark viability region.

3.2 Reduced Global Contraction Functional

The most direct way to track corridor shrinkage is to compare the surviving area at epoch τ with the benchmark area A_0. This defines the reduced contraction functional

$$K(\tau) = 1 - \frac{A(\tau)}{A_0}.$$

This functional has the correct benchmark interpretation.

If

$$A(\tau) = A_0,$$

then

$$K(\tau) = 0,$$

which means that no contraction relative to the benchmark reduced corridor has yet occurred.

If

$$A(\tau) = 0,$$

then

$$K(\tau) = 1,$$

which means that the reduced global corridor has completely collapsed.

Thus

$$0 \leq K(\tau) \leq 1$$

for all admissible benchmark descendants, with intermediate values measuring partial contraction of the reduced survival region.

This is the first global time-dependent observable of Article 89.

3.3 Directional Contraction Functionals

The reduced global corridor is a Cartesian product, and therefore its contraction can be decomposed into independent directional contractions in the strong-field and cosmology sectors.

Define the strong-field contraction functional by

$$K_{\mathrm{sf}}(\tau) = 1 - \frac{\xi_{\max}(\tau) - \xi_{\min}(\tau)}{0.800 - 0.300} = 1 - \frac{\xi_{\max}(\tau) - \xi_{\min}(\tau)}{0.500}.$$

Define the cosmology contraction functional by

$$K_{\cos}(\tau) = 1 - \frac{\beta_{\max}(\tau) - \beta_{\min}(\tau)}{1.239 - 0.761} = 1 - \frac{\beta_{\max}(\tau) - \beta_{\min}(\tau)}{0.478}.$$

These directional contractions satisfy

$$0 \leq K_{\mathrm{sf}}(\tau) \leq 1, 0 \leq K_{\cos}(\tau) \leq 1$$

provided the benchmark descendants remain interval-valued.

They also reconstruct the full reduced contraction exactly. Since

$$A(\tau) = A_0(1 - K_{\mathrm{sf}}(\tau))(1 - K_{\cos}(\tau)),$$

one obtains

$$K(\tau) = 1 - (1 - K_{\mathrm{sf}}(\tau))(1 - K_{\cos}(\tau)).$$

Equivalently,

$$K(\tau) = K_{\mathrm{sf}}(\tau) + K_{\cos}(\tau) - K_{\mathrm{sf}}(\tau)K_{\cos}(\tau).$$

This formula is useful because it separates the two sources of reduced global pressure. A future contraction can be strong-field dominated, cosmology dominated, or genuinely joint.

3.4 The Benchmark Point and Its Directional Margins

The benchmark point is

$$(\xi_{\mathrm{bench}}, \beta_{S,\mathrm{bench}}) = (0.300, 1.000).$$

Its stability inside the reduced corridor is governed by four directional margins:

$$m_{\xi}^{-}(\tau) = \xi_{\mathrm{bench}} - \xi_{\min}(\tau), m_{\xi}^{+}(\tau) = \xi_{\max}(\tau) - \xi_{\mathrm{bench}},$$
$$m_{\beta}^{-}(\tau) = \beta_{S,\mathrm{bench}} - \beta_{\min}(\tau), m_{\beta}^{+}(\tau) = \beta_{\max}(\tau) - \beta_{S,\mathrm{bench}}.$$

At the benchmark epoch τ_0, these are

$$m_{\xi}^{-}(\tau_0) = 0.300 - 0.300 = 0, m_{\xi}^{+}(\tau_0) = 0.800 - 0.300 = 0.500,$$
$$m_{\beta}^{-}(\tau_0) = 1.000 - 0.761 = 0.239, m_{\beta}^{+}(\tau_0) = 1.239 - 1.000 = 0.239.$$

This makes the geometry of the benchmark immediately transparent.

In the cosmology direction, the benchmark is strictly interior and symmetrically placed.

In the strong-field direction, the benchmark lies exactly on the lower admissible boundary.

This is not a minor technical feature. It determines the first expected vulnerability of the reduced FCLET benchmark.

3.5 Benchmark Robustness Functional

The directional margins can be compressed into one scalar robustness object:

$$R_{\mathrm{bench}}(\tau) = \min\{m_{\xi}^{-}(\tau), m_{\xi}^{+}(\tau), m_{\beta}^{-}(\tau), m_{\beta}^{+}(\tau)\}.$$

This quantity has an exact interpretation.

If

$$R_{\mathrm{bench}}(\tau) > 0,$$

the benchmark lies strictly in the interior of the reduced corridor.

If

$$R_{\mathrm{bench}}(\tau) = 0,$$

the benchmark lies on the reduced boundary.

If

$$R_{\mathrm{bench}}(\tau) < 0,$$

the benchmark has been expelled from the reduced corridor.

At the benchmark epoch,

$$R_{\mathrm{bench}}(\tau_0) = 0.$$

Thus the benchmark survives, but not as an interior-supported point. It survives on the reduced boundary. More precisely, it survives on the lower strong-field boundary.

This immediately yields the most important robustness statement of the section:

The benchmark reduced corridor is alive, but its robustness is one-sided and strong-field limited.

3.6 Boundary-Supported Survival versus Interior-Supported Survival

This distinction deserves to be stated explicitly because it changes the meaning of future contractions.

A benchmark point can survive in two very different ways.

It can survive as an **interior-supported** point, in which case modest tightening does not immediately expel it.

Or it can survive as a **boundary-supported** point, in which case any contraction from the relevant side produces immediate benchmark death.

The FCLET reduced benchmark belongs to the second class in the ξ-direction:

$$m_{\xi}^{-}(\tau_0) = 0.$$

By contrast, it belongs to the first class in the β_S-direction:

$$m_{\beta}^{-}(\tau_0) = m_{\beta}^{+}(\tau_0) = 0.239.$$

This means that the earliest plausible benchmark stress is expected to arise from the strong-field lower threshold, not from the current cosmological corridor center.

This is the first genuine forecast implication of the reduced global geometry.

3.7 Reduced Nontriviality under Contraction

The contraction problem is not only geometric. It is also physical. A reduced corridor may shrink while remaining nontrivial, or it may shrink into an observationally inert remnant.

The current benchmark reduced corridor is nontrivial because:

in the strong-field direction,

$$\frac{\delta \mathrm{Re}\ \omega}{\mathrm{Re}\ \omega} \in [+2.6\%, +6.9\%],$$

and in the cosmology direction,

$$\Delta n_T \approx -0.035, r_{\mathrm{FCLET}} \in [0.007, 0.020].$$

Future contraction must therefore be interpreted in two layers.

The first layer is purely geometric:
how much of the benchmark reduced area remains?

The second layer is physical:
does the surviving reduced corridor still carry nontrivial shell and tensor content?

Section 3 defines the first layer exactly through $K(\tau)$. The second layer will be formalized later through the reduced falsification ladder.

3.8 Strong-Field-Dominated versus Cosmology-Dominated Contraction

The directional contraction functionals already allow a first classification of future pressure.

If

$$K_{\mathrm{sf}}(\tau) \gg K_{\mathrm{cos}}(\tau),$$

then the reduced corridor is shrinking mainly through strong-field pressure.

If

$$K_{\mathrm{cos}}(\tau) \gg K_{\mathrm{sf}}(\tau),$$

then the contraction is cosmology dominated.

If

$$K_{\mathrm{sf}}(\tau) \sim K_{\cos}(\tau),$$

then the reduced global problem is entering a genuinely joint contraction regime.

Because the benchmark is currently boundary-supported in strong field and interior-supported in cosmology, the first expected benchmark-level instability is of the first type:

$$K_{\mathrm{sf}}(\tau) > 0 \text{with} \xi_{\min}(\tau) > 0.300.$$

This would kill the benchmark before the reduced corridor necessarily dies.

That distinction is essential and will be formalized in the next sections.

3.9 Reduced Global Contraction Theorem

The results of this section can now be stated in theorem form.

Theorem 2 (Reduced Global Contraction Theorem).
Let the reduced FCLET survival set at epoch τ be

$$S_{\mathrm{global}}^{\mathrm{red}}(\tau) = [\xi_{\min}(\tau), \xi_{\max}(\tau)] \times [\beta_{\min}(\tau), \beta_{\max}(\tau)].$$

Let the benchmark area be

$$A_0 = 0.239.$$

Then the contraction of the reduced global corridor is exactly measured by

$$K(\tau) = 1 - \frac{[\xi_{\max}(\tau) - \xi_{\min}(\tau)][\beta_{\max}(\tau) - \beta_{\min}(\tau)]}{0.239}.$$

Equivalently,

$$K(\tau) = K_{\mathrm{sf}}(\tau) + K_{\cos}(\tau) - K_{\mathrm{sf}}(\tau)K_{\cos}(\tau),$$

where

$$K_{\mathrm{sf}}(\tau) = 1 - \frac{\xi_{\max}(\tau) - \xi_{\min}(\tau)}{0.500}, K_{\cos}(\tau) = 1 - \frac{\beta_{\max}(\tau) - \beta_{\min}(\tau)}{0.478}.$$

Moreover,

$$K(\tau) = 0$$

if and only if no reduced contraction has occurred relative to the benchmark epoch, while

$$K(\tau) = 1$$

if and only if the reduced global survival corridor has collapsed completely.

3.10 Benchmark Boundary Corollary

Corollary 2 (Benchmark Boundary Corollary).
Let the benchmark reduced point be

$$(\xi_{\mathrm{bench}}, \beta_{S,\mathrm{bench}}) = (0.300, 1.000).$$

Then the benchmark reduced FCLET corridor exhibits nontrivial survival while remaining boundary-supported in the strong-field direction:

$$R_{\mathrm{bench}}(\tau_0) = 0.$$

Hence the present reduced benchmark is alive but not strong-field interior-robust. The earliest plausible benchmark-level contraction pressure acts on the lower ξ-boundary.

3.11 What Section 3 Achieves

Section 2 showed that the reduced global corridor exists and is physically nontrivial. Section 3 now converts that result into a dynamical survival problem.

It introduces:

the reduced area functional $A(\tau)$,

the reduced contraction functional $K(\tau)$,

the directional contractions $K_{\mathrm{sf}}(\tau)$ and $K_{\cos}(\tau)$,

and the benchmark robustness functional $R_{\mathrm{bench}}(\tau)$.

Together these objects define the first quantitative time-dependent survival structure of Article 89.

They also reveal the first central asymmetry of the benchmark FCLET global geometry: the theory survives at reduced level, but its benchmark representative is protected differently in the two observational directions. Strong-field support is boundary-limited. Cosmology support is interior-supported.

That asymmetry is not a side remark. It is the first geometric reason why future benchmark pressure is expected to arrive from the strong-field side first.

The next task is therefore clear. Once the reduced corridor has a contraction functional and a robustness functional, it becomes possible to place it on a forecasted time axis and identify near-term, mid-term, and long-term pressure maps.

That is the role of the next section.

4. Forecasted Contraction Scenarios and Near/Mid/Long-Term Pressure Map

Once the reduced global corridor has been identified and its contraction dynamics has been defined, the next question is no longer purely geometric. It becomes temporal. A corridor that is nonempty at the benchmark epoch may remain broad, contract slowly, contract asymmetrically, lose its benchmark representative, or collapse altogether under future pressure. The correct next step is therefore to place the reduced FCLET survival set on a forecasted observational time axis and to ask how the contraction functionals are expected to evolve as the relevant windows become more restrictive.

At the reduced stage, the survival set is

$$S_{\mathrm{global}}^{\mathrm{red}}(\tau) = [\xi_{\min}(\tau), \xi_{\max}(\tau)] \times [\beta_{\min}(\tau), \beta_{\max}(\tau)],$$

with contraction functional

$$K(\tau) = 1 - \frac{A(\tau)}{A_0},$$

directional contractions

$$K_{\mathrm{sf}}(\tau), K_{\cos}(\tau),$$

and benchmark robustness

$$R_{\mathrm{bench}}(\tau).$$

The purpose of the present section is to transform these objects into a forecast framework. The section does not yet require a fully coupled one-parameter bridge. It operates strictly at the reduced level. Its task is to determine which parts of the benchmark corridor are expected to come under pressure first, which contractions are likely to dominate at different observational stages, and under what conditions one should expect benchmark stress, corridor narrowing, or reduced fracture.

4.1 The Time-Dependent Reduced Viability Problem

The reduced corridor is not a timeless object. It evolves because both the strong-field admissible interval and the cosmology admissible interval evolve:

$$S_{\mathrm{sf}}(\tau) = [\xi_{\min}(\tau), \xi_{\max}(\tau)], S_{\cos}(\tau) = [\beta_{\min}(\tau), \beta_{\max}(\tau)].$$

Accordingly,

$$A(\tau) = [\xi_{\max}(\tau) - \xi_{\min}(\tau)][\beta_{\max}(\tau) - \beta_{\min}(\tau)]$$

is itself time-dependent, and so are the directional contractions

$$K_{\mathrm{sf}}(\tau) = 1 - \frac{\xi_{\max}(\tau) - \xi_{\min}(\tau)}{0.500},$$
$$K_{\cos}(\tau) = 1 - \frac{\beta_{\max}(\tau) - \beta_{\min}(\tau)}{0.478}.$$

The first important point is that reduced global contraction is not expected to occur uniformly. The two windows are governed by different observational pipelines, different physical regimes, and different improvement timescales. Therefore the contraction map must be staged.

The second important point is that benchmark stress and corridor stress are not identical. Since the benchmark point is boundary-supported in the strong-field direction but interior-supported in the cosmology direction, one expects

$$R_{\mathrm{bench}}(\tau)$$

to become negative before

$$K(\tau) \to 1$$

in a large class of plausible futures. The benchmark may die before the reduced corridor itself dies.

This distinction is what turns a generic viability map into a real forecast problem.

4.2 Benchmark Asymmetry and the Geometry of First Pressure

The current reduced benchmark point is

$$(\xi_{\mathrm{bench}}, \beta_{S,\mathrm{bench}}) = (0.300, 1.000),$$

with directional margins

$$m_{\xi}^{-}(\tau_0) = 0, m_{\xi}^{+}(\tau_0) = 0.500,$$
$$m_{\beta}^{-}(\tau_0) = 0.239, m_{\beta}^{+}(\tau_0) = 0.239.$$

This is already enough to identify the first likely contraction geometry.

Because

$$m_{\xi}^{-}(\tau_0) = 0,$$

any upward shift of the lower strong-field bound produces immediate benchmark death:

$$\xi_{\min}(\tau) > 0.300 \Longrightarrow R_{\text{bench}}(\tau) < 0.$$

By contrast, the cosmology branch permits symmetric tightening around the benchmark before cosmology benchmark death occurs:

$$\beta_{\min}(\tau) \leq 1.000 \leq \beta_{\max}(\tau)$$

can remain true through substantial narrowing of the cosmology interval.

This asymmetry implies the first forecast principle of the reduced global problem:

The earliest plausible benchmark-level instability is expected at the lower strong-field boundary.

That is not a speculative claim. It is dictated by the present reduced margin geometry.

4.3 Scenario Taxonomy for Reduced Corridor Evolution

The reduced corridor admits four geometrically distinct forecast scenarios.

Scenario I: Weak global contraction

Both intervals remain broad enough that

$$0 < K(\tau) \ll 1,$$

while

$$R_{\text{bench}}(\tau) \geq 0.$$

In this regime the reduced benchmark survives, the corridor remains broad, and the theory experiences only mild forecast tightening.

Scenario II: Strong-field-led contraction

The strong-field interval contracts significantly faster than the cosmology interval:

$$K_{\text{sf}}(\tau) \gg K_{\cos}(\tau).$$

This is the most natural early benchmark-stress scenario because the benchmark already lies on the lower strong-field boundary. In this regime the benchmark can die even while the reduced corridor remains nonempty.

Scenario III: Cosmology-led contraction

The cosmology interval contracts more strongly than the strong-field interval:

$$K_{\cos}(\tau) \gg K_{\text{sf}}(\tau).$$

This is geometrically allowed, but less likely as the first benchmark instability because the present cosmology benchmark position is interior rather than boundary-supported.

Scenario IV: Joint contraction

Both directional intervals contract significantly:

$$K_{\mathrm{sf}}(\tau) \sim K_{\cos}(\tau),$$

and the full reduced global corridor narrows substantially:

$$K(\tau) \to 1.$$

This is the path toward full reduced fracture.

These four scenarios are exhaustive at the reduced stage. Every future of the reduced FCLET corridor belongs to one of them.

4.4 Near-Term Pressure Map

The near-term reduced forecast is governed by the windows that are either already active or can tighten the reduced corridors without requiring a fully new observational infrastructure. In reduced language, the dominant near-term sources are:

the detector-facing strong-field event family,
the current and next-step cosmological tensor constraints,
and the broader relic-consistency pressure acting indirectly on the benchmark cosmology interval.

At the reduced level, the single most important feature of the near-term problem is not breadth but asymmetry. Because the benchmark point already satisfies

$$\xi_{\mathrm{bench}} = \xi_{\min}(\tau_0),$$

the strong-field lower edge is already maximally exposed. This means that even modest strong-field tightening can produce

$$R_{\mathrm{bench}}(\tau) < 0$$

before the reduced area is dramatically reduced.

The near-term regime is therefore expected to be dominated by Scenario II:

$$K_{\mathrm{sf}}^{\mathrm{near}} > K_{\cos}^{\mathrm{near}}.$$

This does not mean that the cosmology corridor is irrelevant in the near term. It means that the first benchmark-level warning signal is most naturally expected from the strong-field side, not from the present cosmology center.

In practical terms, the near-term reduced forecast should be monitored through three benchmark observables:

the motion of the lower strong-field bound $\xi_{\min}(\tau)$,
the sign of $R_{\mathrm{bench}}(\tau)$,
and the growth of $K_{\mathrm{sf}}(\tau)$ relative to $K_{\cos}(\tau)$.

4.5 Mid-Term Pressure Map

The mid-term regime is the stage at which the reduced contraction problem becomes more balanced. By this point one expects both windows to have sharpened enough that the reduced global corridor is no longer controlled by only one edge of one interval. Instead, both strong-field and cosmology admissibility begin to contribute materially to the remaining benchmark volume.

At this stage the correct reduced question is no longer merely whether the lower strong-field boundary rises above 0.300. It is whether the benchmark remains inside both intervals at once and whether the surviving corridor remains broad enough to count as substantive:

$$R_{\mathrm{bench}}(\tau) \geq 0, A(\tau) \ll A_0 \text{ or not.}$$

The mid-term epoch therefore tends to move from Scenario II toward Scenario IV:

$$K_{\mathrm{sf}}^{\mathrm{mid}} \sim K_{\cos}^{\mathrm{mid}},$$

or at least toward a regime in which the cosmology contraction is no longer negligible.

This is also the epoch in which one must begin to distinguish clearly between three different states:

benchmark survival,

corridor survival without benchmark,

corridor failure.

The benchmark may be lost in the mid-term while the reduced corridor remains alive. That case is weaker than present reduced viability, but stronger than full reduced fracture.

4.6 Long-Term Pressure Map

The long-term reduced forecast is not primarily benchmark-centered. It is corridor-centered. At that stage the relevant question is no longer whether the benchmark point survives, but whether any nontrivial reduced compatibility set remains at all:

$$A(\tau_{\mathrm{long}}) > 0 \text{or} A(\tau_{\mathrm{long}}) = 0.$$

The long-term reduced futures therefore fall into three exact categories:

Long-term reduced survival

$$0 < A(\tau_{\text{long}}) < A_0.$$

The corridor survives, though contracted.

Long-term benchmark loss with corridor survival

$$R_{\text{bench}}(\tau_{\text{long}}) < 0, A(\tau_{\text{long}}) > 0.$$

The benchmark dies, but the reduced theory still has surviving descendants.

Long-term reduced fracture

$$A(\tau_{\text{long}}) = 0, K(\tau_{\text{long}}) = 1.$$

The reduced global viability region is gone.

This distinction matters because a late-stage theory program should not confuse benchmark loss with corridor death. The latter is much stronger and much more consequential.

4.7 Reduced Contraction Trajectories

The forecast problem can now be represented as a time-ordered contraction trajectory

$$\tau \mapsto (K_{\text{sf}}(\tau), K_{\cos}(\tau), K(\tau), R_{\text{bench}}(\tau)).$$

This trajectory contains the entire reduced viability history.

A strong-field-led trajectory is characterized by

$$K_{\text{sf}}(\tau) \uparrow \text{ rapidly}, K_{\cos}(\tau) \uparrow \text{ slowly},$$

with

$$R_{\text{bench}}(\tau) < 0$$

occurring early.

A cosmology-led trajectory reverses this hierarchy.

A joint contraction trajectory drives both directional contractions upward and tends toward

$$K(\tau) \to 1.$$

Thus the reduced corridor has not only a survival geometry but a forecast dynamics.

4.8 Pressure Ordering Principle

The present reduced geometry implies a definite pressure ordering.

Because

$$m_{\xi}^{-}(\tau_0) = 0,$$

the first expected benchmark pressure point is

$$\xi_{\min}(\tau) > 0.300.$$

Because

$$m_{\beta}^{-}(\tau_0) = m_{\beta}^{+}(\tau_0) = 0.239,$$

cosmology benchmark death requires substantially more contraction before it occurs.

The natural reduced pressure ordering is therefore

$$\text{strong-field benchmark pressure} \longrightarrow \text{cosmology benchmark pressure} \longrightarrow \text{full reduced corridor pressure.}$$

This ordering is not merely plausible. It is the direct consequence of the present reduced margin asymmetry.

4.9 Forecasted Reduced Contraction Theorem

The results of this section can now be summarized precisely.

Theorem 3 (Forecasted Reduced Contraction Theorem).
Let

$$S_{\text{global}}^{\text{red}}(\tau) = [\xi_{\min}(\tau), \xi_{\max}(\tau)] \times [\beta_{\min}(\tau), \beta_{\max}(\tau)]$$

be the reduced FCLET survival corridor, and let the benchmark point be

$$(\xi_{\text{bench}}, \beta_{S,\text{bench}}) = (0.300, 1.000).$$

Suppose the current directional margins are

$$m_{\xi}^{-}(\tau_0) = 0, m_{\xi}^{+}(\tau_0) = 0.500,$$
$$m_{\beta}^{-}(\tau_0) = m_{\beta}^{+}(\tau_0) = 0.239.$$

Then the earliest plausible benchmark-level contraction pressure acts on the lower strong-field boundary. In particular, strong-field benchmark death occurs as soon as

$$\xi_{\min}(\tau) > 0.300,$$

while full reduced global fracture occurs if and only if

$$K(\tau) = 1.$$

Moreover, the reduced global problem naturally admits four contraction scenarios: weak contraction, strong-field-led contraction, cosmology-led contraction, and joint contraction.

4.10 What Section 4 Achieves

Section 2 established reduced compatibility.
Section 3 defined reduced contraction and benchmark robustness.
Section 4 now places those structures on a forecasted time axis.

The section does three exact things.

First, it transforms the reduced global corridor from a static set into a time-dependent viability problem.

Second, it identifies the geometry of first pressure: the benchmark is most fragile at the lower strong-field boundary.

Third, it distinguishes benchmark death from corridor death and weak contraction from joint contraction, thereby providing the correct temporal grammar of reduced viability.

This is the complete reduced forecast map of Article 89.

The next step is now unavoidable. Once a reduced corridor has contraction dynamics and a forecast hierarchy, it must also possess an explicit failure grammar. That is the role of the next section, which formalizes reduced falsification routes and exact benchmark death conditions.

5. Reduced Falsification Routes and Benchmark Death Conditions

The reduced corridor analysis does not end with survival. A viable theory space must also carry an explicit failure grammar. Once a reduced global corridor has been defined, once its contraction dynamics has been written, and once its benchmark asymmetry has been identified, the next indispensable question is exact:

How can the reduced FCLET benchmark corridor die?

This question must be answered with full mathematical separation between different negative outcomes. A benchmark point can die while a nonzero reduced corridor still survives. A reduced corridor can survive while losing nontrivial physical content. And only when the

reduced survival set itself collapses does one obtain full reduced global fracture. These are not the same event. A serious quantitative viability paper must distinguish them sharply.

At the reduced stage of Article 89, the relevant object remains

$$S_{\mathrm{global}}^{\mathrm{red}}(\tau) = [\xi_{\min}(\tau), \xi_{\max}(\tau)] \times [\beta_{\min}(\tau), \beta_{\max}(\tau)],$$

with benchmark point

$$(\xi_{\mathrm{bench}}, \beta_{S,\mathrm{bench}}) = (0.300, 1.000).$$

The present section constructs the full reduced falsification ladder.

5.1 Benchmark Death versus Corridor Death

The first distinction is foundational. The benchmark point represents a preferred FCLET branch, but it is not identical to the entire reduced corridor. Therefore the benchmark can fail while the reduced survival region remains nonempty.

The benchmark survives if and only if

$$\xi_{\min}(\tau) \leq \xi_{\mathrm{bench}} \leq \xi_{\max}(\tau), \beta_{\min}(\tau) \leq \beta_{S,\mathrm{bench}} \leq \beta_{\max}(\tau).$$

By contrast, the reduced corridor survives if and only if

$$\xi_{\min}(\tau) < \xi_{\max}(\tau), \beta_{\min}(\tau) < \beta_{\max}(\tau).$$

These conditions are not equivalent. Benchmark death is a pointwise failure. Corridor death is a setwise failure. The difference is essential because a theory program can lose its canonical benchmark representative before losing all of its reduced descendants.

Article 89 therefore treats benchmark death as a real result, but not yet as full reduced falsification.

5.2 Strong-Field Benchmark Death

The first and most immediate benchmark death route comes from the strong-field side. The benchmark strong-field coordinate is

$$\xi_{\mathrm{bench}} = 0.300,$$

and the benchmark reduced margin on the lower strong-field side is

$$m_{\xi}^{-}(\tau_0) = 0.$$

Therefore the benchmark is already boundary-supported in the ξ-direction. It follows that any upward displacement of the lower strong-field admissible bound expels the benchmark immediately:

$$\xi_{\min}(\tau) > 0.300 \Longrightarrow (\xi_{\text{bench}}, \beta_{S,\text{bench}}) \notin S^{\text{red}}_{\text{global}}(\tau).$$

More generally, strong-field benchmark death occurs if either

$$\xi_{\min}(\tau) > 0.300 \text{or} \xi_{\max}(\tau) < 0.300.$$

The second condition is geometrically possible but not the first expected failure mode. The first is the natural early-pressure route because the benchmark currently lies exactly on the lower strong-field boundary.

This motivates the strong-field benchmark-death indicator

$$D^{\text{bench}}_{\text{sf}}(\tau) = \Theta\left(\xi_{\min}(\tau) - 0.300\right),$$

where Θ is the Heaviside step function. Then

$$D^{\text{bench}}_{\text{sf}}(\tau) = 1$$

signals strong-field benchmark death.

This is the sharpest and most immediate reduced failure channel currently visible in the FCLET benchmark geometry.

5.3 Cosmology Benchmark Death

The second benchmark death route comes from the cosmology side. The benchmark cosmology coordinate is

$$\beta_{S,\text{bench}} = 1.000,$$

and the benchmark cosmology margins are

$$m^{-}_{\beta}(\tau_0) = m^{+}_{\beta}(\tau_0) = 0.239.$$

Thus the benchmark is strictly interior-supported in the cosmology direction. Cosmology benchmark death therefore requires stronger contraction than in the strong-field case. It occurs if

$$\beta_{\min}(\tau) > 1.000 \text{or} \beta_{\max}(\tau) < 1.000.$$

Equivalently, define the cosmology benchmark-death indicator

$$D_{\cos}^{\mathrm{bench}}(\tau) = \Theta\left(\beta_{\min}(\tau) - 1.000\right) + \Theta\left(1.000 - \beta_{\max}(\tau)\right),$$

with any nonzero value indicating cosmology benchmark exclusion.

Because the current benchmark lies inside the cosmology interval with equal left and right margin, cosmology benchmark death is not expected to be the first reduced instability. It is a genuine benchmark failure route, but not the most immediate one.

5.4 Benchmark Death Functional

The two benchmark-death routes can be unified by defining the benchmark-death functional

$$D_{\mathrm{bench}}(\tau) = \max\left\{D_{\mathrm{sf}}^{\mathrm{bench}}(\tau), D_{\cos}^{\mathrm{bench}}(\tau)\right\}.$$

Then

$$D_{\mathrm{bench}}(\tau) = 0$$

means that the benchmark still lies inside the reduced corridor, whereas

$$D_{\mathrm{bench}}(\tau) = 1$$

means that the benchmark has been expelled from at least one reduced direction.

This functional is the exact complement of the robustness functional

$$R_{\mathrm{bench}}(\tau).$$

Indeed,

$$R_{\mathrm{bench}}(\tau) \geq 0 \Leftrightarrow D_{\mathrm{bench}}(\tau) = 0,$$

while

$$R_{\mathrm{bench}}(\tau) < 0 \Leftrightarrow D_{\mathrm{bench}}(\tau) = 1.$$

Thus benchmark survival and benchmark death are now fully formalized.

5.5 Strong-Field Reduced Fracture

Benchmark death is not yet corridor death. Full strong-field reduced fracture occurs only when the strong-field interval itself collapses:

$$\xi_{\min}(\tau) \geq \xi_{\max}(\tau).$$

At this point the strong-field reduced branch is empty, and since the reduced global set is a Cartesian product, one immediately has

$$S^{\mathrm{red}}_{\mathrm{global}}(\tau) = \emptyset.$$

This is the first true corridor-level falsification route.

Its interpretation is exact. The strong-field branch is no longer merely pressuring the benchmark representative. It has ceased to leave any reduced admissible threshold range at all.

5.6 Cosmology Reduced Fracture

Similarly, full cosmology reduced fracture occurs when

$$\beta_{\min}(\tau) \geq \beta_{\max}(\tau).$$

At this point the cosmology reduced branch is empty, and therefore

$$S^{\mathrm{red}}_{\mathrm{global}}(\tau) = \emptyset.$$

This is the second true corridor-level falsification route.

As in the strong-field case, this is stronger than benchmark death. It does not merely expel the benchmark point; it removes the reduced cosmology branch entirely from the global survival problem.

5.7 Full Reduced Global Fracture

The strict reduced global fracture condition is

$$A(\tau) = 0,$$

equivalently,

$$K(\tau) = 1.$$

Since

$$A(\tau) = [\xi_{\max}(\tau) - \xi_{\min}(\tau)][\beta_{\max}(\tau) - \beta_{\min}(\tau)],$$

this occurs if and only if at least one directional corridor has zero measure:

$$\xi_{\min}(\tau) \geq \xi_{\max}(\tau) \text{or} \beta_{\min}(\tau) \geq \beta_{\max}(\tau).$$

This is the strongest reduced-level death state. No reduced-compatible parameter pair remains. The strong-field and cosmology branches are no longer jointly survivable even in reduced product form.

5.8 Reduced Retreat and Loss of Nontriviality

There is, however, a negative outcome that is weaker than full reduced fracture but stronger than ordinary contraction. The reduced corridor may remain formally nonempty while losing substantive physical content.

At the benchmark stage, reduced nontriviality requires both:

in the strong-field direction,

$$\frac{\delta \mathrm{Re}\ \omega}{\mathrm{Re}\ \omega} \not\to 0,$$

and in the cosmology direction,

$$(\Delta n_T, r) \not\to (0,0).$$

This motivates the reduced nontriviality indicator

$$N_{\mathrm{red}}(\tau) = 1$$

if the surviving reduced corridor still retains non-null strong-field deformation and non-inert cosmological tensor content. If instead the surviving reduced set is driven toward shell-null behavior or tensor inertness, then

$$N_{\mathrm{red}}(\tau) = 0.$$

This defines **reduced retreat**:

$$S^{\mathrm{red}}_{\mathrm{global}}(\tau) \neq \emptyset, N_{\mathrm{red}}(\tau) = 0.$$

Reduced retreat is not full reduced fracture. The corridor survives mathematically. But it survives only by losing the physical content that made it important in the first place.

This distinction is essential. A global viability paper must distinguish survival from content-preserving survival.

5.9 Reduced Falsification Route Hierarchy

The reduced geometry therefore yields four distinct negative outcomes.

Route I: Strong-field benchmark death

$$\xi_{\min}(\tau) > 0.300.$$

The benchmark point is expelled from the reduced corridor through the lower strong-field boundary, even though some reduced corridor may remain.

Route II: Cosmology benchmark death

$$\beta_{\min}(\tau) > 1.000 \text{or} \beta_{\max}(\tau) < 1.000.$$

The benchmark point is expelled through the cosmology interval, again without necessarily killing the full reduced corridor.

Route III: Reduced retreat

$$S^{\text{red}}_{\text{global}}(\tau) \neq \emptyset, N_{\text{red}}(\tau) = 0.$$

The corridor survives in formal measure, but no longer in substantive strong-field or cosmological content.

Route IV: Full reduced fracture

$$S^{\text{red}}_{\text{global}}(\tau) = \emptyset, K(\tau) = 1.$$

This is complete reduced global death.

These routes are not interchangeable. They mark distinct levels of failure in the reduced global program.

5.10 Severity Ordering

The reduced falsification routes admit a natural severity hierarchy:

$$\text{benchmark death} \;<\; \text{reduced retreat} \;<\; \text{full reduced fracture.}$$

Within benchmark death itself, the present reduced margin structure strongly suggests the temporal ordering

$$\text{strong-field benchmark death} \;\prec\; \text{cosmology benchmark death,}$$

not because the latter is less severe in principle, but because the former is geometrically much closer under the current benchmark margins.

Thus the reduced benchmark branch is most likely to fail first by strong-field lower-bound pressure, not by immediate cosmology expulsion.

5.11 Reduced Falsification Theorem

The full reduced failure grammar can now be stated as a theorem.

Theorem 4 (Reduced Falsification Theorem).
Let

$$S_{\text{global}}^{\text{red}}(\tau) = [\xi_{\min}(\tau), \xi_{\max}(\tau)] \times [\beta_{\min}(\tau), \beta_{\max}(\tau)]$$

be the reduced FCLET survival corridor, and let the benchmark point be

$$(\xi_{\text{bench}}, \beta_{S,\text{bench}}) = (0.300, 1.000).$$

Then reduced falsification occurs at three distinct levels:

benchmark death, if the benchmark is expelled from one or both reduced intervals;

reduced retreat, if the corridor remains nonempty but loses nontrivial physical content;

full reduced fracture, if

$$S_{\text{global}}^{\text{red}}(\tau) = \emptyset \Leftrightarrow K(\tau) = 1.$$

Moreover, because

$$m_{\xi}^{-}(\tau_0) = 0,$$

the benchmark is presently maximally fragile on the lower strong-field boundary. Hence the earliest plausible reduced falsification route is strong-field benchmark death.

5.12 What Section 5 Achieves

Section 3 introduced the reduced contraction dynamics. Section 4 placed that contraction on a time axis and identified the geometry of first pressure. The present section now completes the reduced viability analysis by adding an explicit falsification grammar.

It does four exact things.

First, it separates benchmark death from corridor death.

Second, it formalizes the strong-field and cosmology benchmark-death routes.

Third, it distinguishes reduced retreat from full reduced fracture.

Fourth, it shows that the current benchmark geometry is already telling us something predictive: the most immediate reduced failure route is the lower strong-field boundary.

This means that the reduced global program of Article 89 is now complete. It has:

a nonempty reduced survival set,

a benchmark-normalized contraction functional,

a robustness functional,

a forecasted pressure map,

and a falsification ladder.

The next step is therefore the decisive one. The reduced corridor must now be replaced by a true one-parameter bridge law so that the strong-field and cosmology windows are no longer merely jointly admissible in product form, but explicitly coupled through one common continuation structure.

That is the role of the next section.

6. From the Reduced Corridor to the True Bridge — Constructing $\beta_S(\xi)$ and the One-Parameter Global Set

The reduced global program developed in the previous sections is already mathematically meaningful. It established a nonempty benchmark compatibility region, defined its contraction dynamics, and formalized its failure ladder. But the reduced corridor still leaves one decisive question unresolved. The strong-field branch is parameterized by the threshold coordinate

$$\xi \equiv \Xi_{\mathrm{crit}},$$

whereas the cosmological branch is parameterized by the saturation-coupling variable

$$\beta_S.$$

As long as these variables remain independent, the global structure remains only partially unified. The reduced product

$$S_{\mathrm{global}}^{\mathrm{red}} = S_{\mathrm{sf}}^{\xi} \times S_{\mathrm{cos}}^{\beta}$$

shows compatibility, but it does not yet prove that one and the same continuation law underlies both benchmark sectors.

The next step is therefore unavoidable. The residual independence of the reduced variables must be removed by constructing a bridge law

$$\beta_S = \beta_S(\xi).$$

Once such a law is introduced, the FCLET global problem ceases to be a Cartesian product of two reduced intervals and becomes a true one-parameter survival problem. This is the exact purpose of the present section.

6.1 Why a True Bridge Is Necessary

The reduced compatibility result

$$S_{\text{global}}^{\text{red}} \neq \emptyset$$

already proves that the strong-field and cosmological branches do not contradict one another at benchmark level. But it does not yet prove that they are manifestations of one continuous admissible structure. Reduced compatibility means that the two branches can coexist in one rectangular reduced space. It does not yet prove that a single global coordinate traverses both.

The stronger question is:

Does there exist a continuous map
$\beta_S(\xi)$ such that one and the same ξ survives both windows?

This is the first genuinely coupled global question of Article 89. If the answer were negative, then the theory would remain reduced-compatible but not truly globally coupled. If the answer is positive, then the benchmark FCLET architecture advances from reduced coexistence to one-parameter viability.

This is a major conceptual shift. The reduced corridor asked whether two benchmark sectors can live side by side. The true bridge asks whether they can be read as one continuous admissible law.

6.2 Structural Requirements on the Bridge Law

Not every function $\beta_S(\xi)$ is admissible. A physically meaningful bridge law must satisfy four exact requirements.

6.2.1 Benchmark anchoring

The bridge must preserve the reduced benchmark point:

$$\beta_S(\xi_{\text{bench}}) = 1, \xi_{\text{bench}} = 0.300.$$

This is non-negotiable. The benchmark branch already survives in the reduced corridor. The bridge must pass through it, not replace it.

6.2.2 Continuity

The bridge must be continuous over the strong-field admissible interval:

$$\beta_S(\xi) \in C^0([0.300,0.800]).$$

Discontinuous bridge laws would not represent one continuation structure. They would represent piecewise branch stitching.

6.2.3 Nontriviality preservation

The bridge must preserve nontrivial strong-field and cosmological content. It must not map the strong-field branch into an effectively null cosmological face, nor map the cosmology branch into an observationally inert continuation structure.

6.2.4 Compatibility with the reduced cosmology corridor

The bridge image near the benchmark must lie inside the reduced cosmology interval

$$S_{\cos}^{\beta} = [0.761,1.239].$$

Since the benchmark value satisfies

$$1 \in (0.761,1.239),$$

a benchmark-anchored continuous bridge automatically possesses local admissibility. This fact will yield the first true-bridge existence theorem.

6.3 Definition of the One-Parameter Global Set

Given a bridge law $\beta_S(\xi)$, the correct coupled FCLET survival object is

$$S_{\text{global}} = \{\xi \in [0.300,0.800]: \beta_S(\xi) \in [0.761,1.239]\}.$$

This is the true one-parameter global set. It is no longer an area in a reduced (ξ, β_S)-plane. It is a surviving subset of the master coordinate line.

This change matters both mathematically and physically.

Mathematically, the problem changes from a two-dimensional compatibility region to a one-dimensional admissible interval.

Physically, the problem changes from coexistence of two reduced sectors to the survival of one continuous FCLET continuation law.

The reduced corridor remains an important preparation stage, but the present object is stronger. It is the first true coupled viability set of the FCLET benchmark program.

6.4 Continuity Bridge Theorem

The first exact result follows immediately from continuity and anchoring alone.

Theorem 5 (Continuity Bridge Theorem).
Let $\beta_S(\xi)$ be a continuous bridge map on the interval $[0.300, 0.800]$ and suppose it is benchmark-anchored:

$$\beta_S(0.300) = 1.$$

Since

$$1 \in (0.761,1.239),$$

there exists $\varepsilon > 0$ such that

$$\beta_S(\xi) \in [0.761,1.239] \text{for all } \xi \in [0.300,0.300 + \varepsilon].$$

Hence

$$S_{\text{global}} \neq \emptyset,$$

and in fact S_{global} contains a one-sided neighborhood of the benchmark point.

This theorem is decisive. It upgrades reduced compatibility to true one-parameter viability under the minimal physically meaningful assumptions of continuity and benchmark anchoring.

The importance of the theorem is easy to state: the benchmark survives not merely as an accidental pointwise coincidence between two independent reduced windows, but as the endpoint of a genuine one-parameter continuation branch with nonzero local width.

6.5 The Minimal Benchmark Bridge Family

Although existence already follows abstractly, the global problem becomes much sharper once an explicit bridge family is written. The simplest admissible benchmark bridge is the linear family

$$\beta_S^{(1)}(\xi;\lambda) = 1 + \lambda(\xi - 0.300),$$

where λ is the bridge-slope parameter.

This family satisfies the benchmark-anchoring condition exactly:

$$\beta_S^{(1)}(0.300;\lambda) = 1$$

for every value of λ.

The corresponding one-parameter global set is

$$S_{\text{global}}^{(1)}(\lambda) = \{\xi \in [0.300,0.800]: 0.761 \leq 1 + \lambda(\xi - 0.300) \leq 1.239\}.$$

This is the minimal true-bridge realization of the benchmark FCLET program. It is not yet the most general bridge family, but it is the correct first explicit family because it isolates the single new global quantity that now matters: the bridge slope λ.

6.6 Analytic Corridor Length in the Linear Bridge Family

The linear bridge family makes the one-parameter corridor length explicitly calculable.

The reduced cosmology interval allows a deviation from the benchmark of at most

$$| \beta_S - 1 | \leq 0.239.$$

For the linear family,

$$\beta_S^{(1)}(\xi; \lambda) - 1 = \lambda(\xi - 0.300).$$

Hence admissibility requires

$$| \lambda(\xi - 0.300) | \leq 0.239.$$

For $\lambda \neq 0$, this is equivalent to

$$| \xi - 0.300 | \leq \frac{0.239}{| \lambda |}.$$

Since the strong-field interval itself begins at $\xi = 0.300$, the surviving one-parameter corridor is

$$S_{\text{global}}^{(1)}(\lambda) = \left[0.300, \min\left(0.800, 0.300 + \frac{0.239}{| \lambda |}\right)\right]$$

for $\lambda \neq 0$, while for $\lambda = 0$,

$$S_{\text{global}}^{(1)}(0) = [0.300, 0.800].$$

The corridor length is therefore

$$L(\lambda) = \mu(S_{\text{global}}^{(1)}(\lambda)) = \min\left(0.500, \frac{0.239}{| \lambda |}\right)$$

for $\lambda \neq 0$, and

$$L(0) = 0.500.$$

This formula is one of the key outputs of Article 89. It converts the qualitative notion of bridge viability into an analytic one-parameter corridor length.

6.7 Bridge-Slope Regimes

The analytic form of $L(\lambda)$ immediately defines three bridge regimes.

Regime I: weak bridge slope

If

$$|\lambda| \leq 0.478,$$

then

$$\frac{0.239}{|\lambda|} \geq 0.500,$$

and therefore

$$L(\lambda) = 0.500.$$

In this regime the cosmology bridge does not further compress the strong-field width. The entire strong-field reduced interval survives the one-parameter coupling.

Regime II: intermediate bridge slope

If

$$|\lambda| > 0.478,$$

then

$$L(\lambda) = \frac{0.239}{|\lambda|} < 0.500.$$

Here the bridge itself becomes a source of contraction. The one-parameter corridor remains nonempty, but it is narrower than the full strong-field reduced interval.

Regime III: singular steep-slope limit

As

$$|\lambda| \to \infty,$$

the one-parameter corridor collapses:

$$L(\lambda) \to 0.$$

This is not an ordinary reduced-window failure. It is bridge-induced self-destruction of the coupled corridor.

These three regimes show that the bridge law is not a passive reparametrization. It is an active part of the global viability structure.

6.8 Induced One-Parameter Observable Map

Once the bridge law is introduced, the observables of both windows become functions of the same master coordinate.

The strong-field observable branch is

$$\frac{\delta \mathrm{Re}\,\omega}{\mathrm{Re}\,\omega}(\xi) = \alpha_{\mathrm{sf}}\,\xi,$$

with benchmark normalization

$$\alpha_{\mathrm{sf}} = \frac{2.6\%}{0.300} \approx 8.667\%\ \text{per unit}\ \xi.$$

Thus

$$\frac{\delta \mathrm{Re}\,\omega}{\mathrm{Re}\,\omega}(0.300) = 2.6\%, \frac{\delta \mathrm{Re}\,\omega}{\mathrm{Re}\,\omega}(0.800) \approx 6.9\%.$$

The cosmological quantities become

$$\beta_S = \beta_S(\xi), \Delta n_T = \Delta n_T(\beta_S(\xi)), r = r(\beta_S(\xi)).$$

At the benchmark point this yields

$$\Delta n_T(0.300) \approx -0.035, r(0.300) \in [0.007, 0.020].$$

The full one-parameter FCLET observable map is therefore

$$\mathcal{G}(\xi) = \left(\frac{\delta \mathrm{Re}\,\omega}{\mathrm{Re}\,\omega}(\xi), \beta_S(\xi), \Delta n_T(\xi), r(\xi)\right).$$

This is the first true global benchmark map of the late FCLET program.

6.9 True One-Parameter Survival Criterion

The coupled benchmark branch survives if and only if

$$S_{\mathrm{global}} \neq \emptyset.$$

In the linear benchmark family, this condition is satisfied for every finite λ, because continuity and anchoring guarantee at least a one-sided neighborhood of benchmark survival.

A stronger condition is **nontrivial true survival**. This requires not merely that the one-parameter corridor exist, but that it retain substantive strong-field and cosmological content:

$$L(\lambda) > 0,$$

together with

$$\frac{\delta \mathrm{Re}\, \omega}{\mathrm{Re}\, \omega}(\xi) \not\to 0, (\Delta n_T(\xi), r(\xi)) \not\to (0,0)$$

throughout the surviving branch.

The linear bridge family satisfies this stronger condition for all finite admissible λ.

6.10 True Bridge Theorem

The full coupled result can now be stated directly.

Theorem 6 (True Bridge Theorem).
Let the FCLET strong-field interval be

$$S_{\mathrm{sf}}^{\xi} = [0.300, 0.800],$$

let the cosmology interval be

$$S_{\mathrm{cos}}^{\beta} = [0.761, 1.239],$$

and let the bridge law $\beta_S(\xi)$ be continuous and benchmark-anchored:

$$\beta_S(0.300) = 1.$$

Then the one-parameter global set

$$S_{\mathrm{global}} = \{\xi \in [0.300, 0.800] : \beta_S(\xi) \in [0.761, 1.239]\}$$

is nonempty and contains a one-sided neighborhood of the benchmark point.

For the linear benchmark bridge family

$$\beta_S^{(1)}(\xi; \lambda) = 1 + \lambda(\xi - 0.300),$$

the corridor length is

$$L(\lambda) = \min\left(0.500, \frac{0.239}{|\lambda|}\right),$$

and therefore the coupled one-parameter FCLET corridor has strictly positive measure for every finite λ.

This theorem is the decisive upgrade from reduced compatibility to true global viability.

6.11 What Section 6 Achieves

Sections 2–5 completed the reduced global program. They established nonempty reduced survival, contraction dynamics, benchmark robustness, and a reduced falsification ladder. But the theory was still reduced in one crucial sense: the strong-field and cosmological coordinates remained independent.

Section 6 removes that independence.

It introduces the bridge law $\beta_S(\xi)$, defines the true one-parameter global set, proves that it is nonempty under continuity and benchmark anchoring, and constructs the first explicit bridge family for which the corridor length is analytic.

This is the first genuinely coupled global step of Article 89.

The reduced corridor proved that the benchmark strong-field and cosmological branches can coexist.
The true bridge proves that they can be traversed by one continuous admissible FCLET continuation law.

That is a much stronger result.

The next question is then immediate. Once the true one-parameter corridor exists, how does it contract under observational pressure, and how can it fail in a way that the reduced problem could not detect?

That is the subject of the next section, which introduces the true contraction functional

$$K_{\mathrm{true}}(\tau)$$

and the new coupled failure mode of bridge-slope falsification.

7. True Global Contraction $K_{\mathrm{true}}(\tau)$ and Bridge-Slope Falsification

The previous section established the decisive coupled result of Article 89: once a continuous benchmark-anchored bridge law

$$\beta_S = \beta_S(\xi)$$

is introduced, the FCLET benchmark program ceases to be only a reduced compatibility problem and becomes a true one-parameter global survival problem. That step is foundational,

but it is not the end of the global analysis. Once a one-parameter corridor exists, the next question becomes unavoidable:

How does the true one-parameter corridor contract under observational pressure, and how can it fail?

This question is stronger than its reduced predecessor. In the reduced problem, contraction meant shrinkage of a rectangle in the (ξ, β_S) plane. In the true problem, contraction means shrinkage of the actual one-parameter FCLET continuation corridor itself. The present section defines that contraction dynamics and isolates a new global failure mode that does not exist at reduced level: **bridge-slope falsification**.

7.1 The True One-Parameter Survival Set

Let the epoch-dependent strong-field admissible interval be

$$S_{\mathrm{sf}}(\tau) = [\xi_{\min}(\tau), \xi_{\max}(\tau)],$$

and let the epoch-dependent cosmological admissible interval be

$$S_{\cos}(\tau) = [\beta_{\min}(\tau), \beta_{\max}(\tau)].$$

Given a bridge law $\beta_S(\xi)$, define the cosmology-induced preimage in ξ-space by

$$\mathcal{P}_{\cos}(\tau) = \{\xi : \beta_S(\xi) \in [\beta_{\min}(\tau), \beta_{\max}(\tau)]\}.$$

The true one-parameter global corridor is then

$$S_{\mathrm{global}}(\tau) = S_{\mathrm{sf}}(\tau) \cap \mathcal{P}_{\cos}(\tau).$$

This is the exact coupled FCLET survival object. It is no longer an area in a reduced two-parameter space. It is a surviving subset of the master continuation line.

Its measure is therefore a length:

$$L_{\mathrm{true}}(\tau) = \mu\left(S_{\mathrm{global}}(\tau)\right).$$

At the benchmark epoch τ_0, this length is strictly positive by the true bridge theorem. The task of Section 7 is to determine how this length changes under future contraction and under what circumstances it collapses.

7.2 Definition of the True Global Contraction Functional

The natural one-parameter analogue of the reduced area contraction is the length-normalized contraction functional

$$K_{\mathrm{true}}(\tau) = 1 - \frac{L_{\mathrm{true}}(\tau)}{L_{\mathrm{true}}(\tau_0)}.$$

This is the correct global contraction scalar of the coupled benchmark problem.

Its interpretation is exact:

if

$$L_{\mathrm{true}}(\tau) = L_{\mathrm{true}}(\tau_0),$$

then

$$K_{\mathrm{true}}(\tau) = 0,$$

meaning that no contraction of the true one-parameter corridor has yet occurred relative to the benchmark epoch.

If

$$L_{\mathrm{true}}(\tau) = 0,$$

then

$$K_{\mathrm{true}}(\tau) = 1,$$

meaning that the coupled FCLET one-parameter corridor has collapsed completely.

Thus

$$0 \le K_{\mathrm{true}}(\tau) \le 1$$

for every admissible epoch τ.

This functional is strictly stronger than the reduced contraction functional $K(\tau)$. The reduced contraction measured the shrinking of a product geometry. The true contraction measures the shrinking of the actual coupled law.

7.3 Explicit Corridor Length for the Linear Bridge Family

To make the true contraction problem analytic rather than merely formal, consider again the linear benchmark bridge family

$$\beta_S^{(1)}(\xi;\lambda) = 1 + \lambda(\xi - 0.300),$$

where λ is the bridge-slope parameter.

At an observational epoch τ, the one-parameter corridor is defined by the simultaneous conditions

$$\xi \in [\xi_{\min}(\tau), \xi_{\max}(\tau)]$$

and

$$\beta_{\min}(\tau) \leq 1 + \lambda(\xi - 0.300) \leq \beta_{\max}(\tau).$$

For $\lambda > 0$, this second condition becomes

$$0.300 + \frac{\beta_{\min}(\tau) - 1}{\lambda} \leq \xi \leq 0.300 + \frac{\beta_{\max}(\tau) - 1}{\lambda}.$$

For $\lambda < 0$, the interval reverses orientation. It is therefore convenient to define the cosmology-induced ξ-bounds uniformly as

$$\xi^{-}_{\cos}(\tau; \lambda) = \min\left\{0.300 + \frac{\beta_{\min}(\tau) - 1}{\lambda}, 0.300 + \frac{\beta_{\max}(\tau) - 1}{\lambda}\right\},$$
$$\xi^{+}_{\cos}(\tau; \lambda) = \max\left\{0.300 + \frac{\beta_{\min}(\tau) - 1}{\lambda}, 0.300 + \frac{\beta_{\max}(\tau) - 1}{\lambda}\right\}.$$

Then the true corridor is

$$S^{(1)}_{\text{global}}(\tau; \lambda) = [\xi_{\min}(\tau), \xi_{\max}(\tau)] \cap [\xi^{-}_{\cos}(\tau; \lambda), \xi^{+}_{\cos}(\tau; \lambda)].$$

Its length is therefore

$$L_{\text{true}}(\tau; \lambda) = \max\left(0, \min\{\xi_{\max}(\tau), \xi^{+}_{\cos}(\tau; \lambda)\} - \max\{\xi_{\min}(\tau), \xi^{-}_{\cos}(\tau; \lambda)\}\right).$$

This is the exact analytic expression for the true coupled FCLET corridor in the linear bridge family.

7.4 Benchmark Epoch Normalization

At the benchmark epoch τ_0, one has

$$\xi_{\min}(\tau_0) = 0.300, \xi_{\max}(\tau_0) = 0.800,$$
$$\beta_{\min}(\tau_0) = 0.761, \beta_{\max}(\tau_0) = 1.239.$$

Substituting these values yields

$$L_{\mathrm{true}}(\tau_0;\lambda) = \min\left(0.500, \frac{0.239}{|\lambda|}\right)$$

for $\lambda \neq 0$, and

$$L_{\mathrm{true}}(\tau_0;0) = 0.500.$$

Hence the true contraction functional takes the explicit form

$$K_{\mathrm{true}}(\tau;\lambda) = 1 - \frac{L_{\mathrm{true}}(\tau;\lambda)}{\min(0.500, 0.239/|\lambda|)}.$$

This is the correct master contraction observable of the one-parameter bridge problem.

7.5 Benchmark Survival in the Coupled Problem

The benchmark point survives under the true bridge if and only if

$$\xi_{\mathrm{bench}} = 0.300 \in S_{\mathrm{global}}(\tau).$$

Because the bridge is benchmark-anchored,

$$\beta_S(0.300) = 1,$$

benchmark survival is equivalent to the two directional admissibility conditions

$$\xi_{\min}(\tau) \leq 0.300 \leq \xi_{\max}(\tau),$$
$$\beta_{\min}(\tau) \leq 1 \leq \beta_{\max}(\tau).$$

Thus the pointwise benchmark test has the same formal inequalities as in the reduced analysis, but now they refer to one and the same master continuation point rather than to two independent reduced coordinates.

This motivates the coupled benchmark-robustness functional

$$R_{\mathrm{true}}^{\mathrm{bench}}(\tau) = \min\{0.300 - \xi_{\min}(\tau), \xi_{\max}(\tau) - 0.300, 1 - \beta_{\min}(\tau), \beta_{\max}(\tau) - 1\}.$$

As before:

$R_{\mathrm{true}}^{\mathrm{bench}}(\tau) > 0$ means interior-supported benchmark survival,

$R_{\mathrm{true}}^{\mathrm{bench}}(\tau) = 0$ means boundary-supported benchmark survival,

$R_{\mathrm{true}}^{\mathrm{bench}}(\tau) < 0$ means benchmark death.

The difference is that this robustness now belongs to a genuinely coupled one-parameter theory object.

7.6 Bridge-Slope Compression Factor

A phenomenon appears at the true-bridge level that has no analogue in the reduced problem: the bridge slope itself becomes a source of contraction.

Define the bridge-slope compression factor

$$\mathcal{B}_\lambda = \frac{0.239}{|\lambda|}.$$

This quantity measures how the cosmology interval projects back into the ξ-line through the bridge law, relative to the benchmark strong-field width 0.500.

Three regimes follow immediately.

Weak-slope regime

If

$$\mathcal{B}_\lambda \geq 0.500,$$

equivalently

$$|\lambda| \leq 0.478,$$

then the bridge does not compress the benchmark corridor below the full strong-field width.

Intermediate-slope regime

If

$$0 < \mathcal{B}_\lambda < 0.500,$$

equivalently

$$|\lambda| > 0.478,$$

then the bridge itself narrows the one-parameter corridor.

Singular steep-slope regime

As

$$\mathcal{B}_\lambda \to 0 (\text{i.e. } |\lambda| \to \infty),$$

the one-parameter corridor collapses.

This shows that the bridge is not a harmless repackaging of the reduced problem. Its slope is a real source of global pressure.

7.7 Bridge-Slope Falsification

This leads to a new coupled failure mode that is impossible at reduced level.

In the reduced problem, failure could occur only because one of the two reduced intervals collapsed or because the benchmark point was expelled. In the true bridge problem, a new possibility appears:

the reduced intervals may remain separately nonempty, yet no single one-parameter continuation law survives both simultaneously.

This is **bridge-slope falsification**.

Formally, it occurs when

$$L_{\mathrm{true}}(\tau;\lambda) = 0$$

even though

$$\xi_{\min}(\tau) < \xi_{\max}(\tau), \beta_{\min}(\tau) < \beta_{\max}(\tau).$$

In that case the strong-field and cosmology windows remain separately alive, but the bridge law is too steep, too incompatible, or too compressive to allow a common FCLET continuation branch.

This is one of the strongest results of Article 89. It proves that global viability is stronger than reduced compatibility. A theory can remain reduced-compatible and still fail globally through incompatible coupling.

7.8 Critical Bridge Slope

At the benchmark epoch, the critical linear bridge slope separating full-width survival from bridge-compressed survival is determined by

$$\frac{0.239}{|\,\lambda_{\mathrm{crit}}\,|} = 0.500.$$

Hence

$$|\,\lambda_{\mathrm{crit}}\,| = \frac{0.239}{0.500} = 0.478.$$

This number carries immediate meaning.

If

$$|\lambda| \leq 0.478,$$

the benchmark one-parameter corridor occupies the full strong-field width:

$$L_{\text{true}}(\tau_0; \lambda) = 0.500.$$

If

$$|\lambda| > 0.478,$$

the cosmology bridge compresses the true corridor:

$$L_{\text{true}}(\tau_0; \lambda) = \frac{0.239}{|\lambda|} < 0.500.$$

Thus $|\lambda| = 0.478$ is the benchmark true-bridge compression threshold.

7.9 True Global Falsification Ladder

The one-parameter problem admits a richer negative-outcome structure than the reduced problem. The correct ladder is the following.

Level I: benchmark death

The benchmark point is expelled:

$$R_{\text{true}}^{\text{bench}}(\tau) < 0.$$

Level II: true-corridor contraction

The one-parameter corridor survives but narrows:

$$0 < K_{\text{true}}(\tau) < 1.$$

Level III: bridge-slope-induced collapse

The reduced windows remain separately nonempty, but

$$L_{\text{true}}(\tau; \lambda) = 0.$$

This is true global death by incompatible coupling.

Level IV: full reduced-plus-true fracture

The coupled corridor is gone and the reduced compatibility structure is gone as well:

$$S_{\mathrm{global}}(\tau) = \emptyset, S^{\mathrm{red}}_{\mathrm{global}}(\tau) = \emptyset.$$

This is the strongest possible death state of the benchmark program.

This ladder is stronger than the reduced falsification ladder because it detects failure by coupling incompatibility rather than only by separate-window contraction.

7.10 True Global Contraction Theorem

The results of the section can now be stated in theorem form.

Theorem 7 (True Global Contraction Theorem).
Let the one-parameter FCLET bridge be given by a continuous benchmark-anchored law $\beta_S(\xi)$, and let the true global corridor be

$$S_{\mathrm{global}}(\tau) = [\xi_{\min}(\tau), \xi_{\max}(\tau)] \cap \{\xi : \beta_S(\xi) \in [\beta_{\min}(\tau), \beta_{\max}(\tau)]\}.$$

Let its benchmark length be $L_{\mathrm{true}}(\tau_0) > 0$. Then the true one-parameter contraction is exactly measured by

$$K_{\mathrm{true}}(\tau) = 1 - \frac{L_{\mathrm{true}}(\tau)}{L_{\mathrm{true}}(\tau_0)}.$$

For the linear benchmark bridge family

$$\beta_S^{(1)}(\xi; \lambda) = 1 + \lambda(\xi - 0.300),$$

the corridor length is

$$L_{\mathrm{true}}(\tau; \lambda) = \max\left(0, \min\{\xi_{\max}(\tau), \xi^{+}_{\cos}(\tau; \lambda)\} - \max\{\xi_{\min}(\tau), \xi^{-}_{\cos}(\tau; \lambda)\}\right),$$

and the benchmark bridge-compression threshold is

$$| \lambda_{\mathrm{crit}} | = 0.478.$$

Hence the true one-parameter FCLET corridor can fail in two distinct ways:

by ordinary observational contraction of the window intervals,

by bridge-slope incompatibility even when the reduced intervals remain separately nonempty.

7.11 What Section 7 Achieves

Sections 2–5 completed the reduced global program.
Section 6 introduced the true one-parameter bridge and proved nonempty coupled survival.
The present section now turns that true one-parameter set into a dynamical viability object.

It introduces:

the true corridor length $L_{\mathrm{true}}(\tau)$,

the true contraction functional $K_{\mathrm{true}}(\tau)$,

the coupled benchmark robustness functional $R_{\mathrm{true}}^{\mathrm{bench}}(\tau)$,

the bridge-slope compression factor $\mathcal{B}_{\lambda}$,

and the new global failure mode of bridge-slope falsification.

This completes the mathematical transition from reduced compatibility to genuine coupled viability dynamics.

The benchmark FCLET program is therefore now equipped with two distinct global contraction theories:

a reduced contraction theory, measuring joint benchmark-area survival in (ξ, β_S) space,

a true contraction theory, measuring the survival of the actual one-parameter FCLET continuation law.

The second is stronger, and it is the one that matters for genuine global viability.

The only remaining task is to synthesize the full meaning of the paper. The next section therefore closes Article 89 by showing exactly what has been established: FCLET is not merely reduced-compatible, but globally viable at the first continuous one-parameter coupling level.

8. Conclusion — From Reduced Nontrivial Survival to True One-Parameter Global Viability

The purpose of Article 89 was not to introduce a new observational branch, a new effective field, or a new formal sector into the FCLET program. Its purpose was more exact and more demanding. Once the strong-field shell benchmark, the detector-facing identifiability corridor, the locked confrontation architecture, the cosmological tensor corridor, the microstate closure, and the multi-messenger judgment framework had already been constructed, one decisive quantitative question remained:

Do the strong-field and cosmological benchmark branches admit a genuine common survival structure?

This paper was written to answer that question, and it now has.

The first result of the paper is that the answer is positive at reduced level. The strong-field benchmark corridor and the cosmological benchmark corridor were placed into one reduced survival geometry,

$$S_{\mathrm{global}}^{\mathrm{red}} = S_{\mathrm{sf}}^{\xi} \times S_{\mathrm{cos}}^{\beta},$$

and this reduced set was shown to be nonempty:

$$S_{\mathrm{global}}^{\mathrm{red}} \neq \emptyset.$$

This was already a significant result. It established that the benchmark detector-facing shell branch and the benchmark cosmological tensor branch are not numerically inconsistent as soon as they are written side by side in one explicit admissibility framework. More importantly, the reduced global set was shown to be physically nontrivial. In the strong-field sector, the surviving branch retains a genuinely non-null detector-facing spectral deformation range. In the cosmology sector, the surviving branch retains a genuinely non-inert tensor sector. Thus the reduced survival result is not a hollow compatibility statement. It is a nontrivial compatibility statement.

The second result of the paper is that reduced compatibility can be turned into an exact contraction problem. The area-normalized functional

$$K(\tau) = 1 - \frac{A(\tau)}{A_0}$$

was introduced to measure how the reduced corridor shrinks under future pressure. This transformed the problem from a static compatibility question into a time-dependent viability problem. It also revealed the first crucial asymmetry of the benchmark geometry. The benchmark point survives at reduced level, but it does not survive symmetrically. In the cosmology direction it is interior-supported. In the strong-field direction it lies exactly on the lower admissible boundary. The benchmark corridor is therefore alive, but it is not equally robust in all directions. This is a precise and meaningful result: it identifies the first likely source of benchmark-level pressure before any full global collapse occurs.

The third result is that reduced survival and reduced death are not binary opposites with no internal structure. Article 89 has established a full reduced falsification ladder. The benchmark point can die while the reduced corridor still survives. The reduced corridor can survive while losing substantive physical content. And only after that does one reach full reduced fracture. These distinctions matter. They prevent the global viability problem from collapsing into one vague language of “tension” or “failure.” The paper therefore gives the benchmark FCLET program a genuine survival grammar and a genuine death grammar already at the reduced level.

But reduced compatibility is not the final goal of Article 89. It is only the correct starting point. A theory can survive in reduced product form without yet possessing a true coupled continuation law. The decisive advance of the paper therefore comes in the transition from reduced compatibility to a true one-parameter bridge.

That bridge is defined by

$$\beta_S = \beta_S(\xi),$$

subject to the minimal physically meaningful conditions of continuity and benchmark anchoring:

$$\beta_S(0.300) = 1.$$

Once this law is introduced, the FCLET global problem ceases to be a Cartesian product of independent reduced coordinates and becomes a true one-parameter survival problem:

$$S_{\text{global}} = \left\{\xi : \xi \in S_{\text{sf}}^{\xi},\, \beta_S(\xi) \in S_{\cos}^{\beta}\right\}.$$

This is the central mathematical step of the paper. It upgrades the program from coexistence of two reduced corridors to survival of one continuous admissible continuation law.

The decisive theorem then follows. Under continuity and benchmark anchoring, the true one-parameter global set is nonempty. The benchmark does not survive merely as an isolated reduced coincidence. It survives as the endpoint of a genuine one-parameter continuation corridor. This is stronger than reduced nontrivial survival. It is the first explicit proof that the benchmark FCLET construction is globally viable at a continuous coupling level.

That result alone would already justify the paper. But the paper goes further. Once the true one-parameter corridor is written, it too becomes a contraction problem. The correct coupled contraction functional is

$$K_{\text{true}}(\tau) = 1 - \frac{L_{\text{true}}(\tau)}{L_{\text{true}}(\tau_0)}.$$

This is not merely the one-dimensional analogue of the reduced area contraction. It is the contraction law of the actual coupled FCLET continuation branch. The theory is no longer judged by how much of a rectangular reduced compatibility region survives. It is judged by how much of its true one-parameter corridor survives.

At this point, a new failure mode appears that the reduced problem could never detect: bridge-slope falsification. The strong-field and cosmological windows may remain separately nonempty, and yet no single one-parameter continuation law may survive both simultaneously. In the linear benchmark bridge family

$$\beta_S^{(1)}(\xi;\lambda) = 1 + \lambda(\xi - 0.300),$$

the true corridor length becomes explicitly calculable, and the benchmark compression threshold is

$$|\ \lambda_{\mathrm{crit}}\ | = 0.478.$$

Below this threshold, the bridge does not compress the benchmark corridor below the full strong-field width. Above it, the bridge itself becomes a source of contraction. In the singular steep-slope limit, the one-parameter corridor becomes self-destructive. This is a genuinely global result. It shows that global viability depends not only on separate window survival, but on the geometry of the coupling law itself.

This is one of the strongest conclusions of Article 89. It demonstrates that FCLET can now be judged in three progressively stronger senses:

reduced compatibility,

reduced nontrivial survival with contraction dynamics,

true one-parameter global viability with bridge-slope falsification criteria.

These are not three different papers pretending to say the same thing. They are three nested levels of global mathematical maturity, and Article 89 traverses all three.

The full logic of the paper can therefore be written as one theorem chain:

reduced compatibility ⟶ reduced nontrivial survival ⟶ reduced contraction dynamics
⟶ reduced falsification ladder ⟶ true bridge construction
⟶ true one-parameter survival ⟶ true contraction dynamics
⟶ bridge-slope falsification.

This is not an organizational summary for convenience. It is the actual mathematical architecture of the paper.

The scientific meaning of Article 89 is therefore exact.

The paper does **not** claim that the full FCLET program has already passed final empirical judgment across every future messenger window. That would be a different and later achievement. What Article 89 proves is more precise and foundational: the benchmark detector-facing strong-field branch and the benchmark cosmological tensor branch admit both a reduced nontrivial survival region and a genuinely coupled one-parameter global continuation corridor. The benchmark FCLET program is therefore not merely branch-wise admissible. It is quantitatively globally viable at the first nontrivial coupling level.

That is exactly what this paper needed to establish.

Final Viability Theorem

Theorem 8 (From Reduced Nontrivial Survival to True One-Parameter Global Viability).
Let the benchmark reduced FCLET corridors be

$$S_{\mathrm{sf}}^{\xi} = [0.300,0.800], S_{\cos}^{\beta} = [0.761,1.239],$$

and let the benchmark point be

$$(\xi_{\mathrm{bench}}, \beta_{S,\mathrm{bench}}) = (0.300,1.000).$$

Suppose the bridge law $\beta_S(\xi)$ is continuous and benchmark-anchored:

$$\beta_S(0.300) = 1.$$

Then the following hold:

the reduced global corridor is nonempty and physically nontrivial:

$$S_{\mathrm{global}}^{\mathrm{red}} \neq \emptyset;$$

the reduced benchmark branch admits explicit contraction and falsification structures through

$$K(\tau), R_{\mathrm{bench}}(\tau);$$

the true one-parameter global set

$$S_{\mathrm{global}} = \{\xi : \xi \in S_{\mathrm{sf}}^{\xi}, \beta_S(\xi) \in S_{\cos}^{\beta}\}$$

is nonempty and contains a one-sided neighborhood of the benchmark point;

the true one-parameter benchmark branch admits explicit coupled contraction and falsification structures through

$$K_{\mathrm{true}}(\tau), R_{\mathrm{true}}^{\mathrm{bench}}(\tau),$$

together with the genuinely global failure mode of bridge-slope collapse.

Hence the benchmark FCLET program is not merely reduced-compatible. It is globally viable at the first continuous one-parameter coupling level.

Appendix A. Reduced Survival Geometry and Benchmark Measure

The reduced FCLET global viability problem is defined on the Cartesian benchmark corridor

$$S_{\mathrm{global}}^{\mathrm{red}} = S_{\mathrm{sf}}^{\xi} \times S_{\cos}^{\beta},$$

with

$$S_{\mathrm{sf}}^{\xi} = [0.300,0.800], S_{\cos}^{\beta} = [0.761,1.239].$$

The reduced benchmark point is

$$(\xi_{\mathrm{bench}}, \beta_{S,\mathrm{bench}}) = (0.300,1.000).$$

The reduced benchmark area is

$$A_0 = (0.800 - 0.300)(1.239 - 0.761) = 0.500 \times 0.478 = 0.239.$$

This is the benchmark normalization scale for the reduced global viability problem. It measures the size of the admissible benchmark product corridor before any later contraction is imposed.

The directional benchmark margins are

$$m_{\xi}^{-} = \xi_{\mathrm{bench}} - \xi_{\min}, m_{\xi}^{+} = \xi_{\max} - \xi_{\mathrm{bench}},$$
$$m_{\beta}^{-} = \beta_{S,\mathrm{bench}} - \beta_{\min}, m_{\beta}^{+} = \beta_{\max} - \beta_{S,\mathrm{bench}}.$$

At the benchmark epoch,

$$m_{\xi}^{-} = 0, m_{\xi}^{+} = 0.500,$$
$$m_{\beta}^{-} = 0.239, m_{\beta}^{+} = 0.239.$$

This shows that the benchmark corridor is asymmetric. The cosmology benchmark is interior-supported, while the strong-field benchmark is boundary-supported on the lower ξ-edge.

The reduced nontriviality conditions are encoded by the survival of both a non-null strong-field deformation sector and a non-inert cosmological tensor sector:

$$\frac{\delta \mathrm{Re}\,\omega}{\mathrm{Re}\,\omega} \in [+2.6\%, +6.9\%],$$
$$\Delta n_T \approx -0.035, r_{\mathrm{FCLET}} \in [0.007,0.020].$$

Thus the reduced corridor is not only nonempty, but physically nontrivial in both observational directions.

Appendix B. Reduced Contraction, Benchmark Robustness, and Forecast Dynamics

At observational epoch τ, define the evolving reduced intervals

$$S_{\mathrm{sf}}(\tau) = [\xi_{\min}(\tau), \xi_{\max}(\tau)], S_{\cos}(\tau) = [\beta_{\min}(\tau), \beta_{\max}(\tau)].$$

The reduced global area is

$$A(\tau) = [\xi_{\max}(\tau) - \xi_{\min}(\tau)][\beta_{\max}(\tau) - \beta_{\min}(\tau)].$$

The reduced contraction functional is

$$K(\tau) = 1 - \frac{A(\tau)}{A_0}.$$

The directional contractions are

$$K_{\mathrm{sf}}(\tau) = 1 - \frac{\xi_{\max}(\tau) - \xi_{\min}(\tau)}{0.500},$$
$$K_{\cos}(\tau) = 1 - \frac{\beta_{\max}(\tau) - \beta_{\min}(\tau)}{0.478}.$$

These satisfy

$$K(\tau) = K_{\mathrm{sf}}(\tau) + K_{\cos}(\tau) - K_{\mathrm{sf}}(\tau)K_{\cos}(\tau).$$

The benchmark robustness functional is

$$R_{\mathrm{bench}}(\tau) = \min\{0.300 - \xi_{\min}(\tau), \xi_{\max}(\tau) - 0.300, 1 - \beta_{\min}(\tau), \beta_{\max}(\tau) - 1\}.$$

Its interpretation is exact:

$R_{\mathrm{bench}}(\tau) > 0$: interior-supported benchmark survival,

$R_{\mathrm{bench}}(\tau) = 0$: boundary-supported benchmark survival,

$R_{\mathrm{bench}}(\tau) < 0$: benchmark death.

The reduced contraction trajectory is therefore

$$\tau \mapsto (K_{\mathrm{sf}}(\tau), K_{\cos}(\tau), K(\tau), R_{\mathrm{bench}}(\tau)).$$

This quadruple gives the full reduced forecast dynamics of the benchmark FCLET corridor.

Appendix C. Reduced Falsification Ladder

The reduced FCLET benchmark program admits four distinct negative outcomes.

C.1 Strong-field benchmark death

The strong-field benchmark dies as soon as

$$\xi_{\min}(\tau) > 0.300 \text{or} \xi_{\max}(\tau) < 0.300.$$

The first condition is the expected early-pressure channel because the benchmark currently sits on the lower strong-field boundary.

C.2 Cosmology benchmark death

The cosmology benchmark dies if

$$\beta_{\min}(\tau) > 1.000 \text{or} \beta_{\max}(\tau) < 1.000.$$

Because the benchmark cosmology point is currently interior-supported, this requires stronger contraction than the strong-field benchmark death route.

C.3 Reduced retreat

Reduced retreat occurs when the reduced corridor remains formally nonempty,

$$S^{\text{red}}_{\text{global}}(\tau) \neq \emptyset,$$

but loses nontrivial physical content:

$$N_{\text{red}}(\tau) = 0.$$

This is weaker than full reduced fracture, but stronger than benign contraction. The reduced corridor survives only by becoming physically inert.

C.4 Full reduced fracture

Full reduced fracture occurs when

$$S^{\text{red}}_{\text{global}}(\tau) = \emptyset,$$

equivalently,

$$A(\tau) = 0 \Leftrightarrow K(\tau) = 1.$$

This is the strongest reduced-level death state.

The reduced falsification hierarchy is therefore

$$\text{benchmark death} \prec \text{reduced retreat} \prec \text{full reduced fracture}.$$

Within benchmark death itself, the present geometry implies the likely temporal ordering

$$\text{strong-field benchmark death} \prec \text{cosmology benchmark death}.$$

Appendix D. True Bridge Construction and One-Parameter Global Set

The true coupled FCLET problem is obtained by introducing a bridge law

$$\beta_S = \beta_S(\xi),$$

subject to continuity and benchmark anchoring:

$$\beta_S(0.300) = 1.$$

The true one-parameter global set is

$$S_{\text{global}} = \{\xi \in [0.300,0.800]: \beta_S(\xi) \in [0.761,1.239]\}.$$

The minimal benchmark bridge family is the linear family

$$\beta_S^{(1)}(\xi;\lambda) = 1 + \lambda(\xi - 0.300),$$

where λ is the bridge-slope parameter.

For this family, the benchmark one-parameter corridor is

$$S_{\text{global}}^{(1)}(\lambda) = \left[0.300, \min\left(0.800, 0.300 + \frac{0.239}{|\lambda|}\right)\right]$$

for $\lambda \neq 0$, while

$$S_{\text{global}}^{(1)}(0) = [0.300,0.800].$$

Hence the true corridor length is

$$L(\lambda) = \mu(S_{\text{global}}^{(1)}(\lambda)) = \min\left(0.500, \frac{0.239}{|\lambda|}\right).$$

This yields the bridge regimes:

weak-slope regime

$$|\lambda| \leq 0.478 \Longrightarrow L(\lambda) = 0.500,$$

bridge-compressed regime

$$|\lambda| > 0.478 \Longrightarrow L(\lambda) = \frac{0.239}{|\lambda|} < 0.500,$$

singular steep-slope limit

$$|\lambda| \to \infty \Longrightarrow L(\lambda) \to 0.$$

Thus the bridge law is itself a genuine global viability object rather than a passive reparametrization.

Appendix E. True Global Contraction and Bridge-Slope Falsification

Given the epoch-dependent strong-field interval

$$[\xi_{\min}(\tau), \xi_{\max}(\tau)]$$

and cosmology interval

$$[\beta_{\min}(\tau), \beta_{\max}(\tau)],$$

the true one-parameter corridor is

$$S_{\text{global}}(\tau) = [\xi_{\min}(\tau), \xi_{\max}(\tau)] \cap \{\xi : \beta_S(\xi) \in [\beta_{\min}(\tau), \beta_{\max}(\tau)]\}.$$

Its measure is

$$L_{\text{true}}(\tau) = \mu(S_{\text{global}}(\tau)).$$

The true contraction functional is

$$K_{\text{true}}(\tau) = 1 - \frac{L_{\text{true}}(\tau)}{L_{\text{true}}(\tau_0)}.$$

For the linear benchmark bridge family,

$$\beta_S^{(1)}(\xi;\lambda) = 1 + \lambda(\xi - 0.300),$$

define

$$\xi_{\cos}^{-}(\tau;\lambda) = \min\left\{0.300 + \frac{\beta_{\min}(\tau) - 1}{\lambda}, 0.300 + \frac{\beta_{\max}(\tau) - 1}{\lambda}\right\},$$
$$\xi_{\cos}^{+}(\tau;\lambda) = \max\left\{0.300 + \frac{\beta_{\min}(\tau) - 1}{\lambda}, 0.300 + \frac{\beta_{\max}(\tau) - 1}{\lambda}\right\}.$$

Then

$$L_{\text{true}}(\tau;\lambda) = \max\left(0, \min\{\xi_{\max}(\tau), \xi_{\cos}^{+}(\tau;\lambda)\} - \max\{\xi_{\min}(\tau), \xi_{\cos}^{-}(\tau;\lambda)\}\right).$$

The true benchmark robustness functional is

$$R_{\text{true}}^{\text{bench}}(\tau) = \min\{0.300 - \xi_{\min}(\tau), \xi_{\max}(\tau) - 0.300, 1 - \beta_{\min}(\tau), \beta_{\max}(\tau) - 1\}.$$

A new global failure mode appears at this stage:

E.1 Bridge-slope falsification

Bridge-slope falsification occurs if

$$L_{\text{true}}(\tau;\lambda) = 0$$

even though the reduced intervals remain separately nonempty:

$$\xi_{\min}(\tau) < \xi_{\max}(\tau), \beta_{\min}(\tau) < \beta_{\max}(\tau).$$

This is a genuinely coupled death mode. It means the strong-field and cosmology windows remain separately alive, but no single one-parameter continuation law survives both simultaneously.

E.2 True global falsification ladder

The coupled problem therefore admits the following ladder:

benchmark death

$$R_{\text{true}}^{\text{bench}}(\tau) < 0,$$

true-corridor contraction

$$0 < K_{\text{true}}(\tau) < 1,$$

bridge-slope-induced collapse

$$L_{\text{true}}(\tau;\lambda) = 0 \text{with reduced intervals still nonempty,}$$

full reduced-plus-true fracture

$$S_{\text{global}}(\tau) = \emptyset, S^{\text{red}}_{\text{global}}(\tau) = \emptyset.$$

This appendix completes the global viability grammar of Article 89 by adding the exact coupled failure mode that cannot be detected at reduced level.

Modified Background Expansion, Sound-Horizon Transport, and the Hubble-Tension Interface in the Finite-Capacity Latency–Erasure Theory

From Saturation-Weighted Early-Universe Transport and Effective Acoustic-Horizon Renormalization to a Quantitative FCLET Prediction for $H(z)$, r_s, and the Inferred Hubble Scale

Article 90

Abstract

We construct the first explicit Hubble-sector interface of the finite-capacity latency–erasure theory by deriving its modified background expansion and early-universe sound-horizon transport structure in a form suitable for quantitative confrontation with the Hubble tension. Earlier FCLET studies established the strong-field shell benchmark, detector-facing ringdown confrontation logic, the primordial tensor corridor, the shell–cosmology bridge, the microstate completion of the burden–latency–overwrite framework, and the first reduced and true global survival geometry linking strong-field and cosmological sectors. What remained absent was a closed background-level derivation of the Hubble interface itself. In particular, the program already possessed a viable tensor-sector mechanism and a plausible transport-channel route through which finite-capacity saturation can renormalize the sound horizon, but it did not yet possess a full FCLET background equation for $H(z)$, nor a quantitative derivation of how that modification propagates into the inferred late-time Hubble scale. The present article provides that derivation.

The paper proceeds in three stages. First, we derive the effective FCLET background equation by introducing a saturation-weighted correction to the homogeneous cosmological evolution law, expressed through the finite-capacity load variable and its associated latency functional. Second, we derive the acoustic transport sector and show how a finite-capacity correction to the pre-recombination sound speed modifies the sound horizon,

$$r_s^{\mathrm{FCLET}} = \int_{z_*}^{\infty} \frac{c_s^{\mathrm{FCLET}}(z)}{H_{\mathrm{FCLET}}(z)}\, dz,$$

thereby shifting the CMB-inferred Hubble scale even when the late-time expansion history remains near standard form. Third, we combine the background and transport sectors to obtain a quantitative FCLET mapping

$$\{I(z), \chi(z), \alpha_\chi, \beta_S\} \longrightarrow \{H(z), r_s, D_A(z), H_0^{\inf}\},$$

and identify the parameter region in which the theory can reduce the sound horizon enough to move the inferred Hubble scale upward without destroying the cosmological corridor already established in Article 89.

The result is not a loose qualitative claim that FCLET may influence the Hubble tension. It is the first closed Hubble-interface derivation of the program. The paper distinguishes sharply between two mechanisms: genuine background modification through the FCLET effective Friedmann sector, and transport-only renormalization through the pre-recombination sound speed. This distinction is decisive because the theory need not solve the Hubble tension by a brute-force late-time expansion anomaly. It may instead act by a controlled early-universe saturation correction that leaves the tensor corridor and the global viability map intact. The outcome of the article is therefore a quantitative FCLET prediction for whether the theory merely relaxes the Hubble tension or can genuinely shift the inferred H_0 into the local-measurement range.

Keywords: modified background expansion; sound-horizon transport; Hubble tension; cosmological background dynamics; distance ladder interface; early-time transport; late-time expansion history; bridge cosmology; CMB–BAO consistency; expansion-rate shift; FCLET cosmology; tension diagnostics

1. Introduction: Why the Hubble Interface Must Now Be Closed

The finite-capacity latency–erasure theory has already reached a stage at which broad theoretical architecture alone is no longer sufficient. The program now contains a strong-field sector with explicit detector-facing shell benchmarks, a locked event-level confrontation protocol for compact-binary merger data, a cosmological tensor sector with a nontrivial primordial saturation corridor, a microstate completion of the burden–latency–overwrite hierarchy, and a first quantitative global-survival analysis linking strong-field and cosmological benchmark branches through reduced and true one-parameter viability structures. At that level of maturity, a new standard becomes unavoidable. The theory must no longer be judged only by whether it can generate interesting sectors. It must also be judged by whether those sectors close the major observational interfaces that a serious gravitational program is expected to confront.

One such interface remains structurally incomplete: the Hubble sector.

This incompleteness must be stated with precision. The FCLET program already possesses two fully derived observational arenas. The first is the strong-field ringdown sector, where Articles 83–85 produced explicit benchmark shell structure, detector-facing waveform logic,

locked confrontation rules, and a characteristic real-frequency displacement at benchmark level. The second is the primordial tensor and relic-background sector, where Article 86 derived a nontrivial tensor saturation structure, a scalar–tensor closure relation, and a benchmark tensor-tilt correction capable of feeding directly into pulsar-timing and large-scale tensor observables. These two arenas are real. They are not rhetorical placeholders. They contain explicitly derived quantitative content.

The Hubble interface does not yet stand at that same level.

That is the exact reason this paper is necessary.

At present, the FCLET program already contains a plausible route by which finite-capacity saturation can affect the inferred Hubble scale. The key idea is straightforward. If finite-capacity saturation modifies the effective pre-recombination propagation properties of the baryon–photon medium, then the acoustic sound horizon can be renormalized. If the sound horizon is reduced while the late-time angular structure remains appropriately controlled, then the CMB-inferred value of the Hubble constant shifts upward. In conceptual terms, the theory already has a direction of influence. What it has not yet had is a closed background-level derivation of that direction. In particular, the program has not yet provided a full FCLET background expansion equation for $H(z)$, nor has it fully separated the two mechanisms that must be distinguished if the Hubble interface is to become scientifically serious:

genuine background modification, in which finite-capacity saturation changes the homogeneous cosmological expansion law itself, and

transport-only renormalization, in which the dominant effect appears through pre-recombination acoustic propagation and the effective sound horizon rather than through a large late-time deformation of the background.

This distinction is decisive.

A theory may influence the Hubble sector in more than one way. It may alter the entire background evolution. It may alter only the acoustic transport sector. Or it may do both in a controlled mixed form. Without separating these possibilities, the Hubble interface remains conceptually blurred and mathematically incomplete. A serious cosmological paper cannot afford such ambiguity. If the FCLET program is to claim a real Hubble-sector prediction, it must state explicitly which channel is responsible, how that channel enters the equations, and whether the resulting shift in the inferred Hubble scale remains compatible with the cosmological corridor already established in the tensor sector and the global-survival geometry already established in Article 89.

This paper is written to provide exactly that closure.

The need for such a paper is sharpened by a broader methodological issue. It is tempting, once a theory possesses several interesting observational directions, to summarize them as if they already stand on equal derivational footing. That temptation must be resisted. A gravitational theory is not strengthened by speaking as though every arena is already fully derived when it is not. General relativity became historically decisive not because it gestured toward many

phenomena, but because it produced explicit, quantitative, and falsifiable predictions. The FCLET program must be held to the same internal standard. It is therefore scientifically healthier to say that the Hubble interface is unfinished and to finish it properly than to overstate what has already been derived.

The present article is the paper in which that unfinished interface is closed.

Its scientific role is exact. It does not reopen the strong-field shell benchmark. It does not rebuild the primordial tensor corridor. It does not replace the microstate completion. It does not supersede the global-survival geometry. Instead, it does the one thing still missing between those achievements and a broader four-arena observational posture: it derives the effective FCLET background equation and the corresponding pre-recombination transport correction in a form that allows a quantitative prediction for

$$H(z), r_s, D_A(z_*), H_0^{\mathrm{inf}}.$$

That is the central task of the paper.

The first conceptual move is to treat the homogeneous cosmological sector as a genuine FCLET dynamical interface rather than as a passive backdrop inherited from standard cosmology. If the finite-capacity framework is physically real, then the same burden fraction, latency structure, and overwrite hierarchy that govern strong-field saturation and primordial tensor evolution must also leave a controlled imprint on the homogeneous cosmological background. This does not mean that the late-time expansion law must deviate wildly from ΛCDM. On the contrary, a viable theory may require that the background remain very close to standard form at low load. But "close to standard form" is not the same as "identical to standard form," and the Hubble interface is precisely where even small early-universe deviations can matter. The first task of the paper is therefore to derive an effective FCLET background expansion law in which the homogeneous sector is written explicitly in terms of finite-capacity variables rather than treated as an unmodified external input.

The second conceptual move is to recognize that the Hubble problem is not purely a background problem. In the standard cosmological inference chain, the inferred value of H_0 is not extracted independently of early-universe transport. It is tied to the acoustic horizon. Therefore an FCLET modification may act not only through

$$H_{\mathrm{FCLET}}(z),$$

but also through

$$c_s^{\mathrm{FCLET}}(z),$$

the effective pre-recombination sound speed of the baryon–photon medium once finite-capacity saturation and latency effects are taken into account. This is the transport channel. It is the minimal route by which the theory can renormalize the sound horizon without requiring

a dramatic late-time expansion anomaly. That route is already conceptually visible in the program, but not yet mathematically closed. This paper closes it.

The third conceptual move is to combine the two channels rather than confuse them. A theory may have a small background correction and a moderate transport correction. It may have a dominant transport correction with negligible background shift. Or it may have a mixed branch in which both act together. These branches are not equivalent, and they do not carry the same empirical consequences. A transport-dominated mechanism may reduce the sound horizon while preserving near-standard late-time expansion. A background-dominated mechanism may shift the expansion history more directly but risk conflict with existing cosmological corridor constraints. A mixed branch may provide the most realistic compromise. The present article therefore treats background modification and acoustic transport as distinct FCLET sectors, derives them separately, and then recombines them in a controlled Hubble-interface map.

This leads directly to the paper's central quantitative question:

Can FCLET shift the inferred Hubble scale upward without destroying the cosmological corridor already established by the program?

That is the right question. It is more precise than asking whether the theory "addresses the Hubble tension." Many theories can influence H_0 in some direction. What matters is whether they do so quantitatively, through a derivable mechanism, and without breaking the rest of their own architecture. In the FCLET case, this means that any successful Hubble-sector shift must remain compatible with the saturation corridor already built into the tensor sector and the global viability structure already formalized in Article 89. A mechanism that raises the inferred Hubble scale only by leaving the established FCLET corridor is not a success. It is a branch conflict. The Hubble interface must therefore be corridor-preserving, not merely shift-producing.

This is what makes Article 90 scientifically harder than a loose cosmological note. It is not enough to derive a modified sound horizon. One must show how the derivation sits inside the already existing FCLET structure.

The paper is organized exactly around this problem.

Section 2 derives the effective homogeneous FCLET background equation and identifies how the burden fraction and latency functional enter the cosmological expansion law. Section 3 derives the pre-recombination transport correction and the FCLET modification of the acoustic sound speed, producing the corresponding renormalized sound-horizon integral. Section 4 translates this renormalization into a shift of the inferred Hubble scale by following the chain from r_s to the angular acoustic scale and the late-time inference of H_0. Section 5 then separates background-driven, transport-driven, and mixed FCLET branches so that the source of any Hubble-sector shift is not left ambiguous. Section 6 identifies the quantitative FCLET parameter window in which the theory either leaves the tension essentially untouched, partially relaxes it, or pushes the inferred Hubble scale into the local-measurement region. Section 7 checks compatibility with the tensor corridor of Article 86 and the global-survival

geometry of Article 89. Section 8 states the falsification criteria of the Hubble interface and closes the paper with a final verdict on whether FCLET fully resolves, partially relieves, or fails to resolve the Hubble tension without violating its own late-stage benchmark corridor.

This structure reflects the exact scientific role of the article.

The paper does not begin by assuming that FCLET solves the Hubble tension. It begins by deriving the Hubble interface from the theory's own finite-capacity architecture. It then asks what the theory actually predicts. This is the only intellectually serious route forward. If the derived FCLET background-and-transport system shifts the inferred Hubble scale enough while remaining corridor-safe, the program gains a third fully derived observational arena. If it shifts H_0 only partially, then the theory still acquires a quantified Hubble-relief branch, which is already a real result. If the required shift can be achieved only by leaving the already established cosmological corridor, then that branch is ruled out and the paper must say so. Any of these outcomes would be scientifically meaningful. What is no longer acceptable is to leave the Hubble interface in an intermediate conceptual state.

That is why Article 90 is necessary, and that is what it is written to do.

The paper therefore stands at a specific threshold in the FCLET program. Before it, one could say only that finite-capacity saturation plausibly modifies early-universe transport and may therefore influence the inferred Hubble scale. After it, one should be able to say something much stronger and much more exact: the theory predicts a specific class of background and transport modifications, shifts the acoustic horizon by a calculable amount, and therefore moves the inferred Hubble scale by a quantified corridor-compatible amount—or fails to do so.

That is the standard this article adopts.

And that is the standard it will meet.

2. Homogeneous FCLET Cosmology and the Effective Background Equation

A serious Hubble-sector interface cannot be built from transport arguments alone. If the finite-capacity latency–erasure theory is to confront the Hubble tension at a quantitative level, it must first supply a homogeneous cosmological closure: an explicit background equation for the expansion rate, an explicit definition of the finite-capacity load variable in the homogeneous sector, and an explicit identification of the effective source terms that distinguish the FCLET background from standard ΛCDM. That is the task of the present section.

The derivation proceeds in three steps. First, the homogeneous FRW sector is written as the cosmological reduction of the FCLET source hierarchy. Second, the background burden fraction $I(z)$ and the associated latency functional $\chi(z) = \Upsilon(I(z))$ are defined in terms of a finite homogeneous capacity scale. Third, these quantities are assembled into an effective

modified background equation for $H(z)$, together with its associated acceleration law and effective equation-of-state description.

The result is not an arbitrary deformation of Friedmann cosmology. It is the homogeneous background closure of the same burden–latency framework that already governs the strong-field shell sector and the primordial tensor corridor.

2.1 FRW Reduction of the FCLET Source Hierarchy

We begin with the spatially flat homogeneous and isotropic line element

$$ds^2 = -dt^2 + a^2(t)\,\delta_{ij}dx^i dx^j, H \equiv \frac{\dot{a}}{a}.$$

The standard cosmological source content is

$$\rho_{\mathrm{std}}(z) = \rho_m(z) + \rho_r(z) + \rho_\Lambda,$$

with

$$\rho_m(z) = \rho_{m0}(1+z)^3, \rho_r(z) = \rho_{r0}(1+z)^4, \rho_\Lambda = \text{const.}$$

The central FCLET assumption is that homogeneous cosmology does not evolve on an infinitely slack substrate. It evolves on a finite-capacity background whose local and global load state can be described by a bounded burden fraction. The cosmological background is therefore not merely filled with matter and radiation. It is also characterized by how close its effective homogeneous information load is to a finite admissible capacity scale.

Let $\rho_\star$ denote the homogeneous FCLET capacity density scale. Then the correct homogeneous dimensionless load variable is taken to be

$$I(z) = \frac{\rho_{\mathrm{std}}(z)}{\rho_\star + \rho_{\mathrm{std}}(z)}.$$

This choice is exact in the sense required by the theory:

it guarantees

$$0 < I(z) < 1,$$

it grows monotonically with the standard background density,

it automatically approaches a low-load limit at late times,

and it enters a high-load regime in the early universe.

This is the homogeneous counterpart of the bounded load fraction already used elsewhere in the FCLET program.

The associated homogeneous latency variable is then defined by the same universal saturation functional used in the late program:

$$\chi(z) = \Upsilon(I(z)).$$

For the benchmark cosmological branch developed in the late FCLET sequence, the natural choice is the logarithmic saturation coordinate

$$\Upsilon(I) = -\ln(1 - I).$$

Substituting the homogeneous load definition yields the explicit background latency field

$$\chi(z) = -\ln\left(1 - \frac{\rho_{\mathrm{std}}(z)}{\rho_\star + \rho_{\mathrm{std}}(z)}\right) = \ln\left(1 + \frac{\rho_{\mathrm{std}}(z)}{\rho_\star}\right).$$

This expression is one of the key results of the section. It shows that the homogeneous FCLET background correction is not introduced as an ad hoc function of redshift. It is generated directly by the standard cosmological density through the finite-capacity load relation.

2.2 Effective Homogeneous FCLET Source Sector

The homogeneous FCLET correction must now be written as an effective source contribution to the background equations. The late-stage FCLET program already established that the cosmological sector is governed not only by latency loading but also by a moderated irreversible closure channel. At the homogeneous level, the corresponding two basic structures are:

- a latency-loading contribution driven by $\chi(z)$,
- a moderated overwrite contribution driven by a high-load but non-explosive saturation functional.

We therefore define the homogeneous FCLET source density as

$$\rho_{\mathrm{FCLET}}(z) = \rho_\star\left[\eta_\chi\, \mathcal{F}_\chi(I(z)) + \eta_{\mathrm{ov}}\, \mathcal{F}_{\mathrm{ov}}(I(z))\right],$$

where η_χ and η_{ov} are dimensionless sector weights, and where the two dimensionless structure functions are taken to be

$$\mathcal{F}_\chi(I) = \Upsilon(I) = -\ln(1 - I),$$
$$\mathcal{F}_{\mathrm{ov}}(I) = I(1 - I)e^{-\sigma I}.$$

The interpretation is exact.

The first term is the homogeneous latency burden. It measures how much cosmological loading is induced by finite-capacity saturation itself.

The second term is the homogeneous moderated overwrite sector. It activates in the high-load regime but is bounded and suppressed away from the saturation window. It is the homogeneous counterpart of the moderated erasure logic already used in the FCLET cosmology branch.

The total effective background density is therefore

$$\rho_{\mathrm{eff}}(z) = \rho_{\mathrm{std}}(z) + \rho_{\mathrm{FCLET}}(z).$$

This is the cosmological closure object from which the modified background equation follows.

2.3 The Effective FCLET Background Equation

The homogeneous FCLET background equation is now written in Friedmann form:

$$H^2_{\mathrm{FCLET}}(z) = \frac{8\pi G}{3}\,\rho_{\mathrm{eff}}(z).$$

Substituting the explicit effective density yields

$$H^2_{\mathrm{FCLET}}(z) = \frac{8\pi G}{3}\Big[\rho_m(z) + \rho_r(z) + \rho_\Lambda + \rho_\star\big(\eta_\chi\,\Upsilon(I(z)) + \eta_{\mathrm{ov}}\,I(z)(1-I(z))e^{-\sigma I(z)}\big)\Big].$$

Using the logarithmic homogeneous latency functional, this becomes

$$H^2_{\mathrm{FCLET}}(z) = \frac{8\pi G}{3}\Bigg[\rho_m(z) + \rho_r(z) + \rho_\Lambda + \rho_\star\left(\eta_\chi \ln\left(1+\frac{\rho_{\mathrm{std}}(z)}{\rho_\star}\right) + \eta_{\mathrm{ov}}\,I(z)(1-I(z))e^{-\sigma I(z)}\right)\Bigg].$$

This is the first closed FCLET background equation for the Hubble interface.

Its structure is precisely what the theory requires.

At low load,

$$\rho_{\mathrm{std}}(z) \ll \rho_\star, I(z) \ll 1,$$

so the correction sector is perturbatively small and ordinary background recovery is automatic.

At high load,

$$\rho_{\mathrm{std}}(z) \gtrsim \rho_{\star},$$

the latency and overwrite sectors become non-negligible, and the early-universe expansion law is modified in exactly the epoch in which the acoustic horizon is formed.

This is why the Hubble interface belongs naturally to FCLET. The theory alters the background most where the Hubble inference chain is most sensitive.

2.4 Effective Pressure and the Acceleration Equation

A background equation for H^2 is not yet enough. A full homogeneous closure also requires an effective pressure sector and therefore an acceleration equation.

Let

$$p_{\mathrm{std}}(z) = p_m(z) + p_r(z) + p_\Lambda = 0 + \frac{1}{3}\rho_r(z) - \rho_\Lambda.$$

Define the effective FCLET pressure $p_{\mathrm{FCLET}}(z)$ by homogeneous conservation of the FCLET source sector:

$$\dot{\rho}_{\mathrm{FCLET}} + 3H_{\mathrm{FCLET}}(\rho_{\mathrm{FCLET}} + p_{\mathrm{FCLET}}) = 0.$$

Equivalently, in redshift form,

$$p_{\mathrm{FCLET}}(z) = -\rho_{\mathrm{FCLET}}(z) + \frac{1+z}{3}\,\frac{d\rho_{\mathrm{FCLET}}}{dz}.$$

The total effective pressure is then

$$p_{\mathrm{eff}}(z) = p_{\mathrm{std}}(z) + p_{\mathrm{FCLET}}(z).$$

The homogeneous acceleration equation becomes

$$\dot{H}_{\mathrm{FCLET}}(z) = -4\pi G[\rho_{\mathrm{eff}}(z) + p_{\mathrm{eff}}(z)].$$

Equivalently,

$$\dot{H}_{\mathrm{FCLET}}(z) = -4\pi G\left[\rho_m(z) + \frac{4}{3}\rho_r(z) + \rho_{\mathrm{FCLET}}(z) + p_{\mathrm{FCLET}}(z)\right].$$

This yields the complete homogeneous FCLET background closure:

$$H^2_{\mathrm{FCLET}}(z), \dot{H}_{\mathrm{FCLET}}(z), \rho_{\mathrm{FCLET}}(z), p_{\mathrm{FCLET}}(z).$$

The Hubble interface now has a genuine background dynamics rather than only a heuristic transport idea.

2.5 Effective FCLET Equation of State

For later use it is convenient to define the effective FCLET homogeneous equation-of-state parameter

$$w_{\mathrm{FCLET}}(z) = \frac{p_{\mathrm{FCLET}}(z)}{\rho_{\mathrm{FCLET}}(z)}.$$

Using the conservation form above, this can be written as

$$w_{\mathrm{FCLET}}(z) = -1 + \frac{1+z}{3}\frac{d\ln \rho_{\mathrm{FCLET}}(z)}{dz}.$$

This object is not introduced for rhetorical analogy with dark energy parameterizations. It is introduced because the Hubble interface must distinguish clearly between:

sectors that modify the background mainly through an effective equation-of-state shift,

sectors that modify it mainly through early-universe transport,

and mixed sectors in which both act together.

The FCLET background equation is therefore not just a new $H(z)$ formula. It carries an explicit effective-fluid interpretation, which will be essential in the later decomposition between background-driven and transport-driven Hubble shifts.

2.6 Low-Load Recovery and Early-Universe Enhancement

A successful Hubble interface must do two things at once:

preserve approximate standard background evolution where the universe is low-load,

allow controlled early-universe modification where the acoustic horizon is set.

The present closure does both automatically.

In the low-load limit,

$$\rho_{\mathrm{std}}(z) \ll \rho_\star, I(z) \approx \frac{\rho_{\mathrm{std}}(z)}{\rho_\star},$$

and therefore

$$\Upsilon(I) = -\ln(1-I) \approx I \approx \frac{\rho_{\mathrm{std}}(z)}{\rho_\star}.$$

Similarly,

$$I(1-I)e^{-\sigma I} \approx I \approx \frac{\rho_{\mathrm{std}}(z)}{\rho_\star}.$$

Hence

$$\rho_{\mathrm{FCLET}}(z) \ll \rho_{\mathrm{std}}(z)$$

provided the sector weights remain perturbatively controlled. This gives late-time recovery.

By contrast, in the early high-load regime, the standard density approaches or exceeds the capacity scale:

$$\rho_{\mathrm{std}}(z) \gtrsim \rho_\star.$$

Then

$$I(z) \to \mathcal{O}(1), \chi(z) = \Upsilon(I(z)) \ll /1,$$

and the FCLET correction becomes dynamically relevant. This is precisely the epoch in which the sound horizon integral is accumulated.

The background closure is therefore naturally aligned with the Hubble-tension interface. The theory modifies the cosmological background most where early-universe inference is most sensitive, while recovering standard behavior where late-time expansion must remain near standard form.

2.7 Background-Only Branch, Transport-Only Branch, and Mixed Branch

The structure of the equation derived above already shows that the Hubble interface can be realized in three distinct ways.

Background-only branch

If the dominant effect of FCLET enters through

$$H_{\mathrm{FCLET}}(z) \neq H_{\Lambda\mathrm{CDM}}(z),$$

while the acoustic transport sector remains effectively standard, then the Hubble shift is background-driven.

Transport-only branch

If the background correction remains small but the pre-recombination propagation sector is modified, then the dominant Hubble shift comes through the sound horizon:

$$c_s^{\mathrm{FCLET}}(z) \neq c_s^{\mathrm{std}}(z), H_{\mathrm{FCLET}}(z) \approx H_{\Lambda\mathrm{CDM}}(z).$$

Mixed branch

If both the homogeneous expansion and the acoustic transport are modified in a controlled way, then the Hubble shift is jointly sourced:

$$H_{\mathrm{FCLET}}(z) \neq H_{\Lambda\mathrm{CDM}}(z), c_s^{\mathrm{FCLET}}(z) \neq c_s^{\mathrm{std}}(z).$$

This classification is already implicit in the background closure. It will be formalized explicitly later in the paper. But the distinction must be visible here, because Article 90 is not allowed to blur "background modification" and "sound-horizon renormalization" into one undifferentiated mechanism.

2.8 The Background Closure Theorem

The results of the present section can now be stated as a theorem.

Theorem 1 (Homogeneous FCLET Background Closure Theorem).
Let the homogeneous cosmological load variable be

$$I(z) = \frac{\rho_{\mathrm{std}}(z)}{\rho_\star + \rho_{\mathrm{std}}(z)},$$

and let the homogeneous latency functional be

$$\chi(z) = \Upsilon(I(z)) = -\ln(1 - I(z)).$$

Let the homogeneous FCLET source density be

$$\rho_{\mathrm{FCLET}}(z) = \rho_\star\left[\eta_\chi\, \Upsilon(I(z)) + \eta_{\mathrm{ov}}\, I(z)(1 - I(z))e^{-\sigma I(z)}\right].$$

Then the effective homogeneous FCLET background equation is

$$H_{\mathrm{FCLET}}^2(z) = \frac{8\pi G}{3}\left[\rho_m(z) + \rho_r(z) + \rho_\Lambda + \rho_{\mathrm{FCLET}}(z)\right],$$

with effective pressure

$$p_{\mathrm{FCLET}}(z) = -\rho_{\mathrm{FCLET}}(z) + \frac{1+z}{3}\frac{d\rho_{\mathrm{FCLET}}(z)}{dz},$$

and acceleration equation

$$\dot{H}_{\mathrm{FCLET}}(z) = -4\pi G[\rho_{\mathrm{eff}}(z) + p_{\mathrm{eff}}(z)].$$

Hence FCLET possesses a closed homogeneous cosmological background sector suitable for direct Hubble-interface analysis.

2.9 What Section 2 Achieves

This section completes the first indispensable task of Article 90. It replaces the previously incomplete Hubble-side intuition by an explicit homogeneous background closure. The finite-capacity cosmological load variable has been defined, the associated latency functional has been written in closed form, the effective FCLET source density has been derived, and the corresponding modified background equation for $H(z)$ has been obtained. The paper therefore now has a genuine cosmological background sector rather than only a plausible qualitative mechanism.

But this is still only half of the Hubble problem.

The inferred Hubble scale is not determined by background expansion alone. It is tied to the pre-recombination acoustic horizon. Therefore the next step is not to stop at $H_{\mathrm{FCLET}}(z)$, but to derive the FCLET modification of the sound speed and the resulting sound-horizon renormalization. That is the role of the next section.

3. Pre-Recombination Acoustic Transport and the FCLET Sound Speed

The homogeneous FCLET background equation derived in the previous section is necessary, but it is not sufficient to close the Hubble interface. The inferred Hubble scale is not determined by background expansion alone. It is determined through the acoustic horizon, and the acoustic horizon depends on both the expansion rate and the propagation speed of compressional perturbations in the pre-recombination baryon–photon plasma. Therefore a complete FCLET treatment of the Hubble sector must derive not only

$$H_{\mathrm{FCLET}}(z),$$

but also

$$c_s^{\mathrm{FCLET}}(z),$$

the effective sound speed of the pre-recombination medium in the finite-capacity framework.

This is the central task of the present section.

The logic is exact. If the early universe is a high-load regime of a finite-capacity substrate, then acoustic propagation cannot remain identical to the low-load standard case. The same burden fraction and latency structure that modify the homogeneous background also modify the propagation efficiency of pressure-supported waves. In FCLET language, the baryon–photon fluid does not propagate on an infinitely slack transport medium. It propagates on a background whose update capacity is burdened and whose transport response is latency-limited. The sound horizon must therefore be renormalized.

This section derives that renormalization.

3.1 Standard Acoustic Transport

Before introducing the FCLET correction, it is useful to state the standard acoustic structure in compact form. In the baryon–photon plasma, the standard pre-recombination sound speed is

$$c_s^{\mathrm{std}}(z) = \frac{c}{\sqrt{3(1 + R_b(z))}},$$

where

$$R_b(z) = \frac{3\rho_b(z)}{4\rho_\gamma(z)}.$$

Using the standard redshift scalings,

$$\rho_b(z) = \rho_{b0}(1+z)^3, \rho_\gamma(z) = \rho_{\gamma 0}(1+z)^4,$$

one obtains

$$R_b(z) = \frac{3\rho_{b0}}{4\rho_{\gamma 0}}(1+z)^{-1}.$$

The standard comoving sound horizon at recombination is then

$$r_s^{\mathrm{std}}(z_*) = \int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)}\, dz.$$

This object is central to the Hubble inference chain. If FCLET changes either the numerator or the denominator of the integrand during the pre-recombination era, then it changes the acoustic horizon and therefore changes the inferred Hubble scale.

3.2 Finite-Capacity Interpretation of Acoustic Propagation

The standard derivation treats acoustic propagation as if the medium were characterized only by local thermodynamic inertia and pressure support. FCLET adds an additional ingredient: finite transport capacity.

The physical point is direct. Pre-recombination acoustic propagation requires coherent transfer of compressional information across a rapidly evolving, radiation-dominated plasma. In a finite-capacity universe, that propagation is not controlled solely by local equation-of-state physics. It is also controlled by how much burden the underlying substrate is already carrying. When the background load fraction is high, the transport of acoustic disturbances is

latency-limited. The propagation channel remains real, but it is slowed relative to the low-load idealization.

That is why the sound speed acquires an FCLET correction.

The same homogeneous burden fraction introduced in Section 2,

$$I(z) = \frac{\rho_{\mathrm{std}}(z)}{\rho_\star + \rho_{\mathrm{std}}(z)},$$

now enters as a transport-loading variable. The associated latency functional is

$$\chi(z) = \Upsilon(I(z)).$$

At the benchmark cosmological level of the late FCLET program, the natural choice remains

$$\Upsilon(I) = -\ln(1 - I),$$

so that

$$\chi(z) = \ln\left(1 + \frac{\rho_{\mathrm{std}}(z)}{\rho_\star}\right).$$

The key transport assumption is then that acoustic propagation efficiency is reduced by finite-capacity loading. To first nontrivial order, this reduction is represented by a transport factor

$$\mathcal{T}_\chi(z) = 1 - \alpha_\chi I(z),$$

where α_χ is a dimensionless acoustic transport coefficient.

This is not an arbitrary ansatz in the weak sense. It is the minimal linearized transport representation of the general FCLET statement that propagation efficiency decreases with increasing load. The factor must satisfy three structural requirements:

low-load recovery:

$$\mathcal{T}_\chi(z) \to 1 \mathrm{as} I(z) \to 0,$$

high-load suppression:

$$\frac{d\mathcal{T}_\chi}{dI} < 0,$$

bounded positivity:

$$\mathcal{T}_\chi(z) > 0$$

throughout the admissible cosmological corridor.

The linear transport factor above is the simplest form satisfying all three when α_χ is chosen in the admissible range.

3.3 The FCLET Sound Speed

The effective FCLET sound speed is now defined by multiplying the standard acoustic speed by the finite-capacity transport factor:

$$c_s^{\mathrm{FCLET}}(z) = c_s^{\mathrm{std}}(z)\,\mathcal{T}_\chi(z).$$

Hence

$$c_s^{\mathrm{FCLET}}(z) = \frac{c}{\sqrt{3(1+R_b(z))}}\,[1-\alpha_\chi I(z)].$$

Substituting the explicit homogeneous load variable yields

$$c_s^{\mathrm{FCLET}}(z) = \frac{c}{\sqrt{3(1+R_b(z))}}\left[1-\alpha_\chi \frac{\rho_{\mathrm{std}}(z)}{\rho_\star+\rho_{\mathrm{std}}(z)}\right].$$

This is the first closed FCLET acoustic transport equation for the Hubble interface.

Its meaning is exact. The baryon–photon sound speed is not being altered because the local baryon–photon thermodynamics has been replaced by something exotic. It is being altered because the effective propagation of acoustic information is slowed by finite-capacity loading of the background substrate. The correction is therefore not a replacement of standard microphysics, but a transport renormalization of the medium's ability to carry acoustic phase information.

This distinction is crucial. It is what allows FCLET to modify the inferred sound horizon without requiring an arbitrarily large deformation of the late-time expansion history.

3.4 The FCLET Sound Horizon

The renormalized FCLET sound horizon is defined by

$$r_s^{\mathrm{FCLET}}(z_*) = \int_{z_*}^{\infty} \frac{c_s^{\mathrm{FCLET}}(z)}{H_{\mathrm{FCLET}}(z)}\,dz.$$

Substituting the explicit transport correction gives

$$r_s^{\mathrm{FCLET}}(z_*) = \int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)\,[1-\alpha_\chi I(z)]}{H_{\mathrm{FCLET}}(z)}\,dz.$$

This formula already shows the central structural result of the paper:

r_s^{FCLET} is modified by both background expansion and acoustic transport.

There are therefore two conceptually distinct effects inside the same integral:

the denominator effect:

$$H_{\mathrm{FCLET}}(z) \neq H_{\mathrm{std}}(z),$$

which is the background channel,

the numerator effect:

$$c_s^{\mathrm{FCLET}}(z) \neq c_s^{\mathrm{std}}(z),$$

which is the transport channel.

This is why Article 90 must separate the two rather than blur them together.

3.5 First-Order Sound-Horizon Renormalization

To expose the Hubble mechanism clearly, it is useful to write the sound-horizon shift in perturbative form around the standard branch.

Let

$$H_{\mathrm{FCLET}}(z) = H_{\mathrm{std}}(z)\,[1+\delta_H(z)],$$

with $|\,\delta_H(z)\,| \ll 1$ over the controlled branch, and let

$$c_s^{\mathrm{FCLET}}(z) = c_s^{\mathrm{std}}(z)\,[1-\alpha_\chi I(z)].$$

Then to first order,

$$\frac{c_s^{\mathrm{FCLET}}(z)}{H_{\mathrm{FCLET}}(z)} \approx \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)}[1-\alpha_\chi I(z)-\delta_H(z)].$$

Hence the first-order sound-horizon correction is

$$r_s^{\mathrm{FCLET}} \approx r_s^{\mathrm{std}} - \int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)}[\alpha_\chi I(z)+\delta_H(z)]\,dz.$$

Therefore

$$\delta r_s \equiv r_s^{\mathrm{FCLET}} - r_s^{\mathrm{std}} \approx -\int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)} [\alpha_\chi I(z) + \delta_H(z)]\, dz.$$

This equation makes the FCLET Hubble mechanism completely transparent. The sound horizon is shifted downward by two possible contributions:

a transport suppression term $\alpha_\chi I(z)$,

a background modification term $\delta_H(z)$.

If both are positive in the relevant early-universe interval, then

$$\delta r_s < 0, r_s^{\mathrm{FCLET}} < r_s^{\mathrm{std}}.$$

That is precisely the direction needed to raise the CMB-inferred Hubble scale.

3.6 Pure Transport Branch

The first clean limit of the theory is the pure transport branch, in which the homogeneous background remains close to standard form:

$$H_{\mathrm{FCLET}}(z) \approx H_{\mathrm{std}}(z), \delta_H(z) \approx 0.$$

Then the sound horizon reduces to

$$r_s^{\mathrm{FCLET}} \approx \int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)\,[1 - \alpha_\chi I(z)]}{H_{\mathrm{std}}(z)}\, dz.$$

At first order,

$$r_s^{\mathrm{FCLET}} \approx r_s^{\mathrm{std}} - \alpha_\chi \int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)} I(z)\, dz.$$

Defining the sound-horizon-weighted average load

$$\langle I \rangle_{r_s} = \frac{\displaystyle\int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)} I(z)\, dz}{\displaystyle\int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)}\, dz},$$

one obtains the compact form

$$r_s^{\mathrm{FCLET}} \approx r_s^{\mathrm{std}}(1 - \alpha_\chi \langle I \rangle_{r_s}).$$

This is the cleanest expression of the FCLET transport mechanism. It shows that even if the late-time background remains essentially standard, a finite-capacity early-universe transport correction can renormalize the sound horizon downward and thereby move the inferred Hubble scale upward.

This branch is especially important because it offers a route to Hubble-tension relief without demanding a large deformation of the late-time expansion law.

3.7 Mixed Background–Transport Branch

The second important limit is the mixed branch, in which both channels contribute:

$$H_{\mathrm{FCLET}}(z) \neq H_{\mathrm{std}}(z), c_s^{\mathrm{FCLET}}(z) \neq c_s^{\mathrm{std}}(z).$$

Then the sound-horizon shift is

$$\delta r_s \approx -r_s^{\mathrm{std}}\left(\alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s}\right),$$

where

$$\langle \delta_H \rangle_{r_s} = \frac{\displaystyle\int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)} \delta_H(z)\, dz}{\displaystyle\int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)}\, dz}.$$

This form is especially useful because it makes the background-versus-transport decomposition explicit already at first order. The Hubble interface can therefore be discussed quantitatively without ambiguity about where the sound-horizon shift is coming from.

3.8 Positivity and Admissibility Constraints

The FCLET transport correction must respect two immediate physical constraints.

First, the sound speed must remain positive:

$$c_s^{\mathrm{FCLET}}(z) > 0.$$

Given the linear correction, this requires

$$1 - \alpha_\chi I(z) > 0$$

throughout the relevant pre-recombination interval. Since $0 < I(z) < 1$, the safe condition is

$$\alpha_\chi < \frac{1}{\max I(z)}.$$

Second, the correction must remain inside the cosmological corridor inherited from the late FCLET benchmark structure. That means α_χ, $\rho_\star$, and any mixed-branch background coefficients cannot be pushed arbitrarily high just to force a large sound-horizon reduction. The correction must stay inside the broader late-stage FCLET viability structure, not just produce a desirable Hubble shift in isolation.

This is one of the reasons the present section is only the transport derivation and not yet the final Hubble verdict. The admissible magnitude of α_χ must later be checked against the corridor logic of Articles 86 and 89.

3.9 Acoustic Transport Theorem

The central result of the section can now be stated in theorem form.

Theorem 2 (FCLET Acoustic Transport Theorem).
Let the homogeneous cosmological load variable be

$$I(z) = \frac{\rho_{\mathrm{std}}(z)}{\rho_\star + \rho_{\mathrm{std}}(z)},$$

and let the pre-recombination acoustic transport factor be

$$\mathcal{T}_\chi(z) = 1 - \alpha_\chi I(z).$$

Then the effective FCLET sound speed is

$$c_s^{\mathrm{FCLET}}(z) = c_s^{\mathrm{std}}(z)\,[1 - \alpha_\chi I(z)],$$

and the corresponding FCLET sound horizon is

$$r_s^{\mathrm{FCLET}}(z_*) = \int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)\,[1 - \alpha_\chi I(z)]}{H_{\mathrm{FCLET}}(z)}\,dz.$$

To first order around the standard branch,

$$r_s^{\mathrm{FCLET}} \approx r_s^{\mathrm{std}} - \int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)}\,[\alpha_\chi I(z) + \delta_H(z)]\,dz.$$

Hence FCLET modifies the sound horizon through two distinct channels: background expansion and acoustic transport. In the pure transport limit, the sound horizon renormalizes as

$$r_s^{\mathrm{FCLET}} \approx r_s^{\mathrm{std}}(1 - \alpha_\chi \langle I \rangle_{r_s}).$$

This theorem is the first closed transport-level Hubble-interface result of the FCLET program.

3.10 What Section 3 Achieves

Section 2 supplied the missing homogeneous background equation. Section 3 now supplies the missing acoustic transport equation.

The finite-capacity burden fraction has been promoted from a background load variable to an acoustic transport variable. The FCLET sound speed has been derived in explicit form, the modified sound-horizon integral has been obtained, and the theory's Hubble-sector mechanism has been decomposed into its two fundamental components:

background modification,

transport renormalization.

This is the exact closure that was previously missing. The FCLET program now possesses not just a plausible statement that early-universe saturation may influence the Hubble scale, but an explicit sound-horizon mechanism by which it does so.

The next step is then immediate. Once the sound horizon has been renormalized, one must follow that renormalization into the inferred Hubble scale itself. That is the role of the next section.

4. Sound-Horizon Renormalization and the Inferred Hubble Scale

The previous section established the decisive transport-level result of the Hubble interface: in FCLET the pre-recombination acoustic horizon is renormalized because the effective sound speed is reduced by finite-capacity loading and, in the mixed branch, because the background expansion may also be altered. But the sound horizon is not itself the final observational target. The real target is the inferred Hubble scale. Therefore the next task is exact:

$$\text{How does } r_s^{\mathrm{FCLET}} \text{ propagate into the inferred } H_0?$$

This is the central question of the present section.

The answer is not merely verbal. In the CMB inference chain, the Hubble scale is not measured independently of the acoustic horizon. It is inferred through the angular acoustic scale. Therefore any controlled FCLET reduction of the sound horizon produces an upward shift of the inferred Hubble constant, provided the corresponding angular scale remains fixed or nearly fixed by observation. The purpose of this section is to derive that mapping explicitly.

4.1 The Acoustic Angular Scale

The standard acoustic angular scale is

$$\theta_s = \frac{r_s(z_*)}{D_A(z_*)},$$

where $r_s(z_*)$ is the comoving sound horizon at recombination and $D_A(z_*)$ is the comoving angular-diameter distance to recombination.

In the FCLET framework, this becomes

$$\theta_s^{\mathrm{FCLET}} = \frac{r_s^{\mathrm{FCLET}}(z_*)}{D_A^{\mathrm{FCLET}}(z_*)}.$$

The observed CMB acoustic peak structure fixes θ_s with very high precision. Therefore, to leading order, any shift in the sound horizon must be compensated by a corresponding shift in the distance scale:

$$\frac{\delta\theta_s}{\theta_s} = \frac{\delta r_s}{r_s} - \frac{\delta D_A}{D_A} \approx 0.$$

Hence

$$\frac{\delta D_A}{D_A} \approx \frac{\delta r_s}{r_s}.$$

This equation is the immediate bridge between sound-horizon renormalization and inferred expansion scale. If r_s is reduced, then the inferred distance to last scattering must also be reduced accordingly.

4.2 The Angular-Diameter Distance and the Hubble Scale

The comoving angular-diameter distance to recombination is

$$D_A(z_*) = \frac{1}{1+z_*}\int_0^{z_*} \frac{dz}{H(z)}.$$

In the simplest inference picture, if the detailed dimensionless background shape is held approximately fixed, the dominant scaling is

$$D_A(z_*) \propto H_0^{-1}.$$

Therefore, to leading order,

$$\frac{\delta D_A}{D_A} \approx -\frac{\delta H_0^{\inf}}{H_0^{\inf}}.$$

Combining this with the acoustic-angle relation above gives

$$-\frac{\delta H_0^{\inf}}{H_0^{\inf}} \approx \frac{\delta r_s}{r_s},$$

or equivalently,

$$\frac{\delta H_0^{\inf}}{H_0^{\inf}} \approx -\frac{\delta r_s}{r_s}.$$

This is the key Hubble-interface identity of the paper.

It shows that a downward shift of the sound horizon produces an upward shift of the inferred Hubble scale.

In particular, if

$$r_s^{\mathrm{FCLET}} < r_s^{\mathrm{std}},$$

then

$$H_{0,\inf}^{\mathrm{FCLET}} > H_{0,\inf}^{\mathrm{std}},$$

provided the angular acoustic scale remains observationally fixed.

4.3 First-Order Mapping from FCLET to the Inferred Hubble Scale

Section 3 gave the first-order sound-horizon shift:

$$\delta r_s \equiv r_s^{\mathrm{FCLET}} - r_s^{\mathrm{std}} \approx -\int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)} [\alpha_\chi I(z) + \delta_H(z)]\, dz.$$

Dividing by r_s^{std} gives

$$\frac{\delta r_s}{r_s^{\mathrm{std}}} \approx -\big(\alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s}\big),$$

where

$$\langle I\rangle_{r_s} = \frac{\displaystyle\int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)} I(z)\, dz}{\displaystyle\int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)}\, dz},$$

and

$$\langle \delta_H\rangle_{r_s} = \frac{\displaystyle\int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)} \delta_H(z)\, dz}{\displaystyle\int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)}\, dz}.$$

Therefore

$$\frac{\delta H_0^{\mathrm{inf}}}{H_0^{\mathrm{inf}}} \approx \alpha_\chi \langle I\rangle_{r_s} + \langle \delta_H\rangle_{r_s}.$$

This is the first closed FCLET formula for the inferred Hubble shift.

It separates the two channels transparently:

the **transport channel**

$$\alpha_\chi \langle I\rangle_{r_s},$$

the **background channel**

$$\langle \delta_H\rangle_{r_s}.$$

This formula is one of the most important outputs of Article 90. It converts the previously qualitative Hubble discussion into an explicit prediction map.

4.4 The Pure Transport Limit

The cleanest benchmark branch is the pure transport limit:

$$\delta_H(z) \approx 0.$$

Then the inferred Hubble shift becomes

$$\frac{\delta H_0^{\mathrm{inf}}}{H_0^{\mathrm{inf}}} \approx \alpha_\chi \langle I\rangle_{r_s}.$$

Equivalently,

$$H_{0,\mathrm{inf}}^{\mathrm{FCLET}} \approx H_{0,\mathrm{inf}}^{\mathrm{std}}(1 + \alpha_\chi \langle I \rangle_{r_s}).$$

This is the sharpest early-universe FCLET mechanism for Hubble-tension relief. It shows that the inferred Hubble scale can rise even if the late-time background remains very close to standard form. The shift is driven entirely by the reduction of the sound horizon through finite-capacity transport loading.

This branch is especially attractive because it minimizes the risk of late-time background conflict while still delivering a nontrivial Hubble shift.

4.5 The Mixed Background–Transport Limit

In the more general case, both channels contribute:

$$\frac{\delta H_0^{\mathrm{inf}}}{H_0^{\mathrm{inf}}} \approx \alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s}.$$

Then

$$H_{0,\mathrm{inf}}^{\mathrm{FCLET}} \approx H_{0,\mathrm{inf}}^{\mathrm{std}}\left[1 + \alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s}\right].$$

This decomposition is crucial because it prevents overinterpretation. A positive Hubble shift may come from transport, from background, or from both. The program must know which. That is why Article 90 separates the channels before recombining them.

The mixed branch also makes clear that a given FCLET Hubble shift does not uniquely imply a single mechanism. Different parameter combinations can distribute the effect differently between transport and background. This is why the later parameter-window analysis will matter.

4.6 Effective Sound-Horizon Renormalization Factor

It is convenient to define an effective sound-horizon renormalization factor

$$\mathcal{R}_s \equiv \frac{r_s^{\mathrm{FCLET}}}{r_s^{\mathrm{std}}}.$$

To first order,

$$\mathcal{R}_s \approx 1 - \alpha_\chi \langle I \rangle_{r_s} - \langle \delta_H \rangle_{r_s}.$$

The corresponding inferred Hubble renormalization factor is

$$\mathcal{R}_H \equiv \frac{H_{0,\mathrm{inf}}^{\mathrm{FCLET}}}{H_{0,\mathrm{inf}}^{\mathrm{std}}} \approx \mathcal{R}_s^{-1}.$$

At first order this gives

$$\mathcal{R}_H \approx 1 + \alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s}.$$

This compact notation will be useful later when discussing the quantitative parameter window for Hubble-tension relief versus full resolution.

4.7 The Benchmark Transport Estimate

The benchmark transport estimate already hinted at in the program can now be stated cleanly inside the formal derivation.

If the dominant branch is transport-driven and one finds

$$\alpha_\chi \approx 0.098,$$

then the inferred Hubble shift is approximately

$$\frac{\delta H_0^{\mathrm{inf}}}{H_0^{\mathrm{inf}}} \approx 0.098\, \langle I \rangle_{r_s}.$$

Thus the actual size of the Hubble correction is controlled not by α_χ alone, but by the pre-recombination weighted average load

$$\langle I \rangle_{r_s}.$$

This is an important conceptual clarification. The FCLET Hubble mechanism is not a free multiplicative boost. It is modulated by how burdened the early-universe background actually is over the sound-horizon integral.

This gives the theory exactly the right structure: one tunable transport coefficient and one physically determined weighted load factor.

4.8 Inferred Hubble Shift versus Local Hubble Scale

At this point one must be careful with language. The quantity derived here is

$$H_{0,\mathrm{inf}}^{\mathrm{FCLET}},$$

the Hubble scale inferred from CMB plus acoustic-structure reasoning under the FCLET-modified sound horizon and background.

This is not yet the same as a local direct late-time measurement of H_0. The present paper is deriving the theoretical shift in the inferred cosmological Hubble scale, not replacing the measurement process itself. The Hubble-tension claim is therefore not that FCLET arbitrarily changes "the value of H_0." It is that FCLET changes the early-universe calibration in such a way that the inferred cosmological H_0 shifts upward.

That is the correct and defensible statement.

4.9 Hubble-Interface Theorem

The main result of the section can now be stated in theorem form.

Theorem 3 (FCLET Hubble-Interface Theorem).
Let the FCLET sound horizon be

$$r_s^{\mathrm{FCLET}}(z_*) = \int_{z_*}^{\infty} \frac{c_s^{\mathrm{FCLET}}(z)}{H_{\mathrm{FCLET}}(z)}\, dz,$$

with

$$c_s^{\mathrm{FCLET}}(z) = c_s^{\mathrm{std}}(z)\,[1 - \alpha_\chi I(z)],$$

and

$$H_{\mathrm{FCLET}}(z) = H_{\mathrm{std}}(z)\,[1 + \delta_H(z)].$$

Then, to first order around the standard branch,

$$\frac{\delta r_s}{r_s^{\mathrm{std}}} \approx -\left(\alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s}\right),$$

and therefore the inferred Hubble shift satisfies

$$\frac{\delta H_0^{\mathrm{inf}}}{H_0^{\mathrm{inf}}} \approx \alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s}.$$

In the pure transport limit,

$$\frac{\delta H_0^{\mathrm{inf}}}{H_0^{\mathrm{inf}}} \approx \alpha_\chi \langle I \rangle_{r_s}.$$

Hence FCLET shifts the inferred Hubble scale upward whenever its early-universe finite-capacity correction reduces the acoustic horizon.

This is the first closed Hubble-scale inference theorem of the FCLET program.

4.10 What Section 4 Achieves

Section 2 supplied the missing homogeneous background equation.
Section 3 supplied the missing acoustic transport equation.
Section 4 now closes the inference chain from those equations to the Hubble scale itself.

The paper now possesses an explicit mapping

$$\{I(z), \chi(z), \alpha_\chi, \delta_H(z)\} \longrightarrow \{r_s^{\mathrm{FCLET}}, \theta_s, D_A(z_*), H_{0,\mathrm{inf}}^{\mathrm{FCLET}}\}.$$

That is the exact mathematical closure the Hubble interface previously lacked.

Just as importantly, the section proves something structurally valuable: FCLET does not need a violent late-time expansion anomaly in order to influence the Hubble tension. A controlled early-universe transport correction can already move the inferred Hubble scale upward. This makes the theory far more flexible and far more compatible with the corridor-preserving logic demanded by the late FCLET program.

The next task is therefore to separate rigorously the three possible branches of the Hubble mechanism:

background-dominated,

transport-dominated,

mixed.

That is the role of the next section.

5. Background-versus-Transport Decomposition

The previous sections derived the two ingredients required for a quantitative FCLET Hubble interface: a closed homogeneous background equation and a closed pre-recombination acoustic transport correction. The inferred Hubble shift then followed in compact form:

$$\frac{\delta H_0^{\mathrm{inf}}}{H_0^{\mathrm{inf}}} \approx \alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s}.$$

This formula is already powerful, but by itself it still leaves one decisive ambiguity unresolved. A given upward shift of the inferred Hubble scale does not yet tell us which sector of the theory is actually responsible. The shift may be produced predominantly by finite-capacity acoustic transport, predominantly by the modified homogeneous background, or by a genuinely mixed branch in which both contributions are essential. A serious cosmological interface paper cannot leave this ambiguous. If the Hubble sector is to become scientifically interpretable and falsifiable, the theory must identify which channel is doing the work.

That is the purpose of the present section.

The decomposition introduced here is not cosmetic. It determines how the Hubble interface should be confronted with data, how it should be judged for compatibility with the tensor corridor established in Article 86, and how it should be embedded into the global viability map established in Article 89. The same net shift in $H_{0,\mathrm{inf}}$ can correspond to very different physical branches of the theory, and those branches do not have the same empirical risk profile. A transport-dominated solution may preserve a near-standard late-time background and therefore be relatively safe against low-redshift distance constraints. A background-dominated solution may generate the same Hubble shift while being much more exposed to BAO and expansion-history tests. A mixed solution may achieve the most realistic compromise, but only if both sectors remain corridor-compatible. These distinctions must therefore be made explicit.

5.1 The Two Fundamental Hubble Channels

At first order, the FCLET Hubble-interface result may be written as

$$\Delta_H \equiv \frac{\delta H_0^{\mathrm{inf}}}{H_0^{\mathrm{inf}}} \approx \Delta_{\mathrm{tr}} + \Delta_{\mathrm{bg}},$$

where

$$\Delta_{\mathrm{tr}} \equiv \alpha_\chi \langle I \rangle_{r_s}, \Delta_{\mathrm{bg}} \equiv \langle \delta_H \rangle_{r_s}.$$

The interpretation is exact.

The quantity

$$\Delta_{\mathrm{tr}}$$

is the **transport channel**. It measures how much of the inferred Hubble shift is generated by the FCLET renormalization of the pre-recombination sound speed, and therefore by the acoustic-horizon correction.

The quantity

$$\Delta_{\mathrm{bg}}$$

is the **background channel**. It measures how much of the inferred Hubble shift is generated by the FCLET deformation of the homogeneous expansion law inside the sound-horizon integral.

The total first-order shift is the sum of these two channels. Article 90 must therefore not ask merely whether FCLET can shift $H_{0,\mathrm{inf}}$. It must ask **which channel, or which combination of channels, is responsible**.

5.2 Channel Fractions and Dominance Parameters

To make that question quantitative, define the channel fractions

$$f_{\mathrm{tr}} = \frac{\Delta_{\mathrm{tr}}}{\Delta_H}, f_{\mathrm{bg}} = \frac{\Delta_{\mathrm{bg}}}{\Delta_H},$$

whenever $\Delta_H \neq 0$.

At first order one then has

$$f_{\mathrm{tr}} + f_{\mathrm{bg}} = 1.$$

These fractions allow the Hubble interface to be classified by physical dominance rather than only by net shift magnitude. It is also convenient to define the channel-dominance ratio

$$\mathcal{D}_H = \frac{\Delta_{\mathrm{bg}}}{\Delta_{\mathrm{tr}}} = \frac{\langle \delta_H \rangle_{r_s}}{\alpha_\chi \langle I \rangle_{r_s}}.$$

This quantity measures the relative size of the two FCLET Hubble mechanisms. Its interpretation is immediate:

- $| \mathcal{D}_H | \ll 1$: transport-dominated regime,
- $| \mathcal{D}_H | \gg 1$: background-dominated regime,
- $| \mathcal{D}_H | \sim 1$: mixed regime.

This is the correct first-order diagnostic of which sector is driving the Hubble shift.

5.3 Transport-Dominated Branch

The first clean branch is the **transport-dominated branch**, defined by

$$| \Delta_{\mathrm{tr}} | \gg | \Delta_{\mathrm{bg}} |, | \mathcal{D}_H | \ll 1.$$

In this regime

$$\Delta_H \approx \Delta_{\mathrm{tr}} = \alpha_\chi \langle I \rangle_{r_s},$$

so that

$$\frac{\delta H_0^{\mathrm{inf}}}{H_0^{\mathrm{inf}}} \approx \alpha_\chi \langle I \rangle_{r_s}.$$

The physical interpretation is exact. The dominant FCLET effect is not a large deformation of the homogeneous expansion history. It is a finite-capacity slowing of pre-recombination

acoustic propagation, which reduces the sound horizon and therefore raises the inferred Hubble scale.

This branch is attractive for two reasons.

First, it is conceptually economical. It uses the minimal FCLET mechanism needed to influence the Hubble tension: transport renormalization of the early-universe acoustic horizon.

Second, it is observationally conservative. Since the background remains close to standard form, it is less exposed to late-time expansion-history constraints.

That does not mean it is automatically safe. The transport coefficient α_χ and the weighted early-universe load $\langle I \rangle_{r_s}$ must still remain compatible with the established FCLET corridor. But this branch is the cleanest way for the theory to move $H_{0,\mathrm{inf}}$ upward without introducing a large low-redshift anomaly.

5.4 Background-Dominated Branch

The second clean branch is the **background-dominated branch**, defined by

$$| \Delta_{\mathrm{bg}} | \gg | \Delta_{\mathrm{tr}} |, | \mathcal{D}_H | \gg 1.$$

In this regime

$$\Delta_H \approx \Delta_{\mathrm{bg}} = \langle \delta_H \rangle_{r_s},$$

so that

$$\frac{\delta H_0^{\mathrm{inf}}}{H_0^{\mathrm{inf}}} \approx \langle \delta_H \rangle_{r_s}.$$

Here the main FCLET effect is not the modification of the acoustic transport speed, but the modification of the homogeneous background expansion inside the sound-horizon integral. The acoustic horizon changes because

$$H_{\mathrm{FCLET}}(z) \neq H_{\mathrm{std}}(z)$$

over the relevant pre-recombination interval.

This branch is in principle viable, but it is also the most exposed branch observationally. A background-level deformation sufficiently large to contribute materially to the Hubble shift is more likely to propagate into other cosmological observables tied directly to the expansion history. Therefore a background-dominated Hubble solution is scientifically stronger only if it survives later consistency tests. It is not the naturally safest branch of the theory.

For that reason, this branch must be treated with more scrutiny than the pure transport solution.

5.5 Mixed Branch

The third possibility is the **mixed branch**, defined by

$$| \Delta_{\mathrm{tr}} | \sim | \Delta_{\mathrm{bg}} |, | \mathcal{D}_H | \sim 1.$$

Then

$$\Delta_H \approx \alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s},$$

with both contributions carrying comparable weight.

This branch is in many ways the most flexible. It allows the Hubble shift to be distributed across two FCLET sectors rather than forced entirely through one. That may be advantageous because it can reduce the stress placed on any single parameter or mechanism. A moderate transport correction and a moderate background correction may together yield a substantial upward Hubble shift while remaining individually corridor-safe.

But the mixed branch is also the most subtle. Because two channels are active at once, it is the branch most in need of disciplined decomposition. Without the diagnostics introduced in this section, a mixed solution would be difficult to interpret and easy to overstate. This is exactly why Article 90 must formalize the branch structure before moving on to quantitative parameter windows.

5.6 A Branch Map in FCLET Parameter Space

The branch structure may be expressed directly in terms of the FCLET parameters controlling the Hubble interface.

The transport channel is controlled primarily by

$$\alpha_\chi \text{and} \langle I \rangle_{r_s},$$

while the background channel is controlled by the homogeneous FCLET source sector through

$$\eta_\chi, \eta_{\mathrm{ov}}, \sigma, \rho_\star,$$

and their combined effect on

$$\delta_H(z).$$

Therefore the Hubble branch map is not merely a decomposition in observable space. It is a decomposition in FCLET parameter space:

$$(\alpha_\chi, \rho_\star, \eta_\chi, \eta_{\mathrm{ov}}, \sigma, \beta_S) \longrightarrow (\Delta_{\mathrm{tr}}, \Delta_{\mathrm{bg}}).$$

This map allows the theory to define, for any admissible parameter point, whether the Hubble interface is transport-dominated, background-dominated, or mixed.

5.7 Safe, Relief, and Overdriven Regimes

The branch decomposition also makes it possible to classify the Hubble sector according to physical usefulness.

Safe branch

A parameter point is **safe** if

$$| \Delta_H |$$

remains modest and the induced FCLET correction stays clearly inside the established cosmological corridor. In this regime the theory modifies the Hubble inference chain, but only weakly.

Relief branch

A parameter point lies in the **relief branch** if

$$\Delta_H > 0$$

is large enough to reduce the Hubble tension materially while remaining corridor-compatible. This is the most desirable operational regime short of full resolution.

Overdriven branch

A parameter point lies in the **overdriven branch** if the required Hubble shift is achieved only by making either

$$\alpha_\chi \langle I \rangle_{r_s}$$

or

$$\langle \delta_H \rangle_{r_s}$$

so large that the established FCLET cosmology corridor is no longer plausibly maintained. In that regime the Hubble interface is no longer a success. It becomes a branch conflict.

This classification will be used explicitly in the quantitative window analysis of the next section.

5.8 Background-versus-Transport Consistency Conditions

The two channels cannot be tuned arbitrarily and independently. The FCLET program already imposes structural restrictions on the cosmological sector, especially through the benchmark tensor corridor and the global viability logic established in the previous articles. Therefore a viable Hubble branch must satisfy three consistency conditions.

5.8.1 Positivity of the sound-speed correction

The transport factor must remain positive:

$$1 - \alpha_\chi I(z) > 0$$

throughout the pre-recombination interval relevant for the sound horizon.

5.8.2 Small-to-moderate background deformation

If the branch is advertised as transport-dominated, then

$$| \langle \delta_H \rangle_{r_s} | \ll | \alpha_\chi \langle I \rangle_{r_s} |$$

must actually hold. A nominally transport-based branch that secretly relies on a large background correction is not honestly classified.

5.8.3 Corridor preservation

The parameter values that generate the Hubble shift must remain compatible with the benchmark cosmological corridor already established for the FCLET tensor sector and the global survival logic of Article 89. A branch that raises $H_{0,\mathrm{inf}}$ only by leaving that corridor is not a viable FCLET solution.

These conditions ensure that the decomposition is not merely formal. It has real physical and programmatic consequences.

5.9 A Diagnostic of Branch Purity

To quantify how cleanly a given parameter point belongs to one branch or another, define the branch-purity index

$$\mathcal{P}_{\mathrm{tr}} = \frac{| \Delta_{\mathrm{tr}} |}{| \Delta_{\mathrm{tr}} | + | \Delta_{\mathrm{bg}} |}, \mathcal{P}_{\mathrm{bg}} = \frac{| \Delta_{\mathrm{bg}} |}{| \Delta_{\mathrm{tr}} | + | \Delta_{\mathrm{bg}} |}.$$

Then

$$\mathcal{P}_{\mathrm{tr}} + \mathcal{P}_{\mathrm{bg}} = 1.$$

The interpretation is direct:

$\mathcal{P}_{\mathrm{tr}} \approx 1$: nearly pure transport branch,

$\mathcal{P}_{\mathrm{bg}} \approx 1$: nearly pure background branch,

$\mathcal{P}_{\mathrm{tr}} \sim \mathcal{P}_{\mathrm{bg}} \sim \frac{1}{2}$: mixed branch.

These indices are particularly useful in the later parameter-window discussion because they prevent ambiguous verbal classifications. A given Hubble solution can now be labeled by quantitative branch purity rather than by impressionistic language.

5.10 The Background-versus-Transport Decomposition Theorem

The central result of the section can now be stated in theorem form.

Theorem 4 (Background-versus-Transport Decomposition Theorem).
Let the first-order FCLET Hubble-interface shift be

$$\Delta_H \equiv \frac{\delta H_0^{\mathrm{inf}}}{H_0^{\mathrm{inf}}} \approx \alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s}.$$

Define

$$\Delta_{\mathrm{tr}} = \alpha_\chi \langle I \rangle_{r_s}, \Delta_{\mathrm{bg}} = \langle \delta_H \rangle_{r_s},$$

and the dominance ratio

$$\mathcal{D}_H = \frac{\Delta_{\mathrm{bg}}}{\Delta_{\mathrm{tr}}}.$$

Then every FCLET Hubble-interface solution belongs to one of three branches:

transport-dominated branch, if $| \mathcal{D}_H | \ll 1$;

background-dominated branch, if $| \mathcal{D}_H | \gg 1$;

mixed branch, if $| \mathcal{D}_H | \sim 1$.

Moreover, the inferred Hubble shift is scientifically interpretable only when the branch classification is stated explicitly, since the same net value of Δ_H may arise from physically distinct FCLET mechanisms with different observational risk profiles.

This theorem is the exact interpretive closure of the Hubble-interface derivation.

5.11 What Section 5 Achieves

Section 2 derived the homogeneous background closure.
Section 3 derived the acoustic transport correction.

Section 4 derived the shift in the inferred Hubble scale.
Section 5 now makes that shift scientifically interpretable.

It does three exact things.

First, it decomposes the Hubble effect into transport and background channels.

Second, it defines the three physically distinct FCLET Hubble branches: transport-dominated, background-dominated, and mixed.

Third, it introduces the dominance and purity diagnostics that allow these branches to be identified quantitatively rather than verbally.

This is the point at which the FCLET Hubble interface becomes not only derivable, but classifiable.

The next task is then clear. Once the branches are identified, one must determine where in parameter space the theory produces only weak influence, where it provides genuine Hubble-tension relief, and where it becomes overdriven and corridor-breaking. That is the role of the next section.

6. Quantitative Hubble-Tension Window in FCLET

The previous sections derived the two FCLET channels that can shift the inferred Hubble scale and then decomposed that shift into transport-dominated, background-dominated, and mixed branches. But derivation and decomposition are not yet enough. A serious Hubble-interface paper must go one step further and answer the practical quantitative question:

For which FCLET parameter ranges does the theory do almost nothing, materially relieve the tension, or fully

That is the task of the present section.

The central point is simple. The FCLET Hubble interface is not characterized only by whether the shift

$$\Delta_H \equiv \frac{\delta H_0^{\mathrm{inf}}}{H_0^{\mathrm{inf}}}$$

is positive. It is characterized by how large that shift is, by which channel produces it, and by whether the required parameter values remain structurally reasonable before the later corridor-compatibility test of Section 7 is imposed. Section 6 therefore constructs the **quantitative Hubble-tension window** of the theory.

6.1 The FCLET Hubble Shift as a Parameter-Space Map

At first order, the inferred Hubble shift is

$$\Delta_H \approx \alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s}.$$

The relevant FCLET Hubble-interface parameter space is therefore

$$\mathcal{P}_H = \left(\alpha_\chi, \langle I \rangle_{r_s}, \langle \delta_H \rangle_{r_s}, \beta_S\right),$$

or, more microscopically,

$$\mathcal{P}_H^{\text{full}} = \left(\alpha_\chi,\ \rho_\star,\ \eta_\chi,\ \eta_{\text{ov}},\ \sigma,\ \beta_S\right),$$

with the understanding that these full parameters project onto the effective pair

$$(\Delta_{\text{tr}}, \Delta_{\text{bg}}) = (\alpha_\chi \langle I \rangle_{r_s}, \langle \delta_H \rangle_{r_s}).$$

Thus the Hubble problem is not simply "does FCLET shift H_0 upward?" The correct question is:

What subset of $\mathcal{P}_H$ produces a phenomenologically relevant upward shift?

6.2 Reference Shift Scale

To classify the quantitative effect, define the reference fractional shift required to move the standard-inference Hubble scale to the local-measurement scale:

$$\Delta_\star \equiv \frac{H_{0,\text{loc}} - H_{0,\text{std}}}{H_{0,\text{std}}}.$$

This quantity is deliberately kept symbolic here. The purpose of the present section is not to commit the paper to one particular historical dataset combination, but to define the FCLET window relative to whatever reference standard-versus-local offset is adopted in the confrontation stage.

The inferred FCLET Hubble scale is then

$$H_{0,\text{inf}}^{\text{FCLET}} = H_{0,\text{std}}(1 + \Delta_H).$$

The theory fully reaches the local-inference target if

$$\Delta_H \approx \Delta_\star.$$

It partially relieves the tension if

$$0 < \Delta_H < \Delta_\star.$$

It leaves the tension essentially untouched if

$$|\Delta_H| \ll \Delta_\star.$$

This symbolic normalization makes the branch analysis independent of the exact choice of benchmark datasets while preserving full quantitative interpretability.

6.3 Safe, Relief, Resolution, and Overdriven Regimes

The FCLET Hubble window naturally splits into four operational regimes.

6.3.1 Safe regime

The **safe regime** is defined by

$$0 \le \Delta_H \ll \Delta_\star.$$

In this regime the theory modifies the inferred Hubble scale only weakly. The sound horizon is slightly renormalized, but not enough to materially change the tension. This branch is useful because it demonstrates that the theory can remain close to standard cosmology even while carrying a nonzero early-universe finite-capacity correction.

But it is not yet a Hubble-tension solution. It is only a weak-correction branch.

6.3.2 Relief regime

The **relief regime** is defined by

$$0 < \Delta_H < \Delta_\star,$$

with Δ_H large enough to reduce the discrepancy materially.

This is the most important intermediate regime. It means the theory does not yet fully move the inferred Hubble scale to the local-measurement value, but it does reduce the tension by a non-negligible fraction. A theory that lands here has already earned a real cosmological interface. It does not merely "touch" the Hubble sector. It quantitatively relieves it.

6.3.3 Resolution regime

The **resolution regime** is defined by

$$\Delta_H \approx \Delta_\star.$$

In this regime the FCLET correction is large enough to move the cosmologically inferred Hubble scale into the local-measurement band. This is the strongest possible positive outcome for the Hubble interface.

However, the paper must not overstate this regime. Reaching $\Delta_H \approx \Delta_\star$ is not by itself sufficient for success. It becomes a genuine FCLET solution only if the required parameter values remain admissible after the corridor-compatibility tests of Section 7 are applied.

6.3.4 Overdriven regime

The **overdriven regime** is defined by a shift that is formally large enough to relieve or resolve the Hubble tension, but only by pushing one or both FCLET channels beyond the region that can plausibly remain compatible with the rest of the program:

$$\Delta_H \gtrsim \Delta_\star \text{with structurally excessive } \alpha_\chi, \langle I \rangle_{r_s}, \text{ or } \langle \delta_H \rangle_{r_s}.$$

This regime is not a success. It is exactly the kind of apparent solution that later corridor checks are meant to reject. A theory that resolves the Hubble tension only by leaving its own viability corridor does not solve the problem. It trades one inconsistency for another.

6.4 Transport-Dominated Quantitative Window

In the transport-dominated branch,

$$\Delta_H \approx \Delta_{\mathrm{tr}} = \alpha_\chi \langle I \rangle_{r_s}.$$

The Hubble window is therefore controlled by the product

$$X_{\mathrm{tr}} \equiv \alpha_\chi \langle I \rangle_{r_s}.$$

The branch classification becomes:

safe transport branch

$$X_{\mathrm{tr}} \ll \Delta_\star,$$

relief transport branch

$$0 < X_{\mathrm{tr}} < \Delta_\star,$$

resolution transport branch

$$X_{\mathrm{tr}} \approx \Delta_\star,$$

overdriven transport branch

$$X_{\mathrm{tr}} \gtrsim \Delta_\star$$

only because α_χ or $\langle I \rangle_{r_s}$ has been pushed into a regime that later consistency tests are unlikely to tolerate.

This form is powerful because it shows that the transport mechanism is governed by one effective product, not by α_χ alone. Even a moderately large transport coefficient does not guarantee a large Hubble shift if the weighted early-universe load is small. Conversely, a moderate α_χ can produce a significant shift if the sound-horizon-weighted load is sufficiently high.

6.5 Background-Dominated Quantitative Window

In the background-dominated branch,

$$\Delta_H \approx \Delta_{\mathrm{bg}} = \langle \delta_H \rangle_{r_s}.$$

The classification is then:

safe background branch

$$| \langle \delta_H \rangle_{r_s} | \ll \Delta_\star,$$

relief background branch

$$0 < \langle \delta_H \rangle_{r_s} < \Delta_\star,$$

resolution background branch

$$\langle \delta_H \rangle_{r_s} \approx \Delta_\star,$$

overdriven background branch

$$\langle \delta_H \rangle_{r_s} \gtrsim \Delta_\star$$

at the cost of a background deformation so large that it is unlikely to remain consistent with the rest of the cosmological program.

This classification immediately reveals why the background-dominated branch is more dangerous. A large $\langle \delta_H \rangle_{r_s}$ directly modifies the expansion history in the very sector where many independent cosmological observables live. It is therefore not enough to show that this branch can reach the local H_0 range. One must also show that it does not destroy background-level consistency elsewhere. That is why the background-dominated branch is structurally less conservative than the transport-dominated branch.

6.6 Mixed Quantitative Window

In the mixed branch,

$$\Delta_H \approx \alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s}.$$

This branch is parameterized not by one effective variable, but by a two-channel balance:

$$(X_{\mathrm{tr}}, X_{\mathrm{bg}}) = (\alpha_\chi \langle I \rangle_{r_s}, \langle \delta_H \rangle_{r_s}).$$

The corresponding regimes are:

safe mixed branch

$$X_{\mathrm{tr}} + X_{\mathrm{bg}} \ll \Delta_\star,$$

relief mixed branch

$$0 < X_{\mathrm{tr}} + X_{\mathrm{bg}} < \Delta_\star,$$

resolution mixed branch

$$X_{\mathrm{tr}} + X_{\mathrm{bg}} \approx \Delta_\star,$$

overdriven mixed branch

$$X_{\mathrm{tr}} + X_{\mathrm{bg}} \gtrsim \Delta_\star$$

only through channel values that are individually too large to remain corridor-safe.

The mixed branch is structurally interesting because it may achieve a substantial Hubble shift without pushing either channel to an extreme value. This is exactly why it is a serious FCLET possibility rather than merely a compromise branch. It may provide the smoothest route between “too weak to matter” and “too strong to remain admissible.”

6.7 A Quantitative FCLET Hubble Window Function

To formalize the previous classification, define the FCLET Hubble-window function

$$\mathcal{W}_H = \frac{\Delta_H}{\Delta_\star}.$$

Then:

$\mathcal{W}_H \ll 1$: safe weak-shift regime,

$0 < \mathcal{W}_H < 1$: relief regime,

$\mathcal{W}_H \approx 1$: resolution regime,

$\mathcal{W}_H > 1$: overshoot regime.

This function is useful because it summarizes all branches in one scalar object, while the branch-purity indices from Section 5 specify **how** the shift is being produced.

Together,

$$\left(\mathcal{W}_H, \mathcal{P}_{\mathrm{tr}}, \mathcal{P}_{\mathrm{bg}}\right)$$

form the correct minimal quantitative descriptor of the FCLET Hubble interface.

6.8 The Benchmark Transport Estimate Revisited

The benchmark transport estimate discussed earlier can now be embedded in the quantitative window language. If the transport coefficient is approximately

$$\alpha_\chi \approx 0.098,$$

then in the transport-dominated limit

$$\Delta_H \approx 0.098\, \langle I \rangle_{r_s}.$$

Thus the location of the benchmark branch inside the Hubble window depends directly on the size of the weighted load factor. If $\langle I \rangle_{r_s}$ is modest, the theory lies in the safe or mild-relief regime. If $\langle I \rangle_{r_s}$ is sufficiently large, the same α_χ can move the theory into the strong-relief or resolution regime.

This is exactly the kind of result Article 90 needs. It shows that the FCLET Hubble sector is neither a binary yes/no mechanism nor an unconstrained free shift. It has an explicit quantitative lever arm.

6.9 Provisional Parameter Window Before Corridor Closure

Before Section 7 imposes cross-article compatibility with Articles 86 and 89, the present section can already define a provisional admissibility structure in the Hubble plane:

weak-effect domain

$$\mathcal{W}_H \ll 1,$$

useful-relief domain

$$0 < \mathcal{W}_H < 1,$$

target-resolution domain

$$\mathcal{W}_H \approx 1,$$

overdriven domain

$$\mathcal{W}_H > 1.$$

This provisional window is important because it separates two logically distinct questions:

can FCLET produce the required Hubble shift in principle?

can it do so while remaining compatible with the pre-existing FCLET corridor?

Section 6 answers the first question. Section 7 will answer the second.

6.10 Quantitative Hubble-Window Theorem

The main result of the section can now be stated in theorem form.

Theorem 5 (Quantitative Hubble-Window Theorem).
Let

$$\Delta_H \equiv \frac{\delta H_0^{\inf}}{H_0^{\inf}} \approx \alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s},$$

and let

$$\Delta_\star = \frac{H_{0,\mathrm{loc}} - H_{0,\mathrm{std}}}{H_{0,\mathrm{std}}}$$

be the reference fractional shift required to move the standard cosmological inference to the local-measurement Hubble scale. Define

$$\mathcal{W}_H = \frac{\Delta_H}{\Delta_\star}.$$

Then every FCLET Hubble-interface solution belongs to one of four quantitative regimes:

safe regime, if $\mathcal{W}_H \ll 1$;

relief regime, if $0 < \mathcal{W}_H < 1$;

resolution regime, if $\mathcal{W}_H \approx 1$;

overdriven regime, if $\mathcal{W}_H > 1$.

Moreover, the physical origin of any point in this window is determined by the branch structure of Section 5 through the decomposition

$$\Delta_H = \Delta_{\mathrm{tr}} + \Delta_{\mathrm{bg}}.$$

Hence the FCLET Hubble interface admits a quantitative window structure that is simultaneously magnitude-sensitive and channel-sensitive.

This is the first full parameter-window theorem of the FCLET Hubble sector.

6.11 What Section 6 Achieves

Sections 2–5 derived the FCLET Hubble mechanism and decomposed it into physically distinct branches. Section 6 now turns that mechanism into a quantitative parameter-space map.

It does three exact things.

First, it defines the reference shift scale $\Delta_\star$ and therefore gives the Hubble problem a normalized target.

Second, it classifies the FCLET Hubble sector into safe, relief, resolution, and overdriven regimes.

Third, it shows how these regimes are realized differently in transport-dominated, background-dominated, and mixed branches.

This is the point at which the FCLET Hubble interface becomes not only derivable and interpretable, but quantitatively scorable.

The next question is then unavoidable. A parameter point may lie in the relief or even resolution regime of the Hubble window, yet still fail if the required values of α_χ, $\langle I \rangle_{r_s}$, $\langle \delta_H \rangle_{r_s}$, or β_S are incompatible with the tensor corridor and global-survival structure already established elsewhere in the program. The Hubble interface must therefore now be checked against the rest of the late FCLET architecture.

That is the role of the next section.

7. Compatibility with Article 86 and Article 89

A Hubble-interface mechanism is not scientifically meaningful merely because it can shift the inferred Hubble scale in the desired direction. At this stage of the FCLET program, a Hubble-sector solution counts as real only if it remains compatible with the benchmark cosmological tensor corridor already established in Article 86 and with the reduced and true global survival geometry already established in Article 89. This is not an optional consistency check added for rhetorical caution. It is the exact condition under which the Hubble interface belongs to the FCLET program rather than standing outside it as an isolated auxiliary mechanism.

This point must be stated sharply. Section 6 answered the first quantitative question:

Can FCLET generate a weak, relief-level, or resolution-level Hubble shift in principle?

The present section answers the second:

Can FCLET do so without leaving the cosmological tensor corridor and the global-survival corridor already established elsewhere in the program?

Only if the answer to both questions is positive does Article 90 deliver a genuine third observational arena rather than a disconnected Hubble-sector excursion.

7.1 Why Corridor Compatibility Is Non-Negotiable

The late FCLET sequence already fixed two load-bearing cosmological structures before the present paper began.

First, Article 86 established a benchmark primordial tensor corridor with a nontrivial saturation structure, including the benchmark closure relation

$$\frac{\beta_T}{\beta_S} = 1,$$

together with a tensor-tilt correction of the form

$$\Delta n_T \approx -0.035$$

on the benchmark branch. The point of that article was not merely to show that FCLET can modify primordial tensors. It was to show that the theory admits a cosmological tensor corridor at all.

Second, Article 89 established the first quantitative global viability geometry linking the strong-field shell benchmark and the cosmological benchmark corridor. In reduced form, this gave

$$\xi \in [0.300, 0.800], \beta_S \in [0.761, 1.239],$$

together with the true-bridge logic under which one continuous benchmark-anchored continuation law survives at the first global-coupling level.

These results impose an exact burden on Article 90. A Hubble-sector solution is admissible only if it can be embedded into this pre-existing corridor structure. The Hubble branch is therefore not judged solely by the size of

$$\Delta_H = \frac{\delta H_0^{\inf}}{H_0^{\inf}}.$$

It is judged by whether that shift can be realized while preserving:

the Article 86 tensor corridor,

the Article 89 reduced viability corridor,

and the Article 89 true one-parameter global corridor.

This is the correct standard of programmatic consistency.

7.2 Compatibility with the Article 86 Tensor Corridor

The first compatibility test concerns the cosmological tensor sector. The Hubble interface derived in the present paper is controlled by

$$\Delta_H \approx \alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s},$$

but these quantities are not free of cosmological consequences. If the transport coefficient α_χ, the weighted load factor $\langle I \rangle_{r_s}$, or the background correction $\langle \delta_H \rangle_{r_s}$ are pushed too far, then the same early-universe branch that produces the Hubble shift may also disrupt the tensor corridor inherited from Article 86.

The first structural requirement is therefore the preservation of the benchmark scalar–tensor closure range:

$$\beta_S \in [0.761, 1.239].$$

This condition is already nontrivial. The Hubble solution is not allowed to move the theory into a branch whose required saturation coupling lies outside the Article 86 benchmark corridor.

But this is not yet enough. A parameter point could satisfy the numerical β_S interval while still deforming the tensor sector too strongly through the same background or transport modifications that generate the Hubble shift. To formalize this, let

$$S_T^{(86)}(k; \beta_S)$$

denote the Article 86 benchmark tensor suppression structure, and let

$$S_T^{(90)}(k; \alpha_\chi, \langle \delta_H \rangle_{r_s}, \beta_S)$$

denote the tensor structure after the Hubble-sector correction has been incorporated.

Define the tensor-corridor deformation functional

$$\mathcal{E}_T = \sup_{k\in\mathcal{K}_{\mathrm{CMB/PTA}}} \left| \frac{S_T^{(90)}(k) - S_T^{(86)}(k)}{S_T^{(86)}(k)} \right|.$$

Here $\mathcal{K}_{\mathrm{CMB/PTA}}$ denotes the observational wave-number range relevant to the primordial tensor and relic-background sectors already used in Article 86. The Hubble branch is tensor-compatible only if

$$\mathcal{E}_T \le \varepsilon_T,$$

where ε_T is the admissible tensor-backreaction threshold of the late FCLET cosmology branch.

This is the exact form of the Article 86 compatibility condition. It requires not merely that the Hubble solution sit numerically inside the β_S interval, but that it preserve the tensor branch as a branch.

7.3 Compatibility with the Article 89 Reduced Global Corridor

The second compatibility test concerns the reduced global geometry of Article 89. There the benchmark viability set was

$$S_{\mathrm{global}}^{\mathrm{red}} = [\xi_{\min}, \xi_{\max}] \times [\beta_{\min}, \beta_{\max}] = [0.300, 0.800] \times [0.761, 1.239].$$

The Hubble sector lives in cosmology, but it cannot ignore this reduced global structure because the cosmological benchmark branch used in Article 90 is the same branch that Article 89 already coupled to the strong-field sector. Therefore a Hubble solution remains reduced-globally admissible only if its cosmological parameter values still satisfy

$$(\xi, \beta_S) \in S_{\mathrm{global}}^{\mathrm{red}}$$

for at least one admissible strong-field coordinate

$$\xi \in [0.300, 0.800].$$

This is automatically true if the Hubble branch preserves

$$\beta_S \in [0.761, 1.239],$$

but it becomes important once the Hubble mechanism is embedded into the broader global-survival logic. A Hubble shift that requires a β_S value outside the Article 89 reduced corridor is not an FCLET global solution. It is a corridor-breaking pseudo-solution.

For that reason, define the reduced-corridor compatibility set

$$\mathcal{C}_{89}^{\mathrm{red}} = \{(\alpha_\chi, \langle I\rangle_{r_s}, \langle \delta_H\rangle_{r_s}, \beta_S): \beta_S \in [0.761, 1.239]\}.$$

Any Hubble-interface parameter point outside $\mathcal{C}_{89}^{\mathrm{red}}$ is excluded at reduced-global level.

7.4 Compatibility with the Article 89 True Global Corridor

Reduced compatibility is still not the strongest condition available. Article 89 also constructed a true one-parameter global corridor using a continuous benchmark-anchored bridge law

$$\beta_S = \beta_S(\xi), \beta_S(0.300) = 1.$$

Therefore a Hubble-interface solution is fully compatible with the global-survival architecture only if it can be realized inside the true one-parameter FCLET set

$$S_{\mathrm{global}} = \{\xi \in [0.300, 0.800]: \beta_S(\xi) \in [0.761, 1.239]\}.$$

This is stronger than reduced compatibility because it requires not merely that β_S lie in the cosmological interval, but that it lie there as part of an admissible bridge-compatible continuation branch.

The true-corridor compatibility condition may therefore be written as:

$$\exists\ \xi_H \in S_{\mathrm{global}} \text{such that} \beta_S = \beta_S(\xi_H)$$

for the Hubble-interface parameter point under consideration.

Equivalently, define the true-corridor compatibility set

$$\mathcal{C}_{89}^{\mathrm{true}} = \{(\alpha_\chi, \langle I\rangle_{r_s}, \langle \delta_H\rangle_{r_s}, \beta_S): \exists\ \xi_H \in [0.300, 0.800] \text{ with } \beta_S = \beta_S(\xi_H) \text{ and } \xi_H \in S_{\mathrm{global}}\}.$$

This is the correct global consistency condition for the Hubble interface. A Hubble solution that lives only in the reduced corridor but not in the true bridge corridor is globally weaker than one that preserves the full one-parameter viability structure.

7.5 A Corridor-Preserving Hubble Solution

The preceding logic leads to a precise definition.

A parameter point of the FCLET Hubble sector is **corridor-preserving** if and only if it satisfies all three of the following:

tensor-corridor preservation

$$\beta_S \in [0.761, 1.239], \mathcal{E}_T \leq \varepsilon_T,$$

reduced-global preservation

$$(\alpha_\chi, \langle I \rangle_{r_s}, \langle \delta_H \rangle_{r_s}, \beta_S) \in \mathcal{C}_{89}^{\mathrm{red}},$$

true-global preservation

$$(\alpha_\chi, \langle I \rangle_{r_s}, \langle \delta_H \rangle_{r_s}, \beta_S) \in \mathcal{C}_{89}^{\mathrm{true}}.$$

This definition finally allows the results of Section 6 to be judged honestly. A Hubble-interface point lying in the relief or resolution regime counts as a real FCLET success only if it is also corridor-preserving in the above sense.

7.6 Corridor-Safe Relief, Corridor-Safe Resolution, and Corridor-Breaking Pseudo-Resolution

Once the compatibility structure is imposed, the Section 6 quantitative Hubble window splits into three scientifically distinct success states.

7.6.1 Corridor-safe relief

A parameter point lies in the **corridor-safe relief** regime if

$$0 < \mathcal{W}_H < 1$$

and the point is corridor-preserving.

This is already a genuine success. It means the theory does not fully eliminate the Hubble tension, but it reduces it quantitatively while remaining consistent with the rest of its late-stage architecture.

7.6.2 Corridor-safe resolution

A parameter point lies in the **corridor-safe resolution** regime if

$$\mathcal{W}_H \approx 1$$

and the point is corridor-preserving.

This is the strongest positive outcome available to Article 90. It means the theory reaches the local-inference target without sacrificing the tensor corridor or the global-survival structure.

7.6.3 Corridor-breaking pseudo-resolution

A parameter point lies in the **corridor-breaking pseudo-resolution** regime if

$$\mathcal{W}_H \approx 1 \mathrm{or} \mathcal{W}_H > 1,$$

but the point fails one or more corridor-preservation conditions.

This regime is not a success. It may appear impressive if one looks only at the size of the Hubble shift, but it is programmatically inadmissible. A theory is not strengthened by resolving one anomaly only through a branch that destroys its own already-established benchmark corridor.

This distinction is one of the most important outputs of Article 90.

7.7 Compatibility Budget

The logic above may be summarized as a finite **compatibility budget**. The Hubble interface cannot consume arbitrary amounts of transport correction, background correction, and saturation coupling freedom simultaneously. The late FCLET program already spent part of that budget establishing the tensor corridor and the global-survival corridor. Therefore the Hubble branch must fit inside what remains.

At the effective level, the compatibility budget is carried by the tuple

$$(\alpha_\chi, \langle I \rangle_{r_s}, \langle \delta_H \rangle_{r_s}, \beta_S).$$

A viable Hubble shift requires this tuple to satisfy two competing demands simultaneously:

it must make

$$\mathcal{W}_H$$

large enough to matter,

it must keep

$$\beta_S, \mathcal{E}_T, \xi_H$$

inside the already-admissible FCLET corridor structure.

This is the correct programmatic interpretation of Article 90. The question is not only whether FCLET can move $H_{0,\mathrm{inf}}$. It is whether it can do so within its remaining corridor budget.

7.8 Corridor Compatibility Theorem

The central result of the section can now be stated in theorem form.

Theorem 6 (Corridor Compatibility Theorem).
Let the FCLET Hubble-interface parameter point be

$$p_H = (\alpha_\chi, \langle I \rangle_{r_s}, \langle \delta_H \rangle_{r_s}, \beta_S),$$

and let its normalized Hubble-window coordinate be

$$\mathcal{W}_H = \frac{\Delta_H}{\Delta_\star}.$$

Let the Article 86 tensor corridor be defined by

$$\beta_S \in [0.761,1.239], \mathcal{E}_T \leq \varepsilon_T,$$

and let the Article 89 true global corridor be

$$S_{\text{global}} = \{\xi \in [0.300,0.800]: \beta_S(\xi) \in [0.761,1.239]\}.$$

Then an FCLET Hubble-interface parameter point counts as a genuine program-compatible solution if and only if:

it lies in the desired quantitative Hubble regime,

$$0 < \mathcal{W}_H < 1(\text{relief}) \text{or} \mathcal{W}_H \approx 1(\text{resolution}),$$

it preserves the Article 86 tensor corridor,

it remains inside the Article 89 reduced and true global compatibility structure.

Hence a Hubble-sector shift is scientifically admissible only if it is corridor-preserving as well as shift-producing.

This theorem is the exact bridge between Article 90 and the previously completed late FCLET program.

7.9 Consequences for the Hubble Branches

The compatibility condition immediately reshapes the interpretation of the three Hubble branches defined in Section 5.

Transport-dominated branch

This branch is structurally the most likely to remain corridor-safe, because it can in principle achieve a meaningful Hubble shift without demanding a large deformation of the homogeneous background. It is therefore the leading candidate for corridor-safe relief or corridor-safe resolution.

Background-dominated branch

This branch is structurally the most exposed to corridor failure, because a large $\langle \delta_H \rangle_{r_s}$ is more likely to backreact on the broader cosmological sector. It may still be viable, but it must be treated as the highest-risk route.

Mixed branch

This branch is the most flexible. It may be the best route to corridor-safe relief or even corridor-safe resolution, because the required shift can be shared between transport and background rather than forced through one channel alone.

These are not aesthetic preferences. They are direct consequences of the compatibility logic established above.

7.10 What Section 7 Achieves

Sections 2–6 derived the Hubble mechanism, decomposed it into branches, and placed it inside a quantitative window structure. But until the present section, the Hubble interface remained only internally quantified. It had not yet been checked against the rest of the late FCLET program.

Section 7 now performs that check.

It does four exact things.

First, it imposes compatibility with the Article 86 tensor corridor.

Second, it imposes compatibility with the Article 89 reduced corridor.

Third, it imposes compatibility with the Article 89 true one-parameter global corridor.

Fourth, it distinguishes corridor-safe relief and resolution from corridor-breaking pseudo-resolution.

This is the decisive programmatic closure of Article 90. The paper no longer asks merely whether FCLET can shift the inferred Hubble scale. It asks whether FCLET can do so **as FCLET**, that is, without breaking the benchmark cosmological and global-survival architecture already established by the program.

The only remaining task is then to state the negative outcomes cleanly and close the article with a final verdict: does FCLET fully resolve the Hubble tension, partially relieve it, or fail to shift the inferred Hubble scale enough without leaving its own corridor? That is the role of the final section.

8. Falsification Criteria and Final Hubble-Sector Verdict

The Hubble interface of FCLET is now fully derived in structural form. The theory possesses an explicit homogeneous background equation, an explicit pre-recombination acoustic transport correction, an explicit first-order mapping from finite-capacity loading to the inferred Hubble shift, a branch decomposition into transport-dominated, background-dominated, and mixed mechanisms, and a quantitative Hubble-window structure. It also possesses, through the previous section, an explicit compatibility test against the tensor corridor of Article 86 and the reduced and true global-survival structures of Article 89. At this point, the Hubble interface is no longer a qualitative possibility. It is a quantitative sector of the program.

That means the final task of the paper is no longer derivational. It is judicial.

The theory must now state clearly how the Hubble branch succeeds, how it partially succeeds, and how it fails.

8.1 What Counts as Success in the Hubble Sector

The basic quantity derived in the paper is

$$\Delta_H \equiv \frac{\delta H_0^{\inf}}{H_0^{\inf}} \approx \alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s},$$

together with the normalized Hubble-window coordinate

$$\mathcal{W}_H = \frac{\Delta_H}{\Delta_\star},$$

where $\Delta_\star$ is the reference fractional shift required to move the standard cosmological inference to the local-measurement Hubble scale.

From the standpoint of Article 90, there are three positive outcomes and one negative family of outcomes.

The strongest positive outcome is **corridor-safe resolution**:

$$\mathcal{W}_H \approx 1$$

together with preservation of the Article 86 tensor corridor and the Article 89 reduced and true global corridors.

The intermediate positive outcome is **corridor-safe relief**:

$$0 < \mathcal{W}_H < 1$$

together with the same corridor-preservation conditions.

The weakest positive outcome is **safe weak influence**:

$$0 \leq \mathcal{W}_H \ll 1,$$

which shows that FCLET can enter the Hubble inference chain consistently, even if the resulting shift is too small to matter phenomenologically.

Any apparent resolution or strong relief that breaks the tensor corridor or the global-survival corridor is not counted as success. It is counted as a pseudo-solution.

8.2 What Counts as Failure in the Hubble Sector

The Hubble interface can fail in more than one way, and those failures must be distinguished.

The first failure mode is **insufficient shift**:

$$\mathcal{W}_H \approx 0$$

or, more generally,

$$\mathcal{W}_H \ll 1.$$

In this case FCLET remains compatible with the Hubble sector but does not actually relieve the tension in a meaningful way.

The second failure mode is **corridor-breaking pseudo-relief**. Here

$$0 < \mathcal{W}_H < 1 \text{or} \mathcal{W}_H \approx 1,$$

but the corresponding parameter point violates one or more of the corridor-preservation conditions. In this case the Hubble shift is numerically present but programmatically inadmissible.

The third failure mode is **overdriven pseudo-resolution**:

$$\mathcal{W}_H > 1,$$

with the excess driven by transport or background corrections that push the theory outside its established admissible structure. This is not a real resolution. It is an overcorrection obtained by leaving the theory's viable benchmark branch.

The fourth and strongest failure mode is **branch inconsistency**, in which the Hubble mechanism itself forces the theory into a sector incompatible with the benchmark scalar–tensor corridor or the one-parameter global survival structure. In that case the Hubble interface is not simply ineffective. It is internally inconsistent with the late FCLET program.

8.3 Exact Falsification Criteria

The Hubble branch is therefore falsified at one of three exact levels.

Level I: phenomenological insufficiency

FCLET fails as a Hubble-tension mechanism if

$$\mathcal{W}_H \ll 1$$

throughout the corridor-preserving parameter domain. In this case the theory enters the Hubble interface but cannot produce enough shift to matter.

Level II: corridor-breaking Hubble branch

FCLET fails as a program-compatible Hubble solution if every parameter point satisfying

$$0 < \mathcal{W}_H < 1 \text{or} \mathcal{W}_H \approx 1$$

lies outside the corridor-preserving set. In that case the theory can produce a Hubble shift only by abandoning its previously established tensor or global-survival structure.

Level III: complete Hubble-interface failure

FCLET fails maximally in the Hubble sector if both of the following hold:

no corridor-preserving point yields

$$\mathcal{W}_H > 0$$

at a phenomenologically meaningful level, and

every larger attempted shift requires a branch that violates the tensor corridor or the global-survival corridor.

In this case the Hubble interface is not merely weak. It is closed off as a viable extension of the benchmark program.

8.4 The Hubble Verdict Operator

To summarize the previous logic compactly, define the Hubble verdict operator

$$\mathcal{V}_H \in \{\mathsf{W}, \mathsf{R}, \mathsf{F}, \mathsf{X}\},$$

with the following meanings:

$\mathsf{W} \equiv$ weak but corridor-safe influence,
$\mathsf{R} \equiv$ corridor-safe relief,
$\mathsf{F} \equiv$ corridor-safe full resolution,
$\mathsf{X} \equiv$ failure or pseudo-solution.

The classification rule is exact.

If

$$\mathcal{W}_H \ll 1$$

but the point is corridor-preserving, then

$$\mathcal{V}_H = \mathsf{W}.$$

If

$$0 < \mathcal{W}_H < 1$$

and the point is corridor-preserving, then

$$\mathcal{V}_H = \mathsf{R}.$$

If

$$\mathcal{W}_H \approx 1$$

and the point is corridor-preserving, then

$$\mathcal{V}_H = \mathsf{F}.$$

In every other case,

$$\mathcal{V}_H = \mathsf{X}.$$

This operator is useful because it gives the paper a final judicial object rather than only a collection of verbal scenarios.

8.5 Branch-Specific Final Risk Profiles

The three FCLET Hubble branches now acquire exact final interpretations.

The **transport-dominated branch** remains the cleanest candidate for corridor-safe relief or even corridor-safe resolution. Its advantage is that it can reduce the sound horizon and raise the inferred Hubble scale while leaving the late-time background relatively close to standard form.

The **background-dominated branch** remains the highest-risk candidate. It may produce a large Hubble shift, but it is also the branch most exposed to corridor-breaking backreaction on the broader cosmological sector.

The **mixed branch** remains the most flexible candidate. It may be the natural route to a real solution if the required Hubble shift can be shared between moderate transport and moderate background corrections rather than being forced entirely through one channel.

This ranking is not stylistic. It is a direct consequence of the derivation carried through the paper.

8.6 What Article 90 Has Actually Established

At this point it is essential to state the paper's scope with full honesty.

Article 90 has not claimed, by derivation alone, that FCLET definitely resolves the Hubble tension. What it has done is stronger and cleaner than a vague claim, but narrower than a final data verdict.

It has established:

a closed homogeneous FCLET background equation,

a closed FCLET acoustic transport correction,

an explicit first-order sound-horizon renormalization law,

an explicit first-order inferred-Hubble shift law,

a three-branch decomposition of the Hubble mechanism,

a quantitative Hubble-window structure,

and exact compatibility conditions with Articles 86 and 89.

That is the correct achievement of the paper.

In other words, Article 90 does not yet say, “FCLET has solved the Hubble tension.” It says something more disciplined and more scientifically useful:

("$FCLET\ now\ possesses\ a\ fully\ derived\ Hubble$
$-\ sector\ interface\ whose\ success\ or\ failure\ can\ be\ judged\ quantitatively\ and\ corridor$
$-\ consistently.$")

That is the threshold the program needed to cross.

8.7 Final Hubble-Sector Theorem

The results of the paper can now be summarized in a final theorem.

Theorem 7 (FCLET Hubble-Sector Theorem).
Let the homogeneous FCLET background be defined by

$$H^2_{\mathrm{FCLET}}(z) = \frac{8\pi G}{3}[\rho_{\mathrm{std}}(z) + \rho_{\mathrm{FCLET}}(z)],$$

let the FCLET sound speed be

$$c_s^{\mathrm{FCLET}}(z) = c_s^{\mathrm{std}}(z)\,[1 - \alpha_\chi I(z)],$$

and let the first-order inferred Hubble shift be

$$\Delta_H \equiv \frac{\delta H_0^{\mathrm{inf}}}{H_0^{\mathrm{inf}}} \approx \alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s}.$$

Let

$$\mathcal{W}_H = \frac{\Delta_H}{\Delta_\star}$$

be the normalized Hubble-window coordinate, and let corridor preservation require compatibility with the Article 86 tensor corridor and the Article 89 reduced and true global-survival structures. Then the FCLET Hubble interface admits exactly four verdict states:

weak corridor-safe influence, if

$$\mathcal{W}_H \ll 1$$

and the branch is corridor-preserving;

corridor-safe relief, if

$$0 < \mathcal{W}_H < 1$$

and the branch is corridor-preserving;

corridor-safe resolution, if

$$\mathcal{W}_H \approx 1$$

and the branch is corridor-preserving;

failure or pseudo-solution, in every other case.

Hence the Hubble sector of FCLET is now fully derivable, branch-classifiable, quantitatively scorable, and corridor-testable.

This is the first complete Hubble-interface theorem of the FCLET program.

8.8 Final Verdict of the Paper

The final verdict of Article 90 is therefore exact.

Before this paper, FCLET had only a plausible route by which finite-capacity saturation could affect the Hubble tension.

After this paper, FCLET has:

a genuine background equation,

a genuine acoustic transport correction,

a genuine sound-horizon renormalization law,

a genuine inferred-Hubble prediction,

and a genuine criterion for deciding whether the resulting branch is weak, relieving, resolving, or inadmissible.

That is a major upgrade in the scientific maturity of the program.

The paper therefore closes the Hubble interface in the only way that matters: not by rhetorical suggestion, but by explicit derivation and explicit verdict criteria.

Whether FCLET ultimately delivers weak influence, corridor-safe relief, or corridor-safe resolution is now a question for quantitative evaluation inside the derived parameter window. But the theoretical interface itself is no longer missing.

It is complete.

Appendix A. Homogeneous FCLET Background Closure in Redshift Form

The homogeneous FCLET background sector is defined by the effective expansion law

$$H^2_{\mathrm{FCLET}}(z) = \frac{8\pi G}{3}\,\rho_{\mathrm{eff}}(z),$$

with

$$\rho_{\mathrm{eff}}(z) = \rho_m(z) + \rho_r(z) + \rho_\Lambda + \rho_{\mathrm{FCLET}}(z).$$

The standard sector is

$$\rho_m(z) = \rho_{m0}(1+z)^3, \rho_r(z) = \rho_{r0}(1+z)^4, \rho_\Lambda = \text{const.}$$

The homogeneous finite-capacity load fraction is defined as

$$I(z) = \frac{\rho_{\mathrm{std}}(z)}{\rho_\star + \rho_{\mathrm{std}}(z)}, \rho_{\mathrm{std}}(z) = \rho_m(z) + \rho_r(z) + \rho_\Lambda.$$

The associated latency functional is

$$\chi(z) = \Upsilon(I(z)), \Upsilon(I) = -\ln(1-I),$$

hence

$$\chi(z) = \ln\left(1 + \frac{\rho_{\mathrm{std}}(z)}{\rho_\star}\right).$$

The homogeneous FCLET source density is

$$\rho_{\mathrm{FCLET}}(z) = \rho_\star\left[\eta_\chi\,\Upsilon(I(z)) + \eta_{\mathrm{ov}}\,I(z)(1-I(z))e^{-\sigma I(z)}\right].$$

Therefore the explicit FCLET background equation is

$$H^2_{\mathrm{FCLET}}(z) = \frac{8\pi G}{3}\Big[\rho_m(z) + \rho_r(z) + \rho_\Lambda + \rho_\star\left(\eta_\chi \ln\left(1+\frac{\rho_{\mathrm{std}}(z)}{\rho_\star}\right) + \eta_{\mathrm{ov}} I(z)(1-I(z))e^{-\sigma I(z)}\right)\Big].$$

The effective FCLET pressure is defined by homogeneous conservation:

$$\dot{\rho}_{\mathrm{FCLET}} + 3H_{\mathrm{FCLET}}(\rho_{\mathrm{FCLET}} + p_{\mathrm{FCLET}}) = 0,$$

or equivalently,

$$p_{\mathrm{FCLET}}(z) = -\rho_{\mathrm{FCLET}}(z) + \frac{1+z}{3}\frac{d\rho_{\mathrm{FCLET}}}{dz}.$$

Thus

$$p_{\mathrm{eff}}(z) = p_{\mathrm{std}}(z) + p_{\mathrm{FCLET}}(z), p_{\mathrm{std}}(z) = \frac{1}{3}\rho_r(z) - \rho_\Lambda,$$

and the acceleration equation is

$$\dot{H}_{\mathrm{FCLET}}(z) = -4\pi G[\rho_{\mathrm{eff}}(z) + p_{\mathrm{eff}}(z)].$$

The corresponding FCLET effective equation-of-state parameter is

$$w_{\mathrm{FCLET}}(z) = \frac{p_{\mathrm{FCLET}}(z)}{\rho_{\mathrm{FCLET}}(z)} = -1 + \frac{1+z}{3}\frac{d\ln\rho_{\mathrm{FCLET}}(z)}{dz}.$$

This appendix records the exact homogeneous closure used throughout Article 90.

Appendix B. Acoustic Transport, Sound-Horizon Expansion, and Weighted Early-Load Averages

The standard pre-recombination sound speed is

$$c_s^{\mathrm{std}}(z) = \frac{c}{\sqrt{3(1+R_b(z))}},$$

where

$$R_b(z) = \frac{3\rho_b(z)}{4\rho_\gamma(z)} = \frac{3\rho_{b0}}{4\rho_{\gamma 0}}(1+z)^{-1}.$$

The FCLET acoustic transport factor is

$$\mathcal{T}_\chi(z) = 1 - \alpha_\chi I(z),$$

so that

$$c_s^{\mathrm{FCLET}}(z) = c_s^{\mathrm{std}}(z)\,[1 - \alpha_\chi I(z)].$$

The corresponding sound horizon is

$$r_s^{\mathrm{FCLET}}(z_*) = \int_{z_*}^{\infty} \frac{c_s^{\mathrm{FCLET}}(z)}{H_{\mathrm{FCLET}}(z)}\,dz.$$

Writing

$$H_{\mathrm{FCLET}}(z) = H_{\mathrm{std}}(z)\,[1 + \delta_H(z)],$$

the first-order expansion is

$$\frac{c_s^{\mathrm{FCLET}}(z)}{H_{\mathrm{FCLET}}(z)} \approx \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)}[1 - \alpha_\chi I(z) - \delta_H(z)].$$

Hence

$$r_s^{\mathrm{FCLET}} \approx r_s^{\mathrm{std}} - \int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)}\,[\alpha_\chi I(z) + \delta_H(z)]\,dz.$$

Define the sound-horizon-weighted averages

$$\langle I \rangle_{r_s} = \frac{\displaystyle\int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)} I(z)\,dz}{\displaystyle\int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)}\,dz},$$

and

$$\langle \delta_H \rangle_{r_s} = \frac{\int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)} \delta_H(z)\, dz}{\int_{z_*}^{\infty} \frac{c_s^{\mathrm{std}}(z)}{H_{\mathrm{std}}(z)}\, dz}.$$

Then

$$\frac{\delta r_s}{r_s^{\mathrm{std}}} \approx -\left(\alpha_\chi \langle I \rangle_{r_s} + \langle \delta_H \rangle_{r_s}\right).$$

In the pure transport limit,

$$\langle \delta_H \rangle_{r_s} \approx 0,$$

so that

$$r_s^{\mathrm{FCLET}} \approx r_s^{\mathrm{std}} (1 - \alpha_\chi \langle I \rangle_{r_s}).$$

This is the compact transport formula used repeatedly in the main text.

Appendix C. Hubble-Window Coordinates, Branch Purity, and Regime Classification

The first-order inferred Hubble shift is

$$\Delta_H \equiv \frac{\delta H_0^{\mathrm{inf}}}{H_0^{\mathrm{inf}}} \approx \Delta_{\mathrm{tr}} + \Delta_{\mathrm{bg}},$$

with

$$\Delta_{\mathrm{tr}} = \alpha_\chi \langle I \rangle_{r_s}, \Delta_{\mathrm{bg}} = \langle \delta_H \rangle_{r_s}.$$

The reference shift required to move the standard cosmological inference to the local-measurement scale is

$$\Delta_\star = \frac{H_{0,\mathrm{loc}} - H_{0,\mathrm{std}}}{H_{0,\mathrm{std}}}.$$

The normalized Hubble-window coordinate is

$$\mathcal{W}_H = \frac{\Delta_H}{\Delta_\star}.$$

The branch-dominance ratio is

$$\mathcal{D}_H = \frac{\Delta_{\mathrm{bg}}}{\Delta_{\mathrm{tr}}}.$$

The branch-purity indices are

$$\mathcal{P}_{\mathrm{tr}} = \frac{|\,\Delta_{\mathrm{tr}}\,|}{|\,\Delta_{\mathrm{tr}}\,| + |\,\Delta_{\mathrm{bg}}\,|}, \mathcal{P}_{\mathrm{bg}} = \frac{|\,\Delta_{\mathrm{bg}}\,|}{|\,\Delta_{\mathrm{tr}}\,| + |\,\Delta_{\mathrm{bg}}\,|},$$

with

$$\mathcal{P}_{\mathrm{tr}} + \mathcal{P}_{\mathrm{bg}} = 1.$$

The operational Hubble regimes are:

safe regime

$$\mathcal{W}_H \ll 1,$$

relief regime

$$0 < \mathcal{W}_H < 1,$$

resolution regime

$$\mathcal{W}_H \approx 1,$$

overdriven regime

$$\mathcal{W}_H > 1.$$

The branch labels are:

transport-dominated

$$|\,\mathcal{D}_H\,| \ll 1,$$

background-dominated

$$|\,\mathcal{D}_H\,| \gg 1,$$

mixed

$$|\mathcal{D}_H| \sim 1.$$

Thus the tuple

$$(\mathcal{W}_H, \mathcal{P}_{\mathrm{tr}}, \mathcal{P}_{\mathrm{bg}})$$

provides the minimal quantitative classification of the FCLET Hubble interface.

Appendix D. Corridor Preservation Operators for the Hubble Interface

A Hubble-sector parameter point

$$p_H = (\alpha_\chi, \langle I \rangle_{r_s}, \langle \delta_H \rangle_{r_s}, \beta_S)$$

counts as a genuine FCLET solution only if it preserves the cosmological tensor corridor of Article 86 and the reduced and true global-survival structures of Article 89.

D.1 Article 86 tensor-corridor preservation

The benchmark tensor corridor requires

$$\beta_S \in [0.761, 1.239].$$

Define the tensor-deformation functional

$$\mathcal{E}_T = \sup_{k \in \mathcal{K}_{\mathrm{CMB/PTA}}} \left| \frac{S_T^{(90)}(k) - S_T^{(86)}(k)}{S_T^{(86)}(k)} \right|.$$

Tensor-corridor preservation requires

$$\beta_S \in [0.761, 1.239], \mathcal{E}_T \leq \varepsilon_T.$$

D.2 Article 89 reduced-corridor preservation

The reduced global corridor is

$$S_{\mathrm{global}}^{\mathrm{red}} = [0.300, 0.800] \times [0.761, 1.239].$$

The reduced-corridor compatibility set is therefore

$$\mathcal{C}_{89}^{\mathrm{red}} = \{p_H : \beta_S \in [0.761, 1.239]\}.$$

D.3 Article 89 true-corridor preservation

The true one-parameter corridor is

$$S_{\mathrm{global}} = \{\xi \in [0.300, 0.800] : \beta_S(\xi) \in [0.761, 1.239]\}.$$

The true-corridor compatibility set is

$$\mathcal{C}_{89}^{\mathrm{true}} = \left\{p_H : \exists\, \xi_H \in S_{\mathrm{global}} \text{ such that } \beta_S = \beta_S(\xi_H)\right\}.$$

D.4 Corridor-preserving Hubble branch

A Hubble-sector point is **corridor-preserving** if and only if

$$p_H \in \mathcal{C}_{89}^{\mathrm{red}}, p_H \in \mathcal{C}_{89}^{\mathrm{true}}, \mathcal{E}_T \leq \varepsilon_T.$$

This appendix records the exact consistency operators required to embed Article 90 into the late FCLET architecture rather than treat it as an isolated cosmological add-on.

Appendix E. Verdict Operator and Falsification Ladder for the Hubble Sector

Define the Hubble verdict operator

$$\mathcal{V}_H \in \{\mathsf{W}, \mathsf{R}, \mathsf{F}, \mathsf{X}\},$$

with the meanings:

$\mathsf{W} \equiv$ weak but corridor-safe influence,
$\mathsf{R} \equiv$ corridor-safe relief,
$\mathsf{F} \equiv$ corridor-safe full resolution,
$\mathsf{X} \equiv$ failure or pseudo-solution.

The classification rule is:

if

$$\mathcal{W}_H \ll 1$$

and the point is corridor-preserving, then

$$\mathcal{V}_H = \mathsf{W},$$

if

$$0 < \mathcal{W}_H < 1$$

and the point is corridor-preserving, then

$$\mathcal{V}_H = \mathsf{R},$$

if

$$\mathcal{W}_H \approx 1$$

and the point is corridor-preserving, then

$$\mathcal{V}_H = \mathsf{F},$$
